24 Preoperative and Intraoperative Invasive Staging of the Mediastinum

Gail E. Darling, Ramón Rami-Porta, and Kazuhiro Yasufuku

SUMMARY OF KEY POINTS

- Staging of the mediastinum is a key component in the evaluation of patients with lung cancer and includes both preoperative and intraoperative components.
- The International Association for the Study of Lung Cancer lymph node map provides standard definitions of each nodal station and allows precise, uniform nomenclature when staging mediastinal and pulmonary lymph nodes.
- The importance of lymph node assessment in the staging of nonsmall cell lung cancer is well recognized, but despite this, inadequate lymph node assessment is too common.
- Variation in the extent of mediastinal lymph node staging has been a source of confusion in the literature.
- Systematic sampling may be performed by endobronchial ultrasound–transbronchial needle aspiration (EBUS–TBNA) or endoscopic ultrasound (EUS) or mediastinoscopy prior to a planned resection or at the time of the planned resection.
- Minimally invasive needle techniques including EBUS–TBNA and EUS–fine-needle aspiration are now considered the tests of first choice to confirm mediastinal disease in accessible lymph node stations.

Staging of the mediastinum is a key component in the evaluation of patients with lung cancer and includes both preoperative and intraoperative components. The purpose of mediastinal staging is to distinguish those patients who may benefit from surgery from those who should have other forms of treatment. The preoperative assessment of the mediastinum includes computed tomography (CT) and positron emission tomography (PET) scans and has been addressed in Chapters 21 and 22. Invasive or operative mediastinal staging includes the techniques of mediastinoscopy, mediastinotomy, thoracoscopic staging, staging at the time of planned resection, and needle biopsy techniques such as endobronchial ultrasound (EBUS) or endoscopic ultrasound (EUS). Invasive mediastinal staging provides histologic or cytologic confirmation of the status of the mediastinal lymph nodes. It is important to differentiate mediastinal node assessment for the purpose of staging versus a possible therapeutic benefit. Whether mediastinal lymph node dissection (MLND) improves survival is controversial.

Patients who have proven metastases in mediastinal lymph nodes have a poor prognosis because of increased risk of systemic disease. Identification of N2 disease prior to resection is preferable to avoid a noncurative resection as surgery alone is inadequate, whereas patients without mediastinal node involvement are candidates for surgery.

Pathologic confirmation of nodal status by the techniques described in this chapter is important because the diagnostic accuracy of imaging tests such as CT and PET is insufficient

for clinical decision making. The positive predictive value of CT ranges from 0.18 to 0.88. On average, the likelihood of an enlarged node on CT being positive for metastatic disease is only 60%. Similarly, nodes that are positive on PET are pathologically positive for metastatic disease only 75% to 85% of the time.[1] This means that 15% to 40% of the time patients may be denied curative intent therapy because of imaging tests. Abnormal imaging should be confirmed or refuted pathologically.

This chapter will address the relevant anatomy with respect to the International Association for the Study of Lung Cancer (IASLC) lymph node map (Fig. 24.1), the definitions used in discussing staging of the mediastinum, the indications for invasive staging, the techniques available for invasive staging, and the appropriate use of these techniques.

LYMPH NODE ANATOMY OF THE MEDIASTINUM AND THE IASLC LYMPH NODE MAP

The IASLC lymph node map was published in 2009 (see Fig. 24.1).[2] The map illustrates the key lymph node anatomy of the mediastinum and lung. The goal of the IASLC Staging Committee in creating this new map was to reconcile the differences between the Japanese and Mountain–Dresler lymph node maps and to provide specific anatomic definitions of the lymph node stations.[2] The key changes include the description of level 1 nodes as supraclavicular and suprasternal nodes, the division between right- and left-sided nodes defined as the left lateral border of the trachea, definition of the subcarinal nodes as level 7 (not level 7 and 10 as on the Japanese map), and the clear division of lymph node levels based on clearly identified anatomic landmarks (Table 24.1). This map provides standard definitions of each nodal station and allows precise, uniform nomenclature when staging mediastinal and pulmonary lymph nodes. Mediastinal nodes (N2 and N3) are numbered 1–9. Hilar and intrapulmonary (N1) nodes are numbered 10–14.

LYMPH NODE STATIONS AND CHOICE OF STAGING TECHNIQUE

Standard mediastinoscopy or videomediastinoscopy can access lymph node stations 1, 2R/L, 4R/L, 7, and 10R. Stations 5 and 6 can be accessed by extended mediastinoscopy, parasternal mediastinotomy (Chamberlain procedure) or anterior mediastinoscopy, and video-assisted thoracic surgery (VATS). Prevascular nodes (3a) may be accessible by parasternal mediastinotomy or anterior mediastinoscopy and VATS. VATS can access ipsilateral nodal stations as well as hilar nodes and even interlobar nodes if the fissure is explored.

Needle techniques include EBUS–transbronchial needle aspiration (EBUS–TBNA) and EUS–needle aspiration (EUS–NA).

EBUS–TBNA can access all the nodes accessed by mediastinoscopy and additionally stations 11 and 12 bilaterally. EUS–NA can access stations 8 and 9 as well as the same stations as mediastinoscopy, but not the hilar nodes.

Fig. 24.1. International Association for the Study of Lung Cancer map of regional lymph nodes for the determination of N descriptor during tumor, node, and metastasis staging of lung cancer. *Ao,* Aorta; *Eso,* esophagus; *mPA,* main pulmonary artery; *SVC,* superior vena cava; *T,* trachea. *(Reprinted with permission from International Association for the Study of Lung Cancer.* Staging Manual in Thoracic Oncology. *Orange Park, FL: Editorial Rx Press; 2009.)*

Techniques such as video-assisted mediastinal lymphadenectomy (VAMLA) and transcervical extended mediastinal lymphadenectomy (TEMLA) have been used for staging, but are more appropriately considered as techniques for mediastinal node dissection. These techniques may have therapeutic as well as staging applications.

INDICATIONS FOR INVASIVE MEDIASTINAL STAGING

The American College of Chest Physicians (ACCP) evidence-based clinical practice guidelines,[3] the European Society of Thoracic Surgeons (ESTS) guidelines,[4] and Cancer Care Ontario (CCO) Program in Evidence-Based Care Practice Guidelines[5] are concordant in their recommendations for indications and techniques for invasive staging (Table 24.2). Invasive staging by needle techniques is recommended if available, but surgical biopsies are recommended if the needle techniques are negative because of the low negative predictive value of needle biopsy techniques.[3]

ACCP does not recommend invasive staging for patients with extensive mediastinal infiltration.[3] However, invasive staging techniques may be used for diagnostic purposes. ACCP, ESTS, and

TABLE 24.1 Anatomical Definitions for Each Lymph Node Station and Station Grouping by Nodal Zones in the Map Proposed by the International Association for the Study of Lung Cancer

Lymph Node Station	Anatomical Limits
SUPRACLAVICULAR ZONE	
1: Low cervical, supraclavicular, and sternal notch nodes	Upper border: lower margin of cricoid cartilage. Lower border: clavicles bilaterally and, in the midline, the upper border of the manubrium. 1R designates right-sided nodes, 1L left-sided nodes in this region. For lymph node station 1, the midline of the trachea serves as the border between 1R and 1L.
UPPER ZONE	
2: Upper paratracheal nodes	2R: Upper border: apex of the right lung and pleural space, and, in the midline, the upper border of the manubrium. Lower border: intersection of the caudal margin of innominate vein with the trachea. As for lymph node station 4R, 2R includes nodes extending to the left lateral border of the trachea. 2L: Upper border: apex of the lung and pleural space, and, in the midline, the upper border of the manubrium. Lower border: superior border of the aortic arch.
3 Prevascular and retrotracheal nodes	3a: Prevascular. On the right: Upper border: apex of chest. Lower border: level of carina. Anterior border: posterior aspect of sternum. Posterior border: anterior border of superior vena cava. On the left: Upper border: apex of chest. Lower border: level of carina. Anterior border: posterior aspect of sternum. Posterior border: left carotid artery. 3p: Retrotracheal. Upper border: apex of chest. Lower border: carina.
4: Lower paratracheal nodes	4R: includes right paratracheal nodes, and pretracheal nodes extending to the left lateral border of the trachea. Upper border: intersection of the caudal margin of innominate vein with the trachea. Lower border: lower border of the azygos vein. 4L: includes nodes to the left of the left lateral border of the trachea, medial to the ligamentum arteriosum. Upper border: upper margin of the aortic arch. Lower border: upper rim of the left main pulmonary artery.
AORTOPULMONARY ZONE	
5: Subaortic (aortopulmonary window)	Subaortic lymph nodes lateral to the ligamentum arteriosum. Upper border: the lower border of the aortic arch. Lower border: upper rim of the left main pulmonary artery.
6: Para-aortic nodes (ascending aorta or phrenic	Lymph nodes anterior and lateral to the ascending aorta and aortic arch. Upper border: a line tangential to the upper border of the aortic arch. Lower border: the lower border of the aortic arch.
SUBCARINAL ZONE	
7: Subcarinal nodes	Upper border: the carina of the trachea. Lower border: the upper border of the lower-lobe bronchus on the left; the lower border of the bronchus intermedius on the right.
LOWER ZONE	
8: Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or the left of the midline, excluding subcarinal nodes. Upper border: the upper border of the lower-lobe bronchus on the left; the lower border of the bronchus intermedius on the right. Lower border: the diaphragm.
9: Pulmonary ligament nodes	Nodes lying within the pulmonary ligament. Upper border: the inferior pulmonary vein. Lower border: the diaphragm.
HILAR/INTERLOBAR ZONE	
10: Hilar nodes	Includes nodes immediately adjacent to the mainstem bronchus and hilar vessels including the proximal portions of the pulmonary veins and the main pulmonary artery. Upper border: the lower rim of the azygos vein in the right; upper rim of the pulmonary artery on the left. Lower border: interlobar region bilaterally.
11: Interlobar nodes	Between the origin of the lobar bronchi. 11s: between the upper-lobe bronchus and bronchus intermedius on the right.[a] 11i: between the middle and lower bronchi on the right.[a]
PERIPHERAL ZONE	
12: Lobar nodes	Adjacent to the lobar bronchi.
13: Segmental nodes	Adjacent to the segmental bronchi.
14: Subsegmental nodes	Adjacent to the subsegmental bronchi.

[a]Nodal station number.

CCO guidelines on preoperative mediastinal lymph node staging recommend that invasive mediastinal staging is not required for peripheral stage IA tumors with no suspicion of mediastinal lymph node involvement on CT and PET scans (Fig. 24.2).[3–5]

DEFINITIONS OF MEDIASTINAL LYMPH NODE STAGING

Variation in the extent of mediastinal lymph node staging has been a source of confusion in the literature. The standard

TABLE 24.2 Indications for Invasive Mediastinal Staging

American College of Chest Physician Guidelines[2]
Absence of metastatic disease and one of the following:
   discrete mediastinal node enlargement with or without PET uptake
   PET-positive mediastinal nodes and abnormal nodes on CT
   high suspicion of N2 or N3 based on enlarged nodes on CT or PET
     uptake
   intermediate suspicion of N2 or N3 with a central tumor or N1 disease
European Society of Thoracic Surgeons Guidelines[3]
Any of the following:
   abnormal lymph nodes on CT
   uptake on PET scan
   central tumors
   suspected N1 disease
   low PET uptake by primary tumor
Cancer Care Ontario[4]
Any of the following:
   enlarged mediastinal nodes on CT
   uptake in mediastinal nodes on PET
   central tumors T2–T4
   suspected N1 disease

CT, Computed tomography; *PET,* positron emission tomography.

descriptions listed in Table 24.3 should be used when describing the extent of mediastinal lymph node assessment: sampling or random sampling, systematic sampling (SS), complete MLND, extended MLND, and lobe-specific systematic lymph node dissection (see Table 24.3).[6] The term systematic nodal dissection refers to a combination of mediastinal as well as hilar and intrapulmonary node dissection.[7]

Random sampling is not considered adequate for staging purposes. Certainly any suspicious or enlarged nodes should be removed as part of a lung cancer operation or when performing a staging procedure, but removal of only an enlarged or suspicious node is not sufficient. SS is the minimum assessment considered acceptable and is defined as the removal or biopsy of lymph nodes from predetermined lymph node stations based on the location of the tumor and known lymphatic drainage patterns. The specified stations represent the minimum number of stations to be assessed. MLND is a formal dissection of the lymph node bearing areas of the mediastinum including the paratracheal zone, the subcarinal space, the inferior mediastinum, and, on the left, the subaortic space and the para-aortic space. It is not simply the removal of individual lymph nodes from those regions but rather removal of all the lymph node bearing tissue within predetermined anatomic boundaries.

Extended mediastinal dissection is the formal removal of bilateral mediastinal and cervical lymph nodes. It is usually performed by VAMLA or TEMLA or by open techniques. This may be used for staging, but is more often a therapeutic technique.

Lobe-specific systematic lymph node dissection refers to the formal dissection of lymph node bearing tissues based on the anatomic location of the cancer. For example, for a left lower lobe tumor, the lymph node dissection would include the subcarinal and inferior mediastinal node dissection. Systematic node dissection refers to the combination of systematic mediastinal lymph node sampling (SS) and systematic hilar and intrapulmonary lymph node dissection.

REQUIRED LYMPH NODE STATIONS FOR INVASIVE STAGING

Recommended sampling includes stations 2R/L, 4R/L, and station 7. Any nodes that are enlarged, show increased uptake on PET–CT, or are suspicious in any way should also be sampled. Guidelines from ESTS, National Institute for Health and Care Excellence (NICE), Scottish Intercollegiate Guidelines Network (SIGN), and CCO recommend that appropriate lymph node assessment include SS of at least three mediastinal lymph node stations (preferably 5), one of which should be station 7.[4,5,9]

CHOICE OF STAGING TECHNIQUE

SS may be performed by EBUS–TBNA or EUS or mediastinoscopy prior to a planned resection or at the time of the planned resection. If mediastinal nodes are suspicious for metastases, it is preferable to schedule the staging procedure in advance of the planned resection. If performed at the time of planned resection,

---

TABLE 24.3 Definitions of Mediastinal Lymph Node Assessment

Sampling or random sampling: sampling of lymph nodes guided by preoperative or intraoperative findings; for example, sampling of single enlarged lymph node.

Systematic sampling: sampling of predetermined lymph nodes and lymph node stations; for example, sampling of stations 2R, 4R, 7, and 10R for right-sided tumors.

Mediastinal lymph node dissection: complete removal of all mediastinal lymph node bearing tissue based on anatomic landmarks.

Extended lymph node dissection: removal of bilateral paratracheal and cervical lymph nodes by formal dissection.

Lobe-specific systematic node dissection: removal of mediastinal lymph node bearing tissue based on the location of the tumor.

on-site cytopathology or frozen section analysis is required as the finding of metastases in mediastinal lymph nodes is considered an indication for either nonoperative therapy or perhaps neoadjuvant therapy in selected cases. MLND is usually performed at the time of planned resection and may be performed by open thoracotomy or VATS. MLND may be performed as an alternative to SS based on surgeon preference. If no preresection invasive mediastinal staging has been done, MLND should be performed. MLND also should be performed if any N1 nodes are found to contain metastases or if at the time of resection, SS has identified N2 disease.

There has been considerable controversy over the role of SS compared with MLND. As a staging procedure, SS is adequate in patients with early stage only (clinical T1 or T2, N0 or nonhilar N1 nonsmall cell lung cancer [NSCLC] based on the ACOSOG Z0030 trial). If SS is negative for metastases in such patients, SS is adequate and further dissection by MLND does not confer a survival advantage even though 3.8% of patients in the ACOSOG Z0030 trial were identified by MLND as having occult N2 disease. However, the ACOSOG Z0030 results do not apply to patients with larger tumors (T3/T4) or hilar nodal disease. In such patients, MLND is still recommended.[10]

The importance of lymph node assessment in the staging of NSCLC is well recognized, but despite this, inadequate lymph node assessment is too common.[11,12] The consequence of inadequate staging will be reduced lung cancer survival if nodal disease goes undetected and untreated.

INVASIVE/SURGICAL STAGING TECHNIQUES

Mediastinoscopy

Definition

Mediastinoscopy is a surgical endoscopic technique that allows the exploration of the superior mediastinum along the tracheobronchial axis, from the sternal notch to the subcarinal space and along both main bronchi.[13]

Technique

Under general anesthesia and orotracheal intubation, with the patient in the supine position and the neck slightly extended, a 3-cm to 5-cm collar incision over the sternal notch is performed and carried through the subcutaneous tissue and platysma. The pretracheal muscles are separated laterally to expose the trachea. The pretracheal fascia is incised with scissors and the pretracheal plane is developed. The mediastinum is explored by finger dissection as far caudally as possible (Fig. 24.3). Finger palpation of the superior mediastinum allows the surgeon to identify anatomic landmarks, such as the innominate artery and the aortic arch, and to assess the texture of the mediastinal tissues, the consistency of the paratracheal lymph nodes, and the relation of central tumors to the mediastinal structures.

Finger palpation creates a mediastinal space into which the mediastinoscope is inserted. With the mediastinoscope in place, peritracheal dissection is completed by gently sweeping the adjacent tissues away from the airway with the dissection–suction–coagulation device (Fig. 24.4). Before taking any biopsies, the following structures should be identified: the innominate artery lying anterior to the trachea, the aortic arch lying over the trachea on the left, the azygos vein at the right tracheobronchial angle, and the pulmonary artery anterior to the carina (Fig. 24.5).

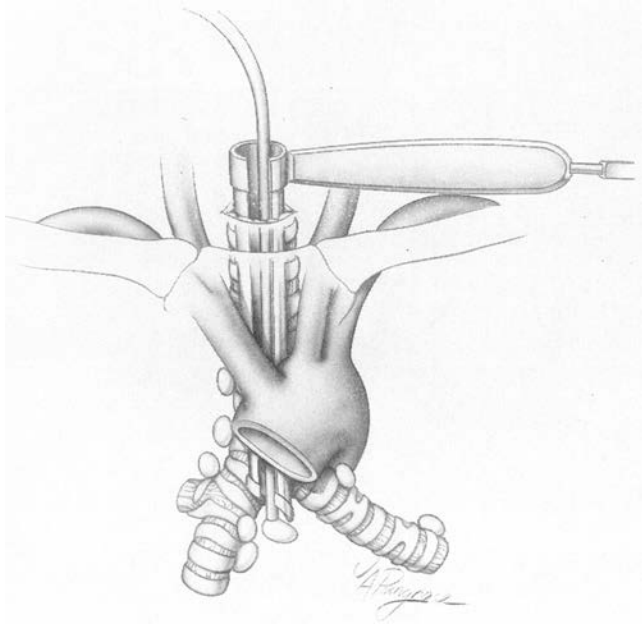
Mediastinoscopy allows biopsies of the pretracheal nodes (station 1), the right and left, superior and inferior, paratracheal nodes (stations 2R/2L and 4R/4L, respectively), the subcarinal nodes


Fig. 24.4. The mediastinoscope is inserted into the superior mediastinum. *(Reprinted with permission from Shields TW, Locicero III J, Reed CE, Feins RH, eds.* General Thoracic Surgery. *7th ed. Vol. 1. Philadelphia, PA: Wolters Kluwer/Lippincott Williams and Wilkins; 2009.)*

(station 7), and the right and left hilar nodes (stations 10R/10L; see Fig. 24.1, Table 24.1). For a clinically acceptable mediastinoscopy in standard clinical practice, the upper and lower paratracheal spaces and the subcarinal space should be explored and any lymph nodes identified should be subjected to biopsy. Any nodes that are enlarged on CT or show metabolic activity on PET scan should be explored and subjected to biopsy.

Nodal exploration should start on the contralateral side of the tumor to rule out N3 disease and then proceed in a systematic way to explore and perform biopsy on all accessible nodal stations. Mediastinoscopy also allows assessment of mediastinal invasion by either the primary tumor (T4) or by mediastinal nodes, which would preclude surgical resection. All biopsy sites should be controlled for bleeding before the incision is closed in two layers.[14]

Results

A review of 26 reports published between 1983 and 2011, including 9267 patients who had undergone conventional mediastinoscopy, reported a median sensitivity of 0.78 and a median negative predictive value of 0.91. An additional series of 995 patients who had undergone video-assisted mediastinoscopy and were reported in seven papers published from 2003 to 2011 showed a median sensitivity of 0.89 and a median negative predictive value of 0.92. By convention, specificity and positive predictive value of mediastinoscopy is 1, although positive results are not confirmed by other tests.[3] Videomediastinoscopy is reported to be more thorough in terms of number of nodes and nodal stations explored but there is no clear evidence of greater safety or improved staging although it has educational advantages.[15]

Complications

Reported complications include pneumothorax, wound infection, mediastinitis, esophageal perforation, tracheobronchial injury, left recurrent laryngeal nerve palsy, chyle leak, hemothorax, and bleeding from any of the vessels of the superior mediastinum,

but complications are rare and occur in about 3% of cases.[16,17] Serious bleeding complications occur in about 0.4% of cases and may be managed by packing, but may require median sternotomy.[18] Mortality related to mediastinoscopy usually is below 0.5%.[19,20]

Limitations

Mediastinoscopy does not reach the subaortic, para-aortic, prevascular, retrotracheal, and inferior mediastinal lymph nodes.

Technical Variants for Mediastinoscopic Lymphadenectomy

VAMLA and TEMLA are procedures performed from the collar incision used for mediastinoscopy;[21–23] their objective is not the taking of biopsies of the mediastinal nodes, but their systematic removal. Experience with these techniques is limited to a few centers.

VAMLA is performed with a two-blade spreadable mediastinoscope and has the objective to remove en bloc the subcarinal and the right inferior paratracheal lymph nodes, and to remove individually the left inferior paratracheal lymph nodes. The initial results from the two groups that developed VAMLA were very good, with sensitivity and negative predictive value of 1.[21,22]

TEMLA is also performed from the cervical incision, but the sternum is elevated with a sternal retractor fixed to a metal frame. The objective of TEMLA is to perform a complete mediastinal lymphadenectomy from the supraclavicular lymph nodes in the midline to the paraesophageal nodes. Most of the operation is performed in the open fashion; the mediastinoscope is used to complete the subcarinal and paraesophageal nodal dissection, and the thoracoscope to facilitate the removal of subaortic and para-aortic lymph nodes.[23] Staging results of TEMLA based on 256 patients are as follows: sensitivity, 0.94; negative predictive value, 0.97; and diagnostic accuracy, 0.98.[24] TEMLA is reported to be superior to mediastinoscopy[25] and to EBUS, EUS, or their combination both for staging and restaging lung cancer after induction therapy.[26]

Parasternal Mediastinotomy

Definition

Parasternal mediastinotomy is a procedure that allows the exploration of the anterior mediastinum through a right or left parasternal incision.[27,28]

Indicatio\ns

The ACCP and the ESTS guidelines on mediastinal staging recommend the exploration of the subaortic (station 5) and para-aortic (station 6) lymph nodes in patients with cancer of the left upper lobe when all other explored lymph nodes are negative. The natural lymphatic dissemination of left upper lobe tumors is to these two nodal stations, which cannot be reached with mediastinoscopy.[3,4] Prevascular lymph nodes (station 3a) if abnormal on CT or PET scan can be accessed by right or left parasternal mediastinotomy. Left parasternal mediastinotomy is especially valuable to explore tumors of the aortopulmonary window and to assess whether there is contact or tumor infiltration of the aortic arch.

Technique

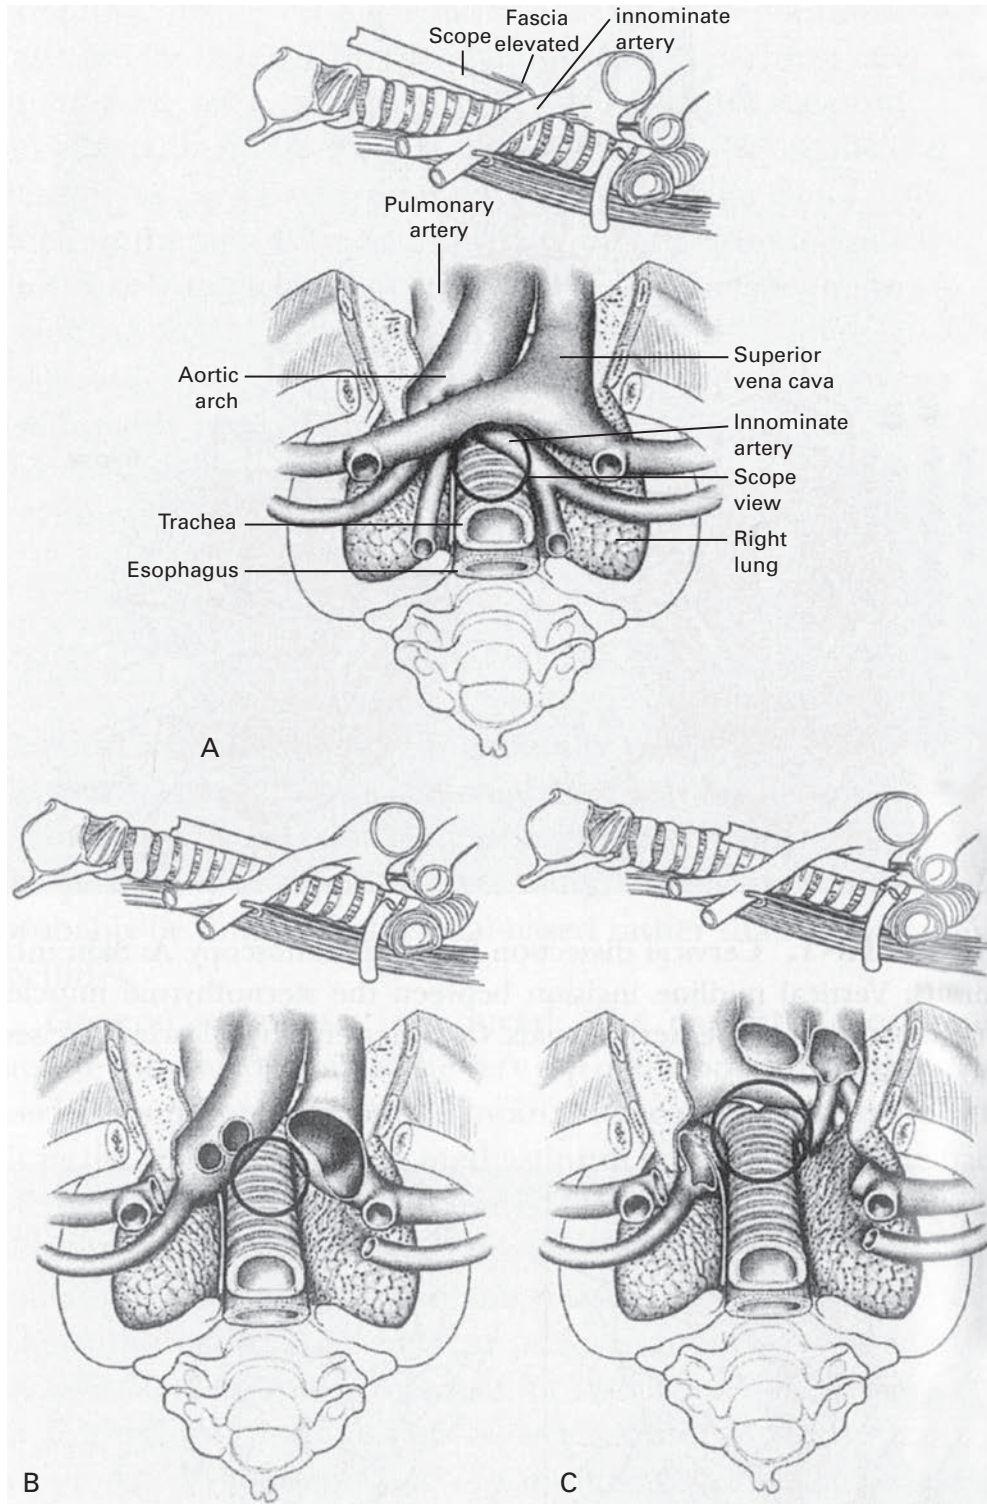
A 4-cm to 7-cm transverse incision is performed over the second costal cartilage on the right or on the left down to the pectoralis muscle. The fibers of the pectoralis major muscle are separated in a craniocaudal fashion exposing the costal


Fig. 24.5. Craniocaudal view from the surgeon's perspective and corresponding lateral view of superior mediastinal structures at three levels: (A) upper trachea, (B) mid trachea, and (C) carina. *(Reprinted with permission from Shields TW, Locicero III J, Reed CE, Feins RH, eds.* General Thoracic Surgery. *7th ed. Vol. 1. Philadelphia, PA: Wolters Kluwer/Lippincott Williams and Wilkins; 2009.)*

cartilage. The cartilage is usually excised subperichondrially or, alternatively, the exploration may be carried out through the intercostal space without cartilage resection. The internal mammary vessels may be ligated or retracted. After this, the mediastinal pleura is separated laterally with finger dissection to expose the anterior mediastinum. On the left, the subaortic space and the ascending aorta can be explored, either directly or with the assistance of a mediastinoscope (anterior mediastinoscopy; Fig. 24.6). On the right, the prevascular nodes can be reached. Parasternal mediastinotomy is a versatile procedure. Besides the exploration of the anterior mediastinum, it also allows the opening of the mediastinal pleura and the

Fig. 24.7. Extended cervical mediastinoscopy. From the cervical incision used for mediastinoscopy, the mediastinoscope is advanced obliquely over the aortic arch. *(Reprinted with permission from Pearson FG, Cooper JD, Deslauriers J, et al., eds.* Thoracic Surgery. *Oxford, UK: Churchill Livingstone; 1995.)*

exploration of the hilum and pleural space. The pericardium can also be opened and explored to rule out direct tumor invasion or metastatic dissemination. Lung biopsies can also be performed from this incision. These additional procedures are best performed with unilateral ventilation.

For closure, the perichondrium and the muscular fibers are approximated in two layers. The subcutaneous tissue and the skin are also sutured in two layers. No pleural drainage is necessary unless the mediastinal pleura is opened during the procedure. A chest tube can be left in place till the last skin suture and then removed after the lung is kept insufflated for a few seconds to allow removal of any intrapleural air.

Results

A combined analysis of four series including a total of 238 patients, published from 1983 to 2006, showed a median sensitivity of 0.71 and a median negative predictive value of 0.91.[3] VATS is increasingly replacing these techniques for staging purposes.

Complications

Complications of parasternal mediastinotomy are rare and include injury to the phrenic nerve and to the left laryngeal recurrent nerve, mediastinitis, and pneumothorax.

Extended Cervical Mediastinoscopy

Definition

Extended cervical mediastinoscopy is an alternative technique to left parasternal mediastinotomy to explore the subaortic space from the cervical incision used for mediastinoscopy.[29]

Indications

For lung cancer staging, extended cervical mediastinoscopy has the same indications as left parasternal mediastinotomy.[3,4] In addition, it may be indicated to diagnose mediastinal tumors that are within its range of exploration.[30]

Technique

Once standard mediastinoscopy is completed and frozen section analyses reveal that there are no lymph node metastases in the superior mediastinum, a passage is created by finger dissection over the aortic arch, between the innominate artery and the left carotid artery. By finger dissection, the plane between the arteries is developed to facilitate the insertion of the mediastinoscope. The mediastinoscope is then introduced into the superior mediastinum and advanced obliquely from the cervical incision over the aortic arch, either anterior or posterior to the left innominate vein (Fig. 24.7). The pulsating aortic arch is clearly seen when the mediastinoscope is advanced. At this point the subaortic nodes are found. By rotating the tip of the scope medially, the para-aortic lymph nodes can be identified and subjected to biopsy. However, the rigid anterior chest wall limits the range of movement of the mediastinoscope in this area.[29,30] Palpation of the subaortic space is also limited from the cervical incision. If palpation is really needed to differentiate mere contact from tumor invasion, it is better to rely on parasternal mediastinotomy that allows not only direct inspection but also finger and instrumental palpation.

Results

Extended cervical mediastinoscopy is infrequently performed, but the few experiences that have been published show that the results are reproducible by different surgeons. VATS is increasingly used to assess the station 5/6 nodes. The combined analyses of 456 patients reported in five articles published between 1987 and 2012 reveal a median sensitivity of 0.71 and a median negative predictive value of 0.91.[3] An additional reported series of 82 patients with left lung carcinoma and suspected N2 disease on PET–CT or T3–T4 tumors underwent extended cervical mediastinoscopy after standard mediastinoscopy. Nodal involvement in subaortic or para-aortic lymph node stations was confirmed in 20 patients and T4 disease in 2, thereby changing the stage in 22 (27%) patients.[31]

Complications

In the largest series published to date, four (2.3%) complications occurred in 221 patients: mediastinitis, treated with antibiotics and drainage; ventricular fibrillation, treated with defibrillation;

superficial wound infection; and bleeding, treated with compression.[32] Other reported complications are pneumothorax and hoarseness, although these may happen in standard mediastinoscopy and are not specific to extended cervical mediastinoscopy.[33,34] One intraoperative death from aortic injury has been reported.[31]

Other Variants of Extended Mediastinoscopy

Retrosternal or Prevascular Mediastinoscopy. In this variant, the mediastinoscope is inserted behind the sternum, in front of the mediastinal vessels. It is rarely indicated for lung cancer staging, but is useful for the occasional patient who presents with lesions in the retrosternal region.

Mediastinoscopic Biopsy of the Scalene Lymph Nodes. From the cervical incision of mediastinoscopy, the mediastinoscope can be advanced behind the insertions of the sternocleidomastoid muscle to reach the scalene fat pad and nodes. Added to mediastinoscopy that has proved N2 disease, unsuspected N3 disease in scalene lymph nodes is found in 15% of patients, and in 68% of those with mediastinal N3 disease at mediastinoscopy.[35]

Mediastino-thoracoscopy: In cases of concomitant mediastinal and pleural lesions, the mediastinal pleura can be opened during mediastinoscopy to reach the pleural space. On the right this is best done between the trachea and the superior vena cava. On the left, the route over the aortic arch used for extended cervical mediastinoscopy can be used to reach and open the mediastinal pleura. Pleural effusion, pleural nodules, or peripheral lung nodules are the main indications of mediastino-thoracoscopy.[36–38]

Mediastinal Lymph Node Dissection

Definition

MLND is a formal dissection of all lymph node bearing tissues within anatomic boundaries and is usually performed at the time of planned resection and therefore only accesses the ipsilateral lymph nodes.

Indications

MLND is indicated when no invasive staging has been performed prior to resection. MLND is performed if at the time of resection SS identifies N1 or N2 disease, or after neoadjuvant therapy.

Technique

The right paratracheal dissection extends from the level of the right innominate artery to the right tracheobronchial angle, from the lateral border of the superior vena cava to the right anterolateral border of the trachea anterior to the right vagus nerve, to the ascending aorta. The mediastinal pleura overlying the superior vena cava posterior to the phrenic nerve is opened and the fatty tissue is dissected off the posterolateral aspect of the superior vena cava. The dissection is performed over the anterior aspect of the trachea to the ascending aorta and then posterolaterally to the vagus nerve. At the lower extent the right tracheobronchial angle and azygos vein are skeletonized. For the subcarinal dissection the mediastinal pleura is opened just at the lower edge of the right main bronchus; then the lymph node bearing tissue is dissected off the carina, the pericardium, and the left main bronchus. The inferior mediastinal dissection extends from the subcarinal space down to the diaphragm, exposing the esophagus and pericardium and taking the inferior pulmonary ligament tissues. On the left the para-aortic dissection removes all the lymph node bearing tissue between the phrenic and vagus nerves baring the aortic arch. The subaortic dissection removes

all the lymph node bearing tissue from the ligamentum arteriosum to the left upper lobe pulmonary artery, from the inferior aspect of the aortic arch to the superior aspect of the left main pulmonary artery. The left recurrent nerve is carefully dissected and preserved.

Complications

Complications of MLND based on the ACOSOG Z0030 trial include recurrent laryngeal nerve injury (0.9%), chylothorax (1.7%), and bleeding (1.1%). In the ACOSOG Z0030 trial, there were no significant differences in complication rates between MLND and SS.[39]

Thoracoscopy and VATS

Definition

Thoracoscopy is the inspection of the chest cavity for diagnostic, staging, or therapeutic purposes.

Indications

Classic thoracoscopy was limited to the assessment of lung cancer with an accompanying pleural effusion and to the taking of small biopsies; however, video thoracoscopy and VATS, performed with the assistance of several ports, allow the surgeon to perform resections of ipsilateral and contralateral additional peripheral nodules to confirm or rule out T3, T4, or M1a disease; to explore the ipsilateral mediastinum from the apex of the pleural cavity to the diaphragmatic dome; to assess the hilar and interlobar lymph nodes; to explore the inferior mediastinal nodes (station 8, paraesophageal nodes, and station 9, pulmonary ligament nodes); and even to open and assess the pericardial cavity to confirm T3, T4, or M1a disease. Thoracoscopy can replace left parasternal mediastinotomy and extended cervical mediastinoscopy to explore the subaortic and para-aortic lymph nodes. Performed immediately before lung resection, thoracoscopy or VATS may help assess tumor extent and disclose unsuspected involvement that may change the therapeutic strategy.[40,41]

Technique

Conventional thoracoscopy or video thoracoscopy for the assessment of pleural effusion or the taking of small pleural, lung, or mediastinal biopsies may be performed under local anesthesia and sedation. The operative thoracoscope has a working channel and, therefore, only one intercostal incision for the insertion of a single port is needed. Alternatively a 7mm semirigid pleuroscope with a 2.8 mm biopsy channel may be used through a 8 mm port. After drainage of the pleural fluid and taking of samples for cytopathologic examination, the parietal and the visceral pleurae are inspected for any abnormalities. Biopsies are taken from all abnormalities with a biopsy forceps. If frozen section examination reveals pleural dissemination, talc pleurodesis may be performed if the lung retains its capacity to reexpand. Lung and mediastinal biopsies can also be taken.

VATS is performed under general anesthesia with lung isolation. Multiple ports are usually required: one for the video thoracoscope and one or more for instruments. VATS offers flexibility for more advanced procedures such as the resection of additional pulmonary nodules, the assessment of hilar or intrapulmonary nodes, the extensive sampling of mediastinal nodes or MLND, and pericardioscopy. The mediastinal pleura may be opened to access paratracheal, hilar, subcarinal, and paraesophageal lymph nodes or even perform MLND. The interlobar nodes may be evaluated by opening the fissure. It is easy to perform a biopsy on pulmonary ligament lymph nodes, or they can be removed

by opening the pulmonary ligament from the diaphragm to the inferior pulmonary vein.

Results

For mediastinal nodal staging, the median sensitivity and negative predictive value in 246 patients from four series published between 2002 and 2007 were 0.95 and 0.96, respectively.[3] In a series of 1306 patients with resectable tumors by standard clinical staging, video thoracoscopy, performed immediately before resection, revealed that 4.4% had unresectable tumors.[42] The most common cause of unresectability was pleural dissemination (2.5%) followed by mediastinal infiltration (1.7%). Global tumor staging was significantly better for video thoracoscopy (73.3%) than for CT (48.7%). Video thoracoscopy correctly matched the T stage with the final pathology report in 96.2% of cases. It also reduced the exploratory thoracotomy rate from 11.6%, before the introduction of routine exploratory video thoracoscopy, to 2.5%, after the implementation of its routine use.[40] In another series of 1381 patients with resectable tumors by standard staging, exploratory video thoracoscopy was possible in 1277, and in 141 cases (10.2%), tumors were considered unresectable by video thoracoscopy because of mediastinal invasion in 81 patients, pleural dissemination in 38, both in 6, and infiltration of the adjacent fissure in patients who could not tolerate pneumonectomy in 16. Exploratory thoracotomy was performed in 43 (3.1%) patients.[41] The same group performed transpleural video pericardioscopy in 91 patients with suspicion of pericardial involvement. Video pericardioscopic findings revealed that 61 patients had resectable tumors, whereas 30 had different degrees of invasion that precluded complete resection: pulmonary artery in 17, pulmonary artery and superior pulmonary vein in 6, pulmonary artery and superior vena cava in 2, and left atrium and pulmonary veins in 5.[41]

Complications

Complications are rare, occurring in about 5% of cases, and include air leak, subcutaneous emphysema, chest pain, bleeding, wound infection, and empyema.

Inferior Mediastinoscopy and Subxiphoid Pericardioscopy

Definition

Inferior mediastinoscopy refers to the inspection of the inferior mediastinum through a subxiphoid approach, whereas subxiphoid pericardioscopy is used to inspect the pericardial cavity. These are uncommon procedures.

Indications

Inferior mediastinoscopy is indicated to diagnose mediastinal lesions located between the anterior pericardium and the sternum or at the cardiophrenic angles that fall out of reach of cervical mediastinoscopy.[43,44] Subxiphoid pericardioscopy is especially indicated in patients with lung cancer and pericardial effusion that has not been diagnosed by pericardiocentesis and cytopathologic examination of the pericardial fluid.[45,46]

Technique

Both operations are performed under general anesthesia and orotracheal intubation. With the patient in the supine decubitus position, a 5-cm vertical incision is made over the xiphoid. The xiphoid is generally excised. For inferior mediastinoscopy, the mediastinoscope is inserted between the anterior pericardium and the sternum. The anterior surface of the pericardium can be explored and the

exploration can be continued to both cardiophrenic angles. Biopsy of lymph nodes or masses is performed with biopsy forceps as for cervical mediastinoscopy. If the mediastinal pleura is not opened, drainage is not necessary. The incision is closed in three layers: midline of the rectus abdominis muscles, subcutaneous tissue, and skin.

The same approach is used for subxiphoid pericardioscopy. Once the xiphoid is excised, the pericardium is grasped and incised. A sample of fluid is taken for cytopathologic examination. After drainage of the pericardial fluid, the mediastinoscope is inserted into the pericardial cavity and the internal surface of the parietal pericardium, the surface of the heart, and the intrapericardial segments of the great vessels are explored. In case of malignancy, pericardiodesis can be performed. A portion of the pericardium also can be excised to create a pericardial window that will drain the pericardial fluid into the subcutaneous tissue. A soft drain is inserted into the pericardium and the incision is closed in three layers as for inferior mediastinoscopy.

Results

Both techniques provide cytohistologic proof of tumor extent, thus increasing the certainty of the staging process. Although they are rarely indicated, they should be kept in mind when the target lesions are beyond the reach of more standard techniques.

Complications

Complications are rare and include wound infection, bleeding, and intraoperative arrhythmias, especially in pericardioscopy.

Endobronchial Ultrasound and Endoscopic Ultrasound

Definitions

EBUS-guided TBNA (EBUS–TBNA) and EUS-guided fine-needle aspiration (EUS–FNA) are minimally invasive endoscopic techniques, which are alternatives to mediastinoscopy and may replace the routine use of mediastinoscopy for invasive staging of NSCLC.

Mediastinal lymph nodes are subjected to biopsy by needle puncture under real-time ultrasound guidance under local or general anesthesia.[47,48]

EUS allows ultrasonographic imaging of structures adjacent to the gastrointestinal tract, which is useful for lymph nodes in the posterior mediastinum and upper retroperitoneum. However, the reach of EUS–FNA does not correspond completely to the reach of mediastinoscopy. EBUS–TBNA can access the same nodes as mediastinoscopy, but also extends to the hilar and interlobar lymph nodes (N1 nodes).[49] The combination of EBUS and EUS allows sampling of most mediastinal lymph nodes as well as N1 nodes (Fig. 24.8). Sonographic features of lymph nodes considered suspicious for malignancy include lymph nodes larger than 1 cm in short axis, round shape, distinct margins, heterogeneous echogenicity, evidence of necrosis, and loss of central hilar structures.[50] Lymph node assessment should be performed in a systematic manner beginning with the N3 nodes followed by N2 and then N1 nodes to avoid contamination and upstaging. Nodes are described and numbered according to the IASLC map.

Technique

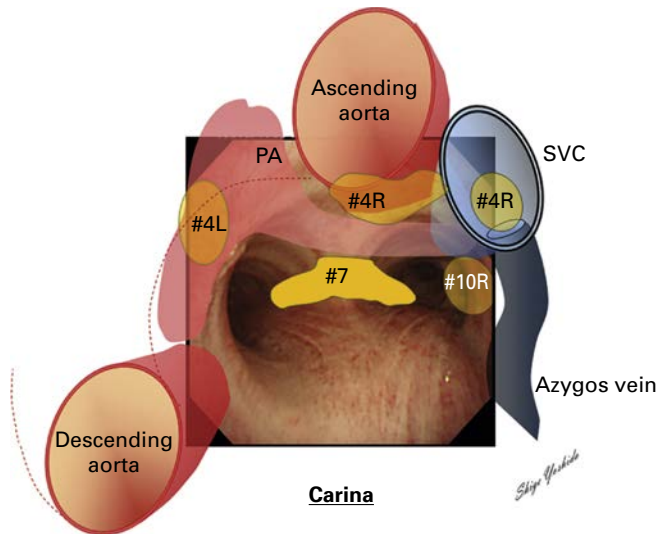
Anesthesia. EBUS–TBNA and EUS–FNA can be performed on an outpatient basis using topical anesthesia and conscious sedation. For EBUS–TBNA, the bronchoscope is usually


Fig. 24.8. Relevant anatomy for endobronchial ultrasound. *PA,* pulmonary artery; *SVC,* superior vena cava. *(Image courtesy Shige Yoshida.)*

inserted orally, because the size of the ultrasound probe on the tip limits nasal insertion. General anesthesia may be used instead and minimizes the cough reflex for EBUS. An endotracheal tube (size 8 or larger) may be used but causes the bronchoscope to lie in the central position within the airway, thus creating difficulty in bringing the ultrasound probe in contact with the wall of the airway. A laryngeal mask airway is a good alternative.

EBUS–TBNA. A standard flexible bronchoscopy is first performed, then the Convex Probe-EBUS (CP-EBUS) scope is passed through the vocal cords by visualizing the anterior angle of the glottis and advanced into the airway until the desired lymph node station is reached. The balloon is inflated with normal saline to achieve a maximum contact with the airway wall, then the tip of the CP-EBUS is flexed and gently pressed against the airway. Specific lymph node stations are identified using ultrasonically visible vascular landmarks (see Fig. 24.8). The Doppler mode is used to confirm and identify surrounding vessels as well as the blood flow within lymph nodes. The bronchoscopic image of the airway is simultaneously visualized to localize the insertion point of the needle. The TBNA needle is advanced through the working channel of the bronchoscope until the sheath can be visualized on the endoscopic image. The tip of the bronchoscope is then flexed up and the lymph node is visualized again on the ultrasonographic image. The needle is passed through the airway into the lymph node avoiding the cartilage. Once the needle is confirmed to be inside the lymph node, the internal stylet is used to clear out the internal lumen, which may become clogged with bronchial epithelium. The internal stylet is then removed and negative pressure is applied with a syringe. For hypervascular nodes, samples may be taken without suction to avoid bloody samples. The needle is moved back and forth inside the lymph node to obtain samples. The needle is then retracted inside the outer sheath and the entire needle is removed from the bronchoscope. The internal stylet is used to push out samples. If on-site cytopathology is available, the initial sample is placed on a slide glass, and smears are made for rapid on-site cytologic evaluation. The rest of the specimen is placed in a 50-mL conical tube filled with normal saline for cell-block preparation. Otherwise the sample is placed in standard cytology preservation solution.

The overall risk of EUS–FNA is approximately 0.5% and may include perforation of the esophagus or posterior pharynx, infection, and hemorrhage.

Complications related to EBUS–TBNA are similar to those of bronchoscopy and conventional TBNA and include pneumothorax, pneumomediastinum, hemomediastinum, mediastinitis, bacteremia, and pericarditis. To date, there are no major complications reported in the literature.

EUS–FNA. The radial EUS scope or radial miniprobe may be inserted first to identify lymph nodes of interest. Next the linear EUS scope is advanced into the stomach and then slowly withdrawn while making circular movements. Anatomic landmarks such as the inferior vena cava, right and left atrium, azygos vein, main pulmonary artery, and aorta are identified. Lymph nodes are described and numbered according to the IASLC map. Biopsy is then performed on lymph nodes using a 22-gauge needle under real-time ultrasound guidance with monitoring of the needle during insertion and aspiration. Similar to EBUS–TBNA, suction may be applied and multiple passes are made in the lymph node.

Results: EBUS–TBNA

Multiple studies have demonstrated high sensitivity, specificity, and diagnostic accuracy of EBUS–TBNA for mediastinal lymph node staging. Prospective studies of EBUS–TBNA for mediastinal staging report sensitivity of 0.94, specificity of 1, positive predictive value of 1, and diagnostic accuracy of 0.96 for mediastinal lymph node staging. The negative predictive value varies from 0.11 to 0.89 depending on the prevalence of malignancy.[51,52] Furthermore, multiple prospective series and meta-analyses have demonstrated the safety, efficacy, and high diagnostic yield of EBUS–TBNA.[53–55]

Comparison of EBUS–TBNA and mediastinoscopy in 153 potentially resectable patients with lung cancer demonstrated that in 91% of patients, there was excellent agreement between the two techniques regarding the staging of the mediastinum, and test characteristics were similar. The specificity and positive predictive value of both tests were 1. The sensitivity, negative predictive value, and diagnostic accuracy for mediastinal lymph node staging for EBUS–TBNA and mediastinoscopy were 0.81, 0.91, and 0.93, and 0.79, 0.90, and 0.93, respectively.[56]

Results: EUS–FNA

EUS–FNA offers a minimally invasive method of examining the posterior and inferior mediastinum in patients with lung cancer with a sensitivity of 0.74–0.92.[42,57–59] Unlike other invasive staging modalities such as EBUS–TBNA and mediastinoscopy, the sensitivity of EUS–FNA seems to be affected by variables such as size of the nodes, size of the tumor, and nodal station. EUS–FNA is reported to have a low negative predictive value of 0.73 and is not a very reliable test in ruling out lymph node spread. Most investigators agree that negative results of EUS–FNA should be verified by other invasive staging modalities, especially in the presence of suggestive imaging.

Comparing EUS–FNA with mediastinoscopy in a prospective study of 60 patients, the sensitivity of EUS–FNA for station 4R was 0.67, versus 0.33 for mediastinoscopy. At station 4L, EUS–FNA was also more sensitive than mediastinoscopy (0.80 vs. 0.33). The sensitivity of EUS–FNA at the subcarinal station (station 7) was 1, versus only 0.70 for mediastinoscopy. In this report the results of the yield for mediastinoscopy are much lower than previously reported; however, for lymph node stations out of the reach of mediastinoscopy, EUS–FNA is appropriate.[58]

Results: Combined EBUS and EUS

By combining EBUS–TBNA and EUS–FNA, the majority of the mediastinum as well as the hilar lymph nodes can be sampled. Using the combined approach for invasive staging, even using

a single EBUS–TBNA scope for both procedures, sensitivity of 0.91 to 1 and negative predictive value of 0.91 to 0.95 have been reported.[60–62] To date, the combined EBUS–EUS approach has been shown to be more sensitive than using EBUS or EUS independently, with a significantly better negative predictive value.

A multicenter randomized controlled trial in 241 patients with resectable NSCLC compared surgical staging alone with a combined EBUS–EUS approach followed by surgical staging if no metastases were found by endosonography.[63] Of the 123 patients who started with endosonography,[64] patients underwent mediastinoscopy, with nodal metastases identified in only 4 patients. The sensitivity of the combined approach was 0.94 and negative predictive value was 0.93. In the mediastinoscopy-alone group, the sensitivity was 0.80 and the negative predictive value was 0.86, which was statistically no different from the combined approach. Despite the lack of difference in negative predictive value, the study demonstrated that the number of unnecessary thoracotomies was reduced by half in the combined-approach group. Based on this study, a new strategy for invasive staging was suggested, which begins with combined EBUS–EUS followed by mediastinoscopy if the lymph node metastasis is not demonstrated.

MEDIASTINAL RESTAGING

Stage IIIA NSCLC represents a heterogeneous group of patients with metastatic disease to N2 lymph nodes as well as T3N1 disease. The management of patients with N2 stage IIIa disease varies widely from resectable tumors with occult microscopic nodal metastases to unresectable bulky multistation nodal disease. The treatment for patients with N2 disease varies depending on the extent of N2 lymph node involvement. Neoadjuvant therapy (chemotherapy ± radiotherapy) followed by surgery for known stage IIIA (N2) disease as a routine therapeutic option is not generally recommended except as a part of a clinical trial.[65] Initial invasive mediastinal staging to confirm N2 disease is mandatory for patients treated with induction chemoradiotherapy as part of a clinical trial. The purpose of restaging is to evaluate whether there is residual involvement of the mediastinal lymph nodes after induction therapy, which would change subsequent treatment for these patients.

Restaging of the mediastinum after induction therapy has been reported by noninvasive imaging modalities (CT and PET scan). CT scan alone is a poor restaging test with false-negative (FN) and false-positive (FP) rates of approximately 40%.[66] PET scan appears to perform better than CT scan alone, although radiation therapy can cause ^{18}F-2-deoxy-D-glucose uptake due to inflammation after induction treatment. The FN and FP rates of PET scan for restaging are 25% and 33%, respectively, based on a systematic review.[66]

Invasive restaging can be performed by remediastinoscopy, VATS, and minimally invasive endoscopic NA modalities such as EBUS–TBNA and EUS–FNA, but there are a very limited number of studies looking at the role of invasive restaging. Remediastinoscopy can be performed safely in experienced hands, but only a few institutions actually perform the procedure because it can be extremely difficult due to fibrotic changes after the initial mediastinoscopy and induction therapy. Based on a systematic review, the results of remediastinoscopy are consistently worse than the initial mediastinoscopy with a pooled sensitivity of 63% and FN rate of 22%.[66] By contrast, EBUS and EUS can be performed with ease with slightly better results with a pooled sensitivity of 84% and FN rate of 14%.[64,67–69] Two studies looked at the role of first-time cervical mediastinoscopy after induction therapy for restaging after initial invasive staging with EBUS and/or EUS.[70,71] This strategy has results similar to initial staging with mediastinoscopy with an excellent sensitivity of 89% and FN rate of 9%.

Minimally invasive needle techniques including EBUS–TBNA and EUS–FNA are now considered the tests of first choice to confirm mediastinal disease in accessible lymph node stations. Thus an ideal algorithm for invasive staging of patients with N2 stage IIIa disease would be to perform initial invasive staging by ultrasound-guided needle-based techniques followed by restaging with needle-based techniques and reserve mediastinoscopy for EBUS/EUS negative cases.

CONCLUSION

Invasive staging of the mediastinum is an essential component of the evaluation of patients with NSCLC. Pathologic confirmation of imaging abnormalities is important because of the frequency of FP imaging tests. Patients at increased risk of mediastinal lymph node metastases such as those with central, larger, or higher T stage tumors or those with evidence of N1 disease should also have invasive mediastinal staging. Needle biopsy techniques offer less invasive options with equivalent results to open techniques for invasive staging. VATS provides access to the entire ipsilateral hemithorax, which increases its utility over some of the older techniques. Regardless of the technique used, it is important to perform a systematic approach by either SS or MLND.

25 The Eighth Edition of the Tumor, Node, and Metastasis Classification of Lung Cancer

Ramón Rami-Porta, Peter Goldstraw, and Harvey I. Pass

SUMMARY OF KEY POINTS

- Size counts: From less than or equal to 1-cm to less than or equal to 5-cm tumor size, every centimeter has prognostic impact and separates into different T categories, and tumors greater than 5 cm but less than 7 cm are now T3; and those greater than 7 cm are now T4.
- Distance to carina does not count: Tumors with endobronchial location less than 2 cm from the carina have similar outcomes to those greater than 2 cm from the carina.
- N status remains largely the same.
- An oligometastasis is now classified as M1b.
- Descriptors for same lobe as well as other lobe intrapulmonary nodules as metastases or synchronous primary lesions are delineated.
- Part-solid adenocarcinoma size will be defined by the size of the solid component on computed tomography and of the invasive component on microscopic examination.

The tumor, node, and metastasis (TNM) classification of malignant tumors is promulgated by the Union for International Cancer Control and the American Joint Committee on Cancer.[1] The TNM classification undergoes periodical revisions based on the reports from the National TNM Committees and on the annual assessment of original articles.[2,3] For the latest two editions of the TNM classification of lung cancer (7th edition of 2009 and 8th edition of 2016), the revisions were based on two international databases collected by the International Association for the Study of Lung Cancer (IASLC).[4,5] These databases were stored, managed, and analyzed by Cancer Research And Biostatistics, a not-for-profit data center based in Seattle, WA, USA, in collaboration with the members of the IASLC Staging and Prognostic Factors Committee. This chapter presents the process of revision leading to the eighth edition of the TNM classification of lung cancer, the innovations introduced, and their clinical implications. The eighth edition of the TNM classification of malignant tumors will be enacted on January 1, 2017.

THE INTERNATIONAL ASSOCIATION FOR THE STUDY OF LUNG CANCER DATABASE FOR THE EIGHTH EDITION

For the second consecutive time, the IASLC registered data from around 100,000 patients with lung cancer. For this revision, the period of diagnosis was from 1999 to 2010. Data originated in 35 different databases in 16 countries of 5 continents. Their geographical origin and number of patients are as follows: Europe, 46,560; Asia, 41,705; North America, 4660; Australia, 1593; and South America, 190, for a total of 94,708 patients. After exclusions, 77,156 patients met the requirements

for analysis: 70,967 with nonsmall cell lung cancer (NSCLC) and 6189 with SCLC. Table 25.1 shows the type of databases contributing to the IASLC Staging Project and the nature of the data.[5] Most data were retrospective, that is, contributors around the world already were registering data on patients with lung cancer and submitted their databases to the IASLC. These databases contained the minimum information regarding TNM descriptors, but some of them lacked the necessary detail needed for deeper analyses. By contrast, data registered through the electronic data capture online system are smaller in numbers but richer in detail and were useful, for example, to analyze the descriptors of the M component because they contained the information on number and location of metastases. Table 25.2 shows the type of treatment undergone by the registered patients with SCLC and NSCLC.[5] The proportion of patients treated with tumor resection either alone or in combination with chemotherapy and/or radiotherapy is higher in this database than in the one used for the seventh edition. This is due to the fact that databases of clinical trials, usually collected for advanced disease, were not submitted. However, surgical registries have complete information on the descriptors of the anatomic extent of the disease and are readily available for analysis. Despite this lack of patients with advanced lung cancer, all findings potentially leading to recommendations for changes were validated in the populations of patients with clinically and pathologically staged tumors, except those of the M component that were exclusively based on clinically staged tumors.

INNOVATIONS IN THE T, N, AND M DESCRIPTORS

T Descriptors

The T component of the classification is complex to analyze because it has many descriptors: tumor size, endobronchial location, atelectasis/pneumonitis, and invasion of various anatomic structures surrounding the lung. For their analyses, the prognostic impact of each descriptor was analyzed individually in five different populations of patients: three with pathologically staged tumors (pT1–4 N0 M0 completely resected [R0]; pT1–4 any N M0 R0; and pT1–4 any N M0 any R, i.e., including resections with microscopic [R1] and macroscopic [R2] evidence of residual tumor) and two with clinically staged tumors (cT1–4 N0 M0 and cT1–4 any N M0). Additional univariate and multivariate analyses were performed after adjustment by histopathologic type, geographical region of origin, age, and sex. These analyses generated multiple survival curves that were closely analyzed to see if the different descriptors were properly assigned to their T category.[6] The results of these analyses can be summarized as follows:

- The 3-cm landmark still separates T1 from T2 tumors.
- Tumor size, analyzed at 1-cm intervals, has more prognostic impact than previously shown in past editions of the TNM classification. From less than or equal to 1-cm to less than or equal to 5-cm tumor size, every centimeter counts and separates different T categories.

- The prognosis of tumors greater than 5 cm to less than or equal to 7 cm was similar to that of T3 tumors.
- The prognosis of tumors greater than 7 cm was similar to that of T4 tumors.
- The prognosis of tumors with endobronchial location less than 2 cm from the carina (a T3 descriptor in the 7th edition) was found to be similar to that of their T2 counterparts (endobronchial location >2 cm from the carina).
- The prognosis of tumors with total atelectasis/pneumonitis (a T3 descriptor in the 7th edition) was found to have a T2 prognosis, similar to that of tumors with partial atelectasis/pneumonitis.

- The prognosis of tumors with invasion of the diaphragm (a T3 descriptor in the 7th edition) was found to be similar to that of T4 tumors.
- The invasion of the mediastinal pleura was rarely used as a unique descriptor.

Based on the aforementioned findings, the recommendations for changes in the T categories are as follows:

- Subdivide T1 into three new subcategories: T1a (≤1 cm), T1b (>1 cm but ≤2 cm), and T1c (>2 cm but ≤3 cm).
- Subdivide T2 into two new subcategories: T2a (>3 cm but ≤4 cm) and T2b (>4 cm but ≤5 cm).
- Reclassify tumors greater than 5 cm but less than or equal to 7 cm as T3.
- Reclassify tumors greater than 7 cm as T4.
- Reclassify tumors with endobronchial location less than or equal to 2 cm from the carina, but without involvement of the carina, as T2.
- Reclassify tumors with total atelectasis/pneumonitis as T2.
- Reclassify tumors with invasion of the diaphragm as T4.
- Delete the invasion of the mediastinal pleura as a descriptor.

When survival is analyzed according to these new T descriptors, survival curves separate well and do not cross over. All survival differences are significant and there is a clear difference between T3 and T4 that was not seen in the seventh edition (Fig. 25.1).

Visceral pleural invasion, defined as the invasion of its elastic layer, is well assigned to the T2 category (Fig. 25.2).[7] There are survival differences between PL1 and PL2, but these are only identifiable at pathologic staging, so they cannot be used to modify the present T2 descriptor based on the extent of visceral pleural invasion. However, they are useful to refine postoperative prognosis in those patients with resected tumors in which visceral pleural invasion is identified. Because visceral pleura involvement impacts prognosis, the use of elastic stains is emphasized again in the eighth edition of the TNM classification of lung cancer, if it is not evident on hematoxylin and eosin stains.

N Descriptors

The N descriptors were analyzed in the population of patients with clinically and pathologically staged tumors. In both

populations, the present N descriptors (N0, N1, N2, and N3) separate tumors with statistically significant prognosis (Fig. 25.3). Therefore, there is no need to suggest any modification in the N component.[8]

Exploratory analyses on the quantification of nodal disease also were performed. Survival was analyzed according to the number of nodal stations involved in the population of patients with pathologically staged tumors and adequate information on the nodal stations explored. There are five groups of tumors according to the number of nodal stations involved:

- N1a: single-station N1
- N1b: multiple-station N1
- N2a1: single-station N2 without N1 disease (skip metastasis)
- N2a2: single-station N2 with N1 disease
- N2b: multiple-station N2.

Fig. 25.4 shows the survival of patients with pathologically staged tumors and nodal disease classified according to the number of nodal stations involved. All survival differences are statistically significant except those between N1b (multiple-station N1) and N2a1 (single-station N2 without N1). When these analyses are performed in the clinical staging setting, these differences cannot be replicated. This is the reason why this suggested subclassification cannot be used to modify the N descriptors, because, in principle, clinical and pathologic descriptors must be identical. However, this subclassification is clinically relevant as it may be used to refine postoperative prognosis for those patients with resected lung cancers harboring nodal disease.[8]

The IASLC regional lymph node map proposed in 2009 was the result of a multidisciplinary and international consensus (Fig. 25.5). No map or anatomic scheme is perfect, and this map is not perfect either. One advantage of this map over the others previously proposed is that this one has clear definitions for each nodal station that can be recognized by radiologists, endoscopists, and thoracic surgeons performing mediastinoscopy and systematic nodal dissection at the time of lung resection (Table 25.3). The IASLC Staging and Prognostic Factors Committee recommends the use of this map for nodal labeling and the prospective collection of data to examine its potential limitations and suggest modifications in the future.[9]

M Descriptors

The electronically captured data, that is, data registered prospectively online, were used for the revision of the M descriptors because they had adequate detail for the planned analyses. Patients with resected metastases were excluded from these analyses. Regarding the M1a descriptors, those defined in the seventh edition (metastasis within the pleural space: contralateral separate

Fig. 25.2. tumor nodules, pleural and pericardial nodules, and malignant pleural and pericardial effusions) could be validated with the database of the eighth edition. Fig. 25.6A shows how similar the survival curves for all these descriptors are. Therefore, there is no need to modify them. For extrathoracic metastases (M1b), it was found that patients with single extrathoracic metastasis had similar survival to that of those with M1a tumors, but significantly worse than those with multiple extrathoracic metastases. The survival of those with multiple extrathoracic metastases in one organ and that of those with multiple extrathoracic metastases in several organs was similar. These analyses showed that the number of extrathoracic metastases had more prognostic impact than their location (Fig. 25.6B). According to these results, the recommendations for changes were the following:

- Keep the M1a descriptors as they are
- Redefine M1b to code tumors with a single extrathoracic metastasis
- Create a new category, M1c, to code tumors with multiple extrathoracic metastases either in one or in several organs.

M1a and M1b tumors have similar prognoses, but it makes sense to code them differently as they represent different anatomic forms of metastatic disease and have a different diagnostic and therapeutic approach.[10]

Stage Grouping

Table 25.4 shows the definitions of the T, N, and M descriptors for the eighth edition of the TNM classification of lung cancer. For the stage grouping, several models were discussed. Table 25.5 shows the model eventually chosen because it is the one that best separates tumors with different prognoses. Stage IA is divided into stages IA1, IA2, and IA3 to accommodate the new T1a, T1b, and T1b tumors with no nodal involvement and no metastasis. Stages IB and IIA will now group T2a and T2b tumors with no spread beyond the lung, respectively. All N1M0 tumors will be grouped in stage IIB,

together with T3 N0 M0, except for T3–T4 N1 M0 tumors that are grouped in stage IIIA. Similarly, all N2M0 tumors are stage IIIA, except for T3–T4 N2 M0 tumors that are in stage IIIB, together with all N3M0 tumors, except for T3–T4 N3 M0 for which a new stage IIIC was created. Finally, stage IV is divided into stage IVA to group M1a and M1b tumors, and stage IVB to include M1c tumors.[11] Fig. 25.7 shows the survival of patients according to clinical and pathologic stages, respectively. The expected worsening in survival is observed as tumor stage increases. All differences are statistically different except that of clinical stages IIIC and IVA. However, it makes sense to separate these tumors into two different stages as they represent different types of anatomic spread of the tumor: locoregional for those in stage IIIC and metastatic for those in stage IVA.

Applicability to SCLC and Bronchopulmonary Carcinoids

The applicability of the TNM classification to SCLC and to bronchopulmonary carcinoids was explored in the revisions leading to the seventh edition. The TNM classification was found to discriminate more prognostic groups at clinical and pathologic staging than the dichotomous classification "limited versus extensive disease" traditionally used for SCLC.[12,13] It also worked well for bronchopulmonary carcinoids, although the TNM classification was analyzed exclusively in the population of patients with resected tumors. The higher survival rates for all categories and stages, including metastatic disease, reflected the more benign nature of this neoplasm.[14] For the eighth edition, there were 4848 patients with clinically staged SCLC tumors; 582 underwent tumor resection with pathologic classification; and 428 patients had tumors clinically and pathologically staged. The analyses performed in these populations showed that the TNM classification works for SCLC, although the different natural history of this disease is clearly reflected in the lower survival rates for most categories and stages. However, it is important to realize that prognosis for early stages (IA1 to IA3) is not so different from that of NSCLC in the same stages.[15]

CLASSIFICATION OF TUMORS THAT DO NOT FIT IN THE DESCRIPTORS

Situations that are not included in the TNM descriptors are difficult to classify. These situations are uncommon, and there are no recommendations based on data. The alternative has been to agree to classify them in a certain way so that everybody classifies them similarly. Table 25.6 shows most of these situations and their recommended classification.[16]

NEW SPECIFIC RULES FOR LUNG CANCER

Measurement of Tumor Size in Part-Solid Nonmucinous Adenocarcinomas

The new classification of adenocarcinoma proposed by the IASLC, the American Thoracic Society, and the European Respiratory Society defined adenocarcinoma in situ, minimally invasive adenocarcinoma, and invasive adenocarcinomas of different cell types.[17] This new classification has been accepted by the World Health Organization and has been included in the latest edition of its book on the pathology of thoracic cancers.[18] These tumors may present as part-solid lesions on computed tomography (CT), with solid and ground-glass components. In general, the solid component on CT corresponds to the invasive part of the tumor at microscopic examination, and the ground-glass component corresponds to the lepidic part, which is the noninvasive

The IASLC Lung Cancer Staging Project. A proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. J Thorac Oncol. 2009;4:568–577.)*

portion of the tumor. There is a growing body of evidence indicating that prognosis is led by the size of the solid component of the tumor.[19–21] Therefore for these part-solid adenocarcinomas, size will be defined by the size of the solid component on CT and of the invasive component on microscopic examination. However, it is recommended to register both the size of the solid/invasive component and the size of the whole tumor in radiology/pathology reports.[22]

Measurement of Tumor Size After Induction Therapy

There are no rules for the measurement of tumor size after induction therapy when there has been some tumor response. A practical way to do it is to multiply the percent of viable tumor cells by the size of the total mass. This is applicable to a single focus or multiple foci of viable tumor.[22]

TABLE 25.3 Limits of the Nodal Stations of the IASLC Lymph Node Map[9]

Lymph Node Station No. (#)	Anatomic Limits
SUPRACLAVICULAR ZONE	
#1: Low cervical, supraclavicular, and sternal notch nodes	• Upper border: lower margin of cricoid cartilage. • Lower border: clavicles bilaterally and, in the midline, the upper border of the manubrium. 1R designates right-sided nodes, 1L left-sided nodes in this region. • For lymph node station 1, the midline of the trachea serves as the border between 1R and 1L.
UPPER ZONE	
#2: Upper paratracheal nodes	• 2R: Upper border: apex of the right lung and pleural space, and, in the midline, the upper border of the manubrium. • Lower border: intersection of caudal margin of the innominate vein with the trachea. • Similar to lymph node station 4R, 2R includes nodes extending to the left lateral border of the trachea. • 2L: Upper border: apex of the lung and pleural space, and, in the midline, the upper border of the manubrium. • Lower border: superior border of the aortic arch.
#3 Prevascular and retrotracheal nodes	• 3a: Prevascular • On the right: upper border: apex of chest. Lower border: level of carina. Anterior border: posterior aspect of sternum. Posterior border: anterior border of the superior vena cava. • On the left: upper border: apex of chest. Lower border: level of carina. Anterior border: posterior aspect of sternum. Posterior border: left carotid artery. • 3p: Retrotracheal • Upper border: apex of chest. Lower border: carina.
#4: Lower paratracheal nodes	• 4R: includes right paratracheal nodes, and pretracheal nodes extending to the left lateral border of the trachea. • Upper border: intersection of caudal margin of the innominate vein with the trachea. • Lower border: lower border of the azygos vein. • 4L: includes nodes to the left of the left lateral border of the trachea, medial to the ligamentum arteriosum. • Upper border: upper margin of the aortic arch. • Lower border: upper rim of the left main pulmonary artery.
AORTOPULMONARY ZONE	
#5: Subaortic (aortopulmonary window)	• Subaortic lymph nodes lateral to the ligamentum arteriosum. • Upper border: the lower border of the aortic arch. • Lower border: upper rim of the left main pulmonary artery.
#6: Para-aortic nodes (ascending aorta or phrenic)	• Lymph nodes anterior and lateral to the ascending aorta and aortic arch. • Upper border: a line tangential to the upper border of the aortic arch. • Lower border: the lower border of the aortic arch.
SUBCARINAL ZONE	
#7: Subcarinal nodes	• Upper border: the carina of the trachea. • Lower border: the upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right.
LOWER ZONE	
#8: Paraesophageal nodes (below carina)	• Nodes lying adjacent to the wall of the esophagus and to the right or the left of the midline, excluding subcarinal nodes. • Upper border: the upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right. • Lower border: the diaphragm.
#9: Pulmonary ligament nodes	• Nodes lying within the pulmonary ligament. • Upper border: the inferior pulmonary vein. • Lower border: the diaphragm.
HILAR/INTERLOBAR ZONE	
#10: Hilar nodes	• Includes nodes immediately adjacent to the main stem bronchus and hilar vessels including the proximal portions of the pulmonary veins and the main pulmonary artery. • Upper border: the lower rim of the azygos vein in the right; upper rim of the pulmonary artery on the left. • Lower border: interlobar region bilaterally.

#11: Interlobar nodes	• Between the origin of the lobar bronchi.
	• Optional notations for subcategories of station:
	  • #11s: between the upper lobe bronchus and bronchus intermedius on the right.
	  • #11i: between the middle and lower bronchi on the right.

PERIPHERAL ZONE	
#12: Lobar nodes	• Adjacent to the lobar bronchi
#13: Segmental nodes	• Adjacent to the segmental bronchi
#14: Subsegmental nodes	• Adjacent to the subsegmental bronchi

TABLE 25.4 Categories, Subcategories, and Descriptors of the Eighth Edition of the TNM Classification of Lung Cancer[11]

T: PRIMARY TUMOR		
Category	**Subcategory**	**Descriptors**
TX		Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.
T0		No evidence of primary tumor.
Tis		Carcinoma in situ:
		Tis(AIS): adenocarcinoma
		Tis(SCIS): squamous cell carcinoma
T1		Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus).[a]
	T1mi	Minimally invasive adenocarcinoma.
	T1a	Tumor 1 cm or less in greatest dimension.[a]
	T1b	Tumor more than 1 cm but not more than 2 cm in greatest dimension.[a]
	T1c	Tumor more than 2 cm but not more than 3 cm in greatest dimension.[a]
T2		Tumor more than 3 cm but not more than 5 cm; or tumor with *any* of the following features:[b]
		• involves main bronchus regardless of distance to the carina, but without involving the carina
		• invades visceral pleura
		• associated with atelectasis or obstructive pneumonitis that extends to the hilar region, either involving part of the lung or the entire lung.
	T2a	Tumor more than 3 cm but not more than 4 cm in greatest dimension.
	T2b	Tumor more than 4 cm but not more than 5 cm in greatest dimension.
T3		Tumor more than 5 cm but not more than 7 cm in greatest dimension or one that directly invades any of the following: parietal pleura (PL3), chest wall (including superior sulcus tumors), phrenic nerve, parietal pericardium; or associated separate tumor nodule(s) in the same lobe as the primary tumor.
T4		Tumors more than 7 cm or one that invades any of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; or separate tumor nodule(s) in a different ipsilateral lobe to that of the primary tumor.
N: REGIONAL LYMPH NODES		
NX		Regional lymph nodes cannot be assessed.
N0		No regional lymph node metastasis.
N1		Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension.
N2		Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s).
N3		Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s).

TABLE 25.4 Categories, Subcategories, and Descriptors of the Eighth Edition of the TNM Classification of Lung Cancer[11]—cont'd

M: DISTANT METASTASIS	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion.[c]
M1b	Single extrathoracic metastasis in a single organ and involvement of a single distant (nonregional) node.
M1c	Multiple extrathoracic metastases in one or several organs.

[a]The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified as T1a.

[b]T2 tumors with these features are classified T2a if 4 cm or less or if size cannot be determined, and T2b if greater than 4 cm but not larger than 5 cm.

[c]Most pleural (pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging descriptor.

TNM, tumor, node, and metastasis.

TABLE 25.5 Stage Grouping of the Eighth Edition of the TNM Classification of Lung Cancer[11]

Stage	T	N	M

	Any T	Any N	M1b
IVB	Any T	Any N	M1c

TNM, tumor, node, and metastasis.

Classification of Lung Cancers With Multiple Lesions

The rules for classifying lung cancers with multiple lesions are ambiguous and prone to multiple interpretations. An ad hoc subcommittee was created within the IASLC Staging and Prognostic Factors Committee to study this problem and to reach a consensus on a homogeneous way to classify these tumors. The subcommittee established four disease patterns to define the different presentations of lung cancer with multiple lesions and recommended the following rules for their classification.[23]

- *Synchronous and metachronous primary lung cancers*: These should be classified separately with a TNM for each tumor. This classification is applied regardless of the tumor location (different lungs, different ipsilateral lobes or same lobe) to grossly identified tumors and to those identified on microscopic examination. Table 25.7 shows the clinical and pathologic criteria for distinguishing second primary tumors from related tumors.[24]
- *Separate tumor nodules of the same histopathologic type (intrapulmonary metastases)*: The classification of these tumors depends on the lobar location of the separate tumor nodules. If the separate tumor nodule(s) is/are in the same lobe of the primary tumor, they are classified as T3; if they are in a different ipsilateral lobe, they are classified as T4; and finally, if they are in the contralateral lung, they are classified as M1a. However, if there were extrathoracic metastases, the tumor would be classified as M1b or M1c depending on the number of metastases. This classification applies to separate tumor nodes identified clinically or grossly and also to those identified microscopically on pathologic examination. Table 25.8 shows the clinical and pathologic criteria for categorizing a separate tumor nodule (intrapulmonary metastasis).[23,25]
- *Multifocal pulmonary adenocarcinomas with ground-glass/lepidic features*: These tumors should be classified by the highest T with the number (#) or (m) for multiple in parentheses, and N and M categories applying to all of the multiple tumors collectively. The largest dimension of the tumor is that of the solid component by CT or of the invasive component on microscopic examination. This classification applies regardless of the location of the tumors—same lobe, same lung, or contralateral lung—and to grossly recognizable tumors as well as those identified on pathologic examination. Table 25.9 presents the clinical and pathologic criteria for characterizing these tumors.[26]
- *Diffuse pneumonic-type lung adenocarcinoma*: If there is one focus of disease, the general TNM classification for lung cancer is applied, with the T category defined by tumor size. In cases of multiple sites, the T and the M categories are defined by the location of the involved areas: T3 if they are in one lobe, including miliary involvement; T4 if other ipsilateral lobes are involved; and M1a if there is involvement of the contralateral lung. In this case, the T category is defined by the T category of the largest tumor. T4 also is applied when size is difficult to determine, but there is evidence of invasion into another ipsilateral lobe. The N category should apply to all pulmonary sites, and the appropriate M category is chosen depending on the anatomic location of the metastases. As for the other disease patterns described, this classification applies to grossly identified tumors and to those discovered on pathologic examination. Table 25.10 shows the clinical and pathologic criteria for characterizing these tumors.[26]

Table 25.11 summarizes the basic radiographic and pathologic features, the recommended TNM classification, and the conceptual view of the four patterns of lung cancer with multiple lesions.[23]

IMPLICATIONS FOR CLINICAL PRACTICE

One of the most important findings that prompted revisions in the eighth edition of the TNM classification of lung cancer is

TABLE 25.6 Guide to Uniform Classification When the Rules Do Not Fit[16]

Description of the Tumor	Classification
Direct invasion of an adjacent lobe, across the fissure or directly if the fissure is incomplete, unless other criteria assign a higher T classification	T2a
Invasion of phrenic nerve	T3
Paralysis of the recurrent laryngeal nerve, superior vena caval obstruction, compression of the trachea or esophagus related to direct extension of the primary tumor	T4
Paralysis of the recurrent laryngeal nerve, superior vena caval obstruction, compression of the trachea or esophagus related to lymph node involvement	N2
Involvement of great vessels: aorta, superior vena cava, inferior vena cava, main pulmonary artery (pulmonary trunk), intrapericardial portions of the right and left pulmonary arteries, intrapericardial portions of the superior and inferior right and left pulmonary veins	T4
Pancoast tumors with evidence of invasion of the vertebral body or spinal canal, encasement of the subclavian vessels, or unequivocal involvement of the superior branches of the brachial plexus (C8 or above)	T4
Pancoast tumors without the above criteria for T4 classification	T3
Direct extension to visceral pericardium	T4
Invasion into hilar fat, unless other criteria assign a higher T	T2a
Invasion into mediastinal fat	T4
Discontinuous tumor nodules in the ipsilateral parietal or visceral pleura	M1a
Discontinuous tumor nodules outside the parietal pleura in the chest wall or in the diaphragm	M1b or M1c

the increased relevance of tumor size as a prognostic factor. Now the smallest coded invasive tumor is that of 1 cm or less in greatest dimension. Nearly 60% of tumors identified in screening programs have this dimension, and they will now be clearly differentiated from others by the new T1a category.[27] These small tumors will be the base ground for further research on growth rate, tumor density, intensity of standardized uptake value, type of resection, and investigation of alternative therapies such as stereotactic body radiation therapy or radiofrequency ablation, molecular profile, and genetic signatures. The presence of tumor size as a descriptor in all T categories will be useful to better

stratify tumors in future clinical trials and will improve our capacity to prognosticate. This means that determining the greatest dimension of the tumor will be more clinically relevant than it was in the previous editions of the TNM classification and, therefore, a greater responsibility for the managing physician.

The fact that the recently described adenocarcinoma in situ (AIS), Tis(AIS), and minimally invasive adenocarcinoma, T1mi,[17] have been included in the classification and have specific categories will increase awareness of them and facilitate the prospective collection of data.[22] In addition, attention will have to be paid when determining the size of the solid component of part-solid

tumors, as the size of the solid component (not the size of the whole tumor) leads prognosis.[22]

Visceral pleura invasion has been confirmed as an important prognostic factor. Even its two categories (PL1 and PL2) have prognostic impact. Therefore, the recommendation for pathologists is to use elastic stain when the invasion of the visceral pleura cannot be determined adequately with hematoxylin and eosin stains. Failure to use elastic stains may underestimate visceral pleura invasion in about 20% of patients thought to have stage IA tumors.[28]

The descriptors of the N component have not been modified, but there is an important learning drawn from the analyses of the database used for the eighth edition: quantification of nodal disease matters. This already was evident from the analyses performed for the seventh edition. They proved that survival rate according to nodal disease depended on the number of nodal zones involved. Prognosis worsened as the number of involved nodal zones increased, but it was also found that single-zone N2 disease had the same prognosis as multiple-zone N1 disease.[29] The analyses on the number of involved nodal stations revealed similar results: the greater the number of involved nodal stations, the worse the prognosis. They also showed other results that have practical implications: there are survival differences

---

TABLE 25.7 Clinical Criteria for Separate Versus Related Pulmonary Tumors[24]

CLINICAL CRITERIA[a]

Tumors may be considered separate primary tumors if:
   They are clearly of a different histologic type (e.g., squamous carcinoma and adenocarcinoma).
Tumors may be considered to be arising from a single tumor source if:
   Matching breakpoints are identified by comparative genomic hybridization.
Relative arguments that favor separate tumors:
   • Different radiographic appearance or metabolic uptake.
   • Different pattern of biomarkers (driver gene mutations).
   • Different rates of growth (if previous imaging is available).
   • Absence of nodal or systemic metastases.
Relative arguments that favor a single tumor source:
   • The same radiographic appearance.
   • Similar growth patterns (if previous imaging is available).
   • Significant nodal or systemic metastases.
   • The same biomarker pattern (and same histotype).

PATHOLOGIC CRITERIA (I.E., AFTER RESECTION)[b]

Tumors may be considered separate primary tumors if:
   • They are clearly of a different histologic type (e.g., squamous carcinoma and adenocarcinoma).
   • They are clearly different by a comprehensive histologic assessment.
   • They are squamous carcinomas that have arisen from carcinoma in situ.
Tumors may be considered to be arising from a single tumor source if:
   • Exactly matching breakpoints are identified by comparative genomic hybridization.
Relative arguments that favor separate tumors (to be considered together with clinical factors):
   • Different pattern of biomarkers.
   • Absence of nodal or systemic metastases.
Relative arguments that favor a single tumor source (to be considered together with clinical factors):
   • Matching appearance on comprehensive histologic assessment.
   • The same biomarker pattern.
   • Significant nodal or systemic metastases.

[a]Note that a comprehensive histologic assessment is not included in clinical staging, as it requires that the entire specimen be resected.
[b]Pathologic information should be supplemented with any clinical information that is available.

TABLE 25.8 Criteria to Categorize a Lesion as a Separate Tumor Nodule (Intrapulmonary Metastasis)[23,25]

CLINICAL CRITERIA

Tumors should be considered to have a separate tumor nodule(s) if:
   • There is a solid lung cancer and a separate tumor nodule(s) with a similar solid appearance and with (presumed) matching histologic appearance.
   • This applies whether or not a biopsy has been performed on the lesions, provided that there is strong suspicion that the lesions are histologically identical.
   • This applies whether or not there are sites of extrathoracic metastases.
AND provided that:
   • The lesions are NOT judged to be synchronous primary lung cancers.
   • The lesions are NOT multifocal GG/L lung cancer (multiple nodules with GG/L features) or pneumonic-type of lung cancer.

PATHOLOGIC CRITERIA

Tumors should be considered to have a separate tumor nodule(s) (intrapulmonary metastasis) if:
   • There is a separate tumor nodule(s) of cancer in the lung with a similar histologic appearance to a primary lung cancer.
AND provided that:
   • The lesions are NOT judged to be synchronous primary lung cancers.
   • The lesions are NOT multiple foci of LPA, MIA, and AIS.

A radiographically solid appearance and the specific histologic subtype of solid adenocarcinoma denote different things.
AIS, adenocarcinoma in situ; *GG/L,* ground glass/lepidic; *LPA,* lepidic predominant adenocarcinoma; *MIA,* minimally invasive adenocarcinoma.

TABLE 25.9 Criteria Identifying Multifocal Ground-Glass/Lepidic Lung Adenocarcinoma[26]

CLINICAL CRITERIA

Tumors should be considered multifocal GG/L lung adenocarcinoma if:
   • There are multiple subsolid nodules (either pure ground glass or part-solid), with at least one suspected (or proven) to be cancer.
   • This applies whether or not a biopsy has been performed of the nodules.
   • This applies if the other nodules are found on biopsy to be AIS, MIA, or LPA.
   • This applies if a nodule has become >50% solid but is judged to have arisen from a GGN, provided there are other subsolid nodules.
   • GGN lesions <5 mm or lesions suspected to be AAH are not counted for the TNM classification.

PATHOLOGIC CRITERIA

Tumors should be considered multifocal GG/L lung adenocarcinoma if:
   • There are multiple foci of LPA, MIA, or AIS.
   • This applies whether a detailed histologic assessment (i.e., proportion of subtypes) shows a matching or different appearance.
   • This applies if one lesion(s) is LPA, MIA, or AIS and there are other subsolid nodules for which a biopsy has not been performed.
   • This applies whether the nodule(s) are identified preoperatively or only on pathologic examination.
   • Foci of AAH are not counted for the TNM classification.

A radiographically solid appearance and the specific histologic subtype of solid adenocarcinoma denote different things.
AAH, atypical adenomatous hyperplasia; *AIS,* adenocarcinoma in situ; *GG/L,* ground glass/lepidic; *GGN,* ground-glass nodule; *LPA,* lepidic predominant adenocarcinoma; *MIA,* minimally invasive adenocarcinoma; *TNM,* tumor, node, and metastasis.

between patients whose tumors are classified as single-station N2 without N1 disease and those with single-station N2 with N1 disease. The former has better survival than the latter and similar survival to those with multiple-station N1 disease.[8] All these findings are derived from pathologic staging and could not be reliably replicated at clinical staging, which precluded its use to subclassify the present N descriptors. However, they have clinical relevance. First, they will help the managing physician to refine postoperative prognosis of those patients whose tumors have been removed and who are found to have nodal disease. Second, the fact that single-station N2 without N1 disease has the same prognosis as multiple-station N1 disease will raise the question of whether upfront surgery could be indicated for these patients. The problem is that determining whether a tumor has single-station N2 disease without N1 at

clinical staging is difficult with the staging methods currently used. One study that tried to determine single-zone N2 disease with systematic CT, positron emission tomography, and selective mediastinoscopy failed in doing so in 19% of the patients who were eventually found to have multiple-zone N2 disease.[30] Third, it seems obvious that if we want to offer upfront tumor resection to patients with single-station N2 disease, we have to preoperatively stage their tumors beyond CT, positron emission tomography, and standard mediastinoscopy. Only with a properly performed transcervical mediastinal lymphadenectomy can single-station or single-zone N2 disease be reliably identified. This may be an argument in favor of video-assisted mediastinoscopic lymphadenectomy and transcervical extended mediastinal lymphadenectomy, which have the objective to remove the mediastinal lymph nodes and the surrounding fatty tissue. Their sensitivity and negative predictive values are 1 or close to 1.[31–35]

Although it would have been very desirable, the fact is that the regional and pulmonary lymph node map proposed by the IASLC has not been universally used.[8,9] This may account for the important differences found when survival according to the N categories is studied by geographic region.[8] The IASLC lymph node map is the first map developed from an international and multidisciplinary consensus. It is our responsibility to use it properly to classify nodal disease in a homogeneous way. This will improve our understanding of the implications of nodal disease in the different anatomic areas.

The M component has undergone an important change in the eighth edition of the TNM classification. Subdividing extrathoracic metastases according to their number (M1b for single extrathoracic metastasis and M1c for multiple extrathoracic metastases in one or in several organs) identifies a group of metastases (M1b) that can be the base for further and deeper research on metastatic disease. Oligometastatic disease and oligoprogression are not uniformly defined because they may comprise tumors with one to five metastatic deposits. There can also be circulating cancer cells and micrometastases that are different forms of metastatic dissemination.[36] Therefore, an immediate implication for clinical practice is that the number and location of metastasis must be registered to determine the M1 category. Pathologic confirmation is desirable, as well as the registration of the largest dimension of the metastasis or the largest dimension of the largest metastases if there are several. The organ location is also important because there might be prognostic differences, although these could not be proved in the analyses leading to the eighth edition of the TNM classification.[10] The new M1b category represents the least extensive disease of extrathoracic dissemination and may constitute the basic component of oligometastatic

TABLE 25.10 Criteria Identifying the Pneumonic Type of Adenocarcinoma[26]

CLINICAL CRITERIA

Tumors should be considered pneumonic-type of adenocarcinoma if:
- The cancer manifests in a regional distribution, similar to a pneumonic infiltrate or consolidation.
- This applies whether there is one confluent area or multiple regions of disease. The region(s) may be confined to one lobe, in multiple lobes, or bilaterally, but should involve a regional pattern of distribution.
- The involved areas may appear to be ground glass, solid consolidation, or a combination thereof.
- This can be applied when there is compelling suspicion of malignancy whether or not a biopsy has been performed of the area(s).
- This should not be applied to discrete nodules (i.e., GG/L nodules).
- This should not be applied to tumors causing bronchial obstruction with resultant obstructive pneumonia or atelectasis.

PATHOLOGIC CRITERIA

Tumors should be considered pneumonic type of adenocarcinoma if:
- There is diffuse distribution of adenocarcinoma throughout a region(s) of the lung, as opposed to a single well-demarcated mass or multiple discrete well-demarcated nodules.
- This typically involves an invasive mucinous adenocarcinoma, although a mixed mucinous and nonmucinous pattern may occur.
- The tumor may show a heterogeneous mixture of acinar, papillary, and micropapillary growth patterns, although it is usually lepidic predominant.

A radiographically solid appearance and the specific histologic subtype of solid adenocarcinoma denote different things.
GG/L, ground glass/lepidic.

TABLE 25.11 Schematic Summary of Patterns of Disease and TNM Classification of Patients With Lung Cancer With Multiple Pulmonary Sites of Involvement[23]

	Second Primary Lung Cancer	Separate Tumor Nodule (Intrapulmonary Metastasis)	Multifocal GG/L Nodules	Pneumonic Type of Adenocarcinoma
Imaging features	Two or more distinct masses with imaging characteristic of lung cancer (e.g., spiculated)	Typical lung cancer (e.g., solid, spiculated) with separate solid nodule	Multiple ground-glass or part-solid nodules	Patchy areas of ground glass and consolidation
Pathologic features	Different histotype or different morphology by comprehensive histologic assessment	Distinct masses with the same morphologic features by comprehensive histologic assessment	Adenocarcinomas with prominent lepidic component (typically varying degrees of AIS, MIA, LPA)	Same histologic features throughout (most often invasive mucinous adenocarcinoma)
TNM classification	Separate cTNM and pTNM for each cancer	Location of separate nodule relative to primary site determines if T3, T4, or M1a; single N and M	T based on highest T lesion with (#/m) indicating multiplicity; single N and M	T based on size or T3 if in single lobe, T4 or M1a if in different ipsilateral or contralateral lobes; single N and M
Conceptual view	Unrelated tumors	Single tumor, with intrapulmonary metastasis	Separate tumors, albeit with similarities	Single tumor, diffuse pulmonary involvement

AIS, adenocarcinoma in situ; *c,* clinical; *GG/L,* ground glass/lepidic; *LPA,* lepidic-predominant adenocarcinoma; *MIA,* minimally invasive adenocarcinoma; *p,* pathologic; *TNM,* tumor, node, and metastasis.

disease. This difference is important because, in contradistinction with polymetastatic disease, where palliation is the main therapeutic objective, the aim of therapy in oligometastatic disease and oligoprogression is radical (that is, the elimination of all known disease) with whatever means are available or are suitable to the size and location of the metastases: surgical resection, standard radiotherapy, stereotactic radiotherapy, radiofrequency ablation, microwave ablation, chemotherapy, or targeted therapy, either alone or in combination.

Finally, the new stage grouping will surely raise questions about the indication for therapy for those tumors that have changed stage by virtue of reclassification. Although therapeutic indications are stage based, the taxonomic changes introduced in the eighth edition of the TNM classification do not necessarily imply an automatic change of therapy.[11] Therapy should be based on properly designed clinical trials. The clinical judgment of the multidisciplinary team will decide the best therapy for the individual patient and tumor after assessment of the best available evidence.[37–39]

In conclusion, the eighth edition of the TNM classification of lung cancer improves our understanding of the anatomic extent of the tumor, enhances our capacity to indicate prognosis at clinical and pathologic staging, and increases the possibilities of research by facilitating tumor stratification in future clinical trials.

26 | Preoperative Functional Evaluation of the Surgical Candidate

Alessandro Brunelli and Pieter E. Postmus

SUMMARY OF KEY POINTS

- Predicted postoperative forced expiratory volume in 1 second (ppoFEV$_1$) has been shown to be inaccurate in predicting actual postoperative FEV$_1$ in patients with chronic obstructive pulmonary disease (COPD). It should not be used alone to select patients for surgery.
- FEV$_1$ and carbon monoxide lung diffusion capacity (DLCO) and their derivate ppoFEV$_1$ and predicted postoperative DLCO (ppoDLCO) should be measured and calculated in all candidates for lung resection by estimating the number of functioning segments to be removed during an operation.
- ppoDLCO has been shown to be a reliable predictor of pulmonary morbidity and mortality in both patients with and patients without COPD.
- Low-technology exercise tests (i.e., Shuttle Walk Test and Stair-Climbing Test) may be used to screen patients before surgery. However, poor performance at these tests (i.e., <25 shuttles or 400 m at Shuttle Walk Test or <22 m at Stair-Climbing Test) indicates functional limitation. These patients should be referred to cardiopulmonary exercise test (CPET).
- CPET assesses the global fitness of the patient expressed as the rate of maximum oxygen (VO$_{2peak}$) consumption and several other direct and derivate measures, which can be used to identify the limiting factor in the oxygen transport system.
- A VO$_{2peak}$ less than 10 mL/kg/min or over 35% of the predicted value indicates high risk for anatomic lung resection.
- Cardiac risk stratification should be performed in all candidates for lung resection. The use of a risk score, such as thoracic Revised Cardiac Risk Index (ThRCRI), is a simple and reliable means to refer patients to noninvasive cardiac evaluation (i.e., ThRCRI >1.5).
- Appropriately aggressive cardiac interventions should be instituted before surgery only for patients who would need such interventions irrespective of the planned surgery. However, prophylactic coronary revascularization before surgery in patients who otherwise do not need such a procedure does not appear to reduce perioperative risk.
- Minimally invasive thoracic surgery (video-assisted thoracoscopic surgery) has been shown to be associated with reduced risk of morbidity and mortality, particularly in high-risk patients.

For stage I and II nonsmall cell lung cancer, resection is the best validated treatment option with the aim of cure. In order for this aim to be achieved, not only should the tumor be resectable, but also the patient should be operable (i.e., fit enough to undergo the resection as well as to have satisfactory postoperative quality of life). Deciding on resectability typically is a team effort and depends on staging based on adequate imaging of the tumor and its potentially metastatic sites, both locoregional and systemic. Operability is based first on the risk of immediate perioperative and postoperative complications and second on the risk of long-term disability after resection of parts of the affected lung (or lungs). Consequently, the decision to proceed with curative-intent surgery should take into account both aspects of operability. This decision is becoming increasingly critical as alternative strategies for resection are gaining ground and outcomes are promising, particularly for patients with smaller (stage 1A) tumors, despite the fact that many patients who are judged to be inoperable receive stereotactic radiotherapy and are not selected for inclusion in phase II studies.[1]

Many patients with lung cancer have been smokers and have comorbidities resulting from damage to sensitive organs and organ systems. Damage to lung tissue resulting in COPD with reduced pulmonary function and atherosclerotic cardiovascular disease are the most common findings in these patients. The presence of such comorbidities makes it critical to evaluate the possibly increased risks of both long-term disability and possible perioperative complications. Preoperative physiologic assessment aims to quantify the magnitude of this risk.

Furthermore, lung cancer is a disease of elderly people and logically many of these patients may have comorbid conditions such as diabetes or renal disease.

EVALUATION OF COMORBIDITY

Comorbid conditions are best evaluated with use of the Charlson Comorbidity Index (Table 26.1),[2] which has been shown to be an independent predictor of surgical mortality as well as long-term survival. A subset of 1844 patients with lung cancer who had had surgical resection in Norway from 1993 to the end of 2005 was evaluated according to the Charlson Comorbidity Index, and potential factors influencing 30-day mortality were analyzed. The overall mortality rate within 30 days postoperatively was 4.4%. Male gender (odds ratio, 1.76), older age (odds ratio, 3.38 for an age between 70 and 79 years), right-sided tumors (odds ratio, 1.73), and extensive procedures (odds ratio, 4.54 for pneumonectomy) were identified as risk factors for postoperative mortality in multivariate analysis. The Charlson Comorbidity Index was identified as an independent risk factor for postoperative mortality (p = 0.017).[2]

TABLE 26.1 Charlson Comorbidity Index Scoring

Score	Condition
1	Coronary artery disease
	Congestive heart failure
	Chronic pulmonary disease
	Peptic ulcer disease
	Peripheral vascular disease
	Mild liver disease
	Cerebrovascular disease
	Connective tissues disease
	Diabetes
	Dementia
2	Hemiplegia
	Moderate-to-severe renal disease
	Diabetes with end-organ damage
	Any prior tumor (within 5 y of diagnosis)
	Leukemia
	Lymphoma
3	Moderate-to-severe liver disease
6	Metastatic solid tumor
	AIDS (not only HIV positive)

AIDS, acquired immune deficiency syndrome; *HIV,* human immunodeficiency virus.

In a study of 433 consecutive patients (340 men and 93 women) who underwent curative resection for the treatment of nonsmall cell lung cancer, the Charlson Comorbidity Index was used to estimate the risk of mortality. The overall 5-year survival rate was 52% among patients with a Charlson Comorbidity Index of 0, 48% among those with an index of 1 or 2, and 28% among those with an index of 3 or more. Multivariate analysis showed that age; a Charlson comorbidity grade of 1 or 2; a Charlson comorbidity grade of 3 or more; bilobectomy; pneumonectomy; and pathologic stages IB, IIB, IIIA, IIIB, and IV were associated with impaired survival.[4]

Combining the score with physiologic parameters should therefore help in deciding whether a patient may be a candidate for surgery.

ESTIMATION OF CARDIAC RISK

The risk of major cardiac events, defined as the occurrence of ventricular fibrillation, pulmonary edema, complete heart block, cardiac arrest, or cardiac death, during admission has been reported to be approximately 3% after major anatomic lung resection.[5,6] Typical candidates for pulmonary surgery for the management of lung cancer usually have both pulmonary and cardiac diseases as a result of cigarette smoking and are potentially at increased risk for perioperative cardiovascular complications. Unfortunately, the available literature specific to cardiac risk in patients undergoing surgery for the management of lung cancer is minimal, and most of what can currently be recommended must be extrapolated from literature on intraabdominal surgery and suprainguinal vascular surgery, both of which, like lung resection, are regarded as high-risk procedures from a cardiac standpoint.[5,7]

A recent study using Surveillance, Epidemiology, and End Results Medicare data on patients undergoing resection for the management of lung cancer within 1 year after coronary stenting showed that patients who had been treated with stenting had higher rates of major cardiovascular events and mortality (9.3% and 7.7%, respectively) in comparison with those who had not (4.9% and 4.6%, respectively; *p* < 0.0001 for both comparisons).[8]

Two organizations have produced guidelines on the evaluation and treatment of cardiac risk factors in candidates for lung resection: (1) the European Respiratory Society/European Society of Thoracic Surgeons (ERS/ESTS) joint task force and (2) the American College of Chest Physicians (ACCP).[9,10]

In general, a detailed evaluation for coronary heart disease is not recommended for patients who have an acceptable exercise tolerance or a Revised Cardiac Risk Index (RCRI) of less than 2.5.[7,11,12]

The RCRI, as originally described by Lee et al.,[5] is a four-class cardiac risk score with six factors, including a history of coronary artery disease, cerebrovascular accident, insulin-dependent diabetes, congestive heart failure, a serum creatinine level of greater than 2 mg/dL, and high-risk surgery. All factors are equally weighted, and one point is assigned for the presence of each factor.[5]

Although the RCRI was cited as the preferred cardiac risk score in the recently published American College of Cardiology/American Heart Association (ACC/AHA) and European Society of Cardiology/European Society of Anaesthesiology guidelines as well as by the joint ERS/ESTS task force on fitness for radical treatment of patients with lung cancer,[7,9,13] this score originally was developed from a generic surgical population that included only a small group of thoracic patients. Brunelli et al.[6] recently recalibrated the RCRI in a study involving a large population of candidates for major anatomic lung resection to obtain a more specific tool for our setting. In that study, only four of the original six factors were found to be reliably associated with major cardiac morbidity and these four factors were assigned different weights (history of coronary artery disease, 1.5 points; cerebrovascular disease, 1.5 points; serum creatinine level of greater than 2 mg/dL, 1 point; and pneumonectomy, 1.5 points). The resulting aggregate score, ranging from 0 to 5.5 points and named the ThRCRI, was found to be more accurate than the traditional score in this population (c index, 0.72 compared with 0.62; *p* = 0.004). The risk of major cardiac events was 23% for patients with an aggregate score of more than 2.5 (class D), compared with 1.5% for those with a score of 0 (class A).

The ThRCRI was subsequently validated in a number of studies.[6,15] Most recently, the score was tested and validated in a large population of patients who were included in the Society of Thoracic Surgeons (STS) database.[16] Major cardiovascular complications were reported in 4.3% of more than 26,000 patients who underwent pulmonary anatomic resection. The average ThRCRI score for patients without major cardiovascular complications was half of that for patients with complications (0.6 compared with 1.1; *p* < 0.0001). Incremental differences in the risk of major cardiovascular complications were noted among the score categories (grade A, 2.9%; grade B, 5.8%; grade C, 11.9%; grade D, 11.1%; *p* < 0.0001). On the basis of this recent evidence, the ACCP guidelines included this parameter in their updated cardiac algorithm.

According to the ACC/AHA guidelines,[7] noninvasive cardiac evaluation is recommended for patients with limited capacity for exercise, those with a ThRCRI of more than 1.5, and those with a known or newly suspected cardiac condition to identify the relatively small proportion of patients who need intensified intervention to control heart failure or arrhythmias or to treat underlying myocardial ischemia.

Appropriately aggressive cardiac interventions should be instituted before surgery only for patients who would need such interventions irrespective of the planned surgery. However, prophylactic coronary revascularization before surgery in patients who otherwise do not need such a procedure does not appear to reduce perioperative risk.[17] McFalls et al.[17] recently demonstrated that, in a population of patients undergoing major elective vascular surgery who had concomitant stenosis of more than 70% in one or more coronary vessels, prophylactic percutaneous coronary intervention or coronary artery bypass grafting did not change the risk of 30-day mortality, postoperative myocardial ischemia, or long-term survival.

Recent data from the Perioperative Ischemic Evaluation study group indicated that although commonly used regimens

of perioperative beta-blockers reduced the risk of cardiovascular death and nonfatal myocardial ischemia (hazard ratio, 0.84), they actually increased the risk of stroke (hazard ratio, 2.17) and overall mortality (hazard ratio, 1.33), perhaps by interfering with stress responses in critically ill patients.[18] Therefore, the new institution of a beta-blocker therapy is not recommended for patients with ischemic heart disease who are not already taking them.

Finally, CPET has been shown to be a useful tool for detecting both overt and occult exercise-induced myocardial ischemia with a diagnostic accuracy similar to single-photon emission computed tomographic myocardial perfusion testing and superior to standard electrocardiographic stress testing.[19–21] For this reason, CPET can be proposed as a noninvasive test for detecting and quantifying myocardial perfusion defects in patients who are at increased risk for coronary artery disease.

PREDICTED POSTOPERATIVE FORCED EXPIRATORY VOLUME IN 1 SECOND

ppoFEV$_1$, which is estimated on the basis of the number of functioning, nonobstructed segments to be removed during an operation, traditionally has been used to stratify respiratory risk in candidates for lung resection. The following equations can be applied to estimate the residual lung function.

For candidates for pneumonectomy, the perfusion method is used with the following formula:

$$ppoFEV_1 = preoperative\ FEV_1 \times$$
$$(1 - fraction\ of\ total\ perfusion\ for\ the\ resected\ lung)$$

A quantitative radionuclide perfusion scan is performed to measure the fraction of total perfusion for the resected lung. For candidates for lobectomy, the anatomic method is used with the following formula:

$$ppoFEV_1 = preoperative\ FEV_1 \times (1 - a/b)$$

The number of functional or unobstructed lung segments to be removed is represented by a, and the total number of functional segments is represented by b.[22]

The findings of bronchoscopy and computerized tomographic scanning should be used to assess and estimate the patency of the bronchus and segmental structure.

Many studies have investigated the role of ppoFEV$_1$ in predicting postoperative complications and in selecting patients for surgery. Olsen et al.[23] were the first to suggest a safety threshold value of 0.8 L as the lower limit for surgical resection. However, Pate et al.[24] found that patients with a mean ppoFEV$_1$ of as low as 0.7 L tolerated thoracotomy for the resection of lung cancer. The main limitation of those early studies is that they used an absolute value of ppoFEV$_1$. This method might prevent older patients, patients of small stature, and female patients, all of whom might tolerate a lower absolute FEV$_1$, from having a potentially curative resection for the management of lung cancer.

Markos et al.[25] were the first to propose using a percentage of the predicted value as the cutoff value. They found that half of the patients with a ppoFEV$_1$ of less than 40% of the predicted value died in the perioperative period. Other authors confirmed that perioperative risk increases substantially when the ppoFEV$_1$ is less than 40% of the predicted normal value.[26–32] The predictive role of ppoFEV$_1$ recently was challenged in investigations that showed an acceptable mortality rate among patients with prohibitive FEV$_1$ or ppoFEV$_1$ values who underwent lung resection.[33,34]

Alam et al.[35] demonstrated that the odds ratio for the development of postoperative respiratory complications increased as the ppoFEV$_1$ and ppoDLCO decreased (with a 10% increase in the

risk of complications for every 5% decrease in predicted postoperative lung function). Brunelli et al.[33] showed that ppoFEV$_1$ was not associated with an increased risk of complications in those with FEV$_1$ less than 70%.

These findings may be partly explained by the so-called lobar volume reduction effect, which can reduce functional loss in patients with airflow limitations. In candidates for lobectomy with lung cancer and moderate-to-severe COPD, resection of the most affected parenchyma may determine an actual improvement in the elastic recoil, a reduction of the airflow resistance, and an improvement in pulmonary mechanics and ventilation–perfusion matching, similar to what happens in typical candidates for lung volume reduction surgery with end-stage heterogeneous emphysema.

In this regard, many studies already have shown the minimal loss or even improvement of pulmonary function after lobectomy in patients with obstruction, calling into question the traditional operability criteria that are primarily based on pulmonary parameters.[36–43]

Brunelli et al.[42] recently found that patients with COPD had significantly lower losses of FEV$_1$ and DLCO compared with patients without COPD at 3 months after lobectomy for the management of lung cancer (8% compared with 16% and 3% compared with 12%, respectively). In that series, 27% of patients with COPD actually had improvement in FEV$_1$ and 34% had improvement in DLCO at 3 months after the operation.

This lobar volume reduction effect takes place very early after lung resection. In fact, 17% of patients with airflow limitation who undergo pulmonary lobectomy actually may have improvement in FEV$_1$ at the time of discharge as compared with preoperative measurement.[44]

The early lobar volume reduction effect was confirmed by Varela et al.[45] who showed that the percentage loss of FEV$_1$ on the first postoperative day after lobectomy was lower in patients with a higher degree of COPD. These findings indicate that ppoFEV$_1$ may not work properly in patients with obstructive disease and cannot be used alone to select patients for surgery, especially those with limited pulmonary function.

Although many studies have shown that ppoFEV$_1$ is fairly accurate for predicting the definitive residual FEV$_1$ at 3 months to 6 months after surgery, Varela et al.[46] recently demonstrated that it substantially overestimates the actual FEV$_1$ in the first postoperative days, when most complications occur. On the first postoperative day, the actual FEV$_1$ was measured to be about 30% lower than predicted.[46] This finding may have serious clinical implications whenever ppoFEV$_1$ is used for patient selection and risk stratification before surgery.

CARBON MONOXIDE LUNG DIFFUSION CAPACITY

In 1988, Ferguson et al.[47] reported that DLCO was a predictor of adverse outcomes after pulmonary resection; in that study, patients with a DLCO of less than 60% had mortality rates as high as 20% and pulmonary complication rates as high as 40%. These findings were subsequently confirmed by other authors.[25,26]

In addition to being a good predictor of immediate postoperative complications, DLCO is probably the objective parameter that is most closely associated with postoperative quality of life.[48]

ppoDLCO, calculated in the same manner as ppoFEV$_1$, was first shown to be a reliable predictor of pulmonary complications and mortality in 1995.[49] In that series, patients with a ppoDLCO of less than 40% had a mortality rate as high as 23%. Those results were subsequently confirmed by Santini et al.[50] who found an inverse linear correlation between pulmonary complications and ppoDLCO. Patients with a ppoDLCO of less than 30% may have a risk of pulmonary complications of greater than 80%. Recent studies have shown that FEV$_1$ and DLCO are poorly correlated and that more than 40% of patients with a normal

FEV_1 (an FEV_1 of more than 80%) may have a DLCO of less than 80% and that 7% of patients with FEV_1 >80% may have a ppoDLCO of 40%.[51] Other studies have demonstrated that a reduced ppoDLCO is a reliable predictor of cardiopulmonary morbidity and mortality not only in patients with reduced FEV_1 but also in those with normal respiratory function.[51,52] In a recent large study involving approximately 8000 patients from the STS General Thoracic Surgery Database who were treated with lung resection, the percentage of predicted DLCO was strongly associated with the occurrence of pulmonary complications.[53] This association was independent from the COPD status.

On the basis of this evidence, recent functional guidelines have recommended the measurement of DLCO in all candidates for lung resection, regardless of the preoperative FEV_1 value.[9,10]

Many patients undergoing major lung resection for the management of cancer receive preoperative chemotherapy. Recent reports have suggested that chemotherapy can be associated with a 10% to 20% reduction in DLCO despite stable or improved spirometric values.[54–57] These changes are associated with drug-induced structural lung damage and have been associated with an increase in postoperative respiratory complications.[55,56,58,59] Therefore reassessment of pulmonary status and DLCO after induction therapy and prior to resection is recommended to ensure that the operative risk has not increased as a result of newly impaired DLCO.[9,10]

VIDEO-ASSISTED THORACOSCOPIC SURGERY

Several reports have shown reduced rates of morbidity among patients who are treated with minimally invasive video-assisted thoracoscopic surgery (VATS) lobectomy.[60–63] This finding is likely explained by the minimal impact of this operation on the chest wall mechanics. This effect is particularly evident in patients with compromised pulmonary function. Berry et al.[64] reported that, in patients with an FEV_1 of less than 60% or a DLCO of less than 60% who underwent pulmonary lobectomy with use of either thoracotomy or VATS, thoracotomy was a strong predictor of complications on multivariable analysis (odds ratio, 3.46; $p = 0.0007$).[64] FEV_1 and DLCO remained predictors of complications in patients undergoing thoracotomy but not thoracoscopy.

Similarly, in a large population of patients in the STS database who underwent lobectomy, multivariable regression analysis showed that thoracotomy (odds ratio, 1.25; $p < 0.001$), decreasing FEV_1% predicted (odds ratio, 1.01 per unit; $p < 0.001$), and DLCO% predicted (odds ratio, 1.01 per unit; $p < 0.001$) independently predicted pulmonary complications.[65] Among patients with an FEV_1 of less than 60%, the rate of pulmonary complications was markedly increased among those who underwent thoracotomy as compared with those who underwent VATS ($p = 0.023$).[65] No significant difference was noted among patients with an FEV_1 of more than 60% of the predicted value. More recently, Burt et al. (Burt BM, Kosinski AS, Shrager JB, Onaitis MW, Weigel T. Thoracoscopic lobectomy is associated with acceptable morbidity and mortality in patients with predicted postoperative forced expiratory volume in 1 second or diffusing capacity for carbon monoxide less than 40% of normal. J Thorac Cardiovasc Surg. 2014 Jul;148(1):19–28) have shown that patients operated on through VATS and with prohibitive ppoFEV₁ or ppoDLCO below 40% of predicted value have a far lower risk of mortality compared with case-matched counterparts operated on through thoracotomy. For patients with ppoFEV₁% less than 40%, mortality was 4.8% in the open group versus 0.7% in the VATS group ($p = 0.003$). Similar results were seen for ppoDLCO% less than 40% (5.2% open, 2.0% VATS, $p = 0.003$).[65a]

Other studies have shown better preservation of pulmonary function compared with preoperative values in patients undergoing VATS lobectomy than in those undergoing thoracotomy.[66,67]

At this time, the evidence is still too limited to justify a change in the current functional guidelines. However, it appears likely that with the increasing number of patients who are treated with the VATS approach, we will be able to verify whether traditional pulmonary thresholds of operability (mostly derived from series of patients undergoing thoracotomy) should be updated.

EXERCISE TESTING

Exercise testing is increasingly used in the preoperative workup of candidates for lung resection. These tests can be used to assess the entire oxygen-transport system and to detect possible deficits that may predispose to postoperative complications.[68]

In fact, exercise increases the utilization of oxygen peripherally and requires the entire interlocking lung–heart–vascular oxygen transport system to react.[68] In the lung, exercise determines an increase in ventilation, VO_2, carbon dioxide excretion, and blood flow, similar to those experienced after lung resection. Therefore the potential exists to evaluate much of the cardiopulmonary system with just one test.

Several tests can be used in clinical practice. These tests can be classified as low-technology tests, involving a limited use of resources and personnel, and high-technology tests, such as the cardiopulmonary test, involving direct measurement of the expired gases during incremental exercise on a bicycle or treadmill.

Low-Technology Tests

The most frequently used low-technology tests in our specialty are the 6-Minute Walking Test, Shuttle Walk Test, and Stair-Climbing Test.

6-Minute Walking Test

Conflicting reports have been published regarding the 6-Minute to 12-Minute Walking Test for the evaluation of candidates for lung resection. Some investigators have not found this type of exercise to be predictive of complications,[25,69] whereas others have found it to be predictive of mortality in patients with high respiratory risk (an FEV_1 of less than 1.6 L). Pierce et al.[26] found that the 6-Minute Walking Test was predictive of respiratory failure but not of mortality or other complications. The test is not a maximal exercise test and may not be stressful enough in all patients to reveal deficits of the oxygen-transport system. Because of these inconsistent findings, the recent ERS/ESTS joint task force on fitness for radical therapy did not recommend its use for preoperative risk-stratification before lung resection.[9]

Shuttle Walk Test

The Shuttle Walk Test is certainly more reproducible than the 6-Minute Walk Test. In one study, regression analysis indicated that 25 shuttles on the Shuttle Walk Test indicate a VO_{2peak} of 10 mL/kg/min.[70]

However, more recent studies have challenged this conclusion, showing that the distance walked on the Shuttle Walk Test did not differ between patients with and without complications and that the test appeared to underestimate exercise capacity at the lower range compared with peak oxygen consumption.[71] Benzo and Sciurba[72] recently showed that VO measured during the Shuttle Walk Test is highly correlated with the level (or minute) of the test. A cutoff of 25 shuttles walked had a positive

predictive value of 90% for predicting a VO_{2peak} of more than 15 mL/kg/min. The recent ACCP functional guidelines recommend use of the Shuttle Walk Test or the Stair-Climbing Test as low-technology exercise tests for patients with lung cancer who are being considered for surgery if either the $ppoFEV_1$ or ppoDLCO is less than 60% of the predicted value and both are above 30% of the predicted value.[10]

Stair-Climbing Test

The Stair-Climbing Test has several advantages in that it is familiar to patients; is economic, requires little in terms of resources, personnel, and equipment; and is rapid and non-invasive. However, it is very stressful for patients in that they are pushed to reach a visible objective represented by the next landing.

The Stair-Climbing Test has been used for decades.[73] Van Nostrand et al.,[74] in what we believe to have been the first published retrospective report in which the Stair-Climbing Test was included in the preoperative evaluation, found that patients who were unable to climb two flights of stairs had a 50% rate of mortality after pneumonectomy.

In a report on 54 patients who performed the Stair-Climbing Test before lung resection, Olsen et al.[75] found that the ability to climb three flights of stairs most clearly separated patients who had a longer hospital stay, postoperative intubation, and a greater frequency of complications. Holden et al.,[28] in a series of high-risk patients with an FEV_1 of less than 1.6 L, found that those who had fatal complications after lung resection had climbed fewer steps than those who had few or no complications (42 compared with 71; $p < 0.05$). Climbing more than 44 steps was predictive of a successful surgical outcome.

In 2001, Girish et al.,[76] in a prospective evaluation of 83 patients undergoing thoracotomy or upper abdominal laparotomy surgery, found that patients with complications climbed significantly fewer flights of stairs than those without complications (2.1 compared with 4.4; $p = 0.00002$). The inability to climb two flights of stairs was associated with a positive predictive value of 80%; conversely, the ability to climb more than five flights of stairs was associated with a negative predictive value of 95%.

In a series on 160 patients, Brunelli et al.[77] found that only 6.5% of patients who climbed more than 14 m in altitude had complications. However, 29% of patients who climbed between 12 m and 14 m and 50% of those who climbed less than 12 m had complications. This progressive increase in the rate of cardiopulmonary morbidity with the reduction in the altitude climbed preoperatively indirectly demonstrates that stair climbing is a stressful test that is capable of revealing severe deficits in maximum aerobic capacity. In the same study, Brunelli et al.[77] observed only four complications and no mortality in a high-risk group of 17 patients with a $ppoFEV_1$ of less than 35% and/or a ppoDLCO of less 35% who were judged to be operable on the basis of the satisfactory performance on the Stair-Climbing Test.

These findings were subsequently confirmed in a larger series of 640 major anatomic resections,[78] in which the height climbed during the preoperative Stair-Climbing Test discriminated between patients with and without complications. In particular, compared with patients who were able to climb more than 22 m, those who did not reach 12 m had a 2.5-fold higher rate of cardiopulmonary complications, a 3-fold higher rate of cardiac complications, and a 13-fold higher mortality rate (13% compared with only 1%). In the 73 patients with prohibitive pulmonary function (a $ppoFEV_1$ <40% or a ppoDLCO <40%, or both), all of those who climbed more than 22 m survived the operation, whereas 2 of the 10 who climbed less than 12 m died.

Brunelli et al.[79] showed a direct correlation between the height climbed and the VO_2 measured during the Stair-Climbing Test with a portable gas analyzer. Ninety-eight percent of patients who climbed more than 22 m had a VO_{2peak} of more than 15 mL/kg/min. The cutoff value of 22 m had a positive predictive value of 86% for predicting a VO_{2peak} of more than 15 mL/kg/min.

On the basis of these findings, the ERS/ESTS guidelines on fitness for radical therapy recommended the Stair-Climbing Test as an alternative screening test in cases in which formal CPET is not readily available.[9] However, in cases of reduced performance (i.e., height of <22 m), patients should be referred for CPETs for a better evaluation of aerobic reserve. Furthermore, the recent ACCP functional guidelines recommended the use of this test as a first-line test for patients with either a $ppoFEV_1$ or a ppoDLCO of between 60% and 30% predicted.[10] For patients climbing less than 22 m, however, a formal CPET is recommended to exactly detect the deficit in the oxygen-transport system.

Cardiopulmonary Exercise Test

The CPET is the criterion standard for the preoperative evaluation of candidates for lung resection. It is performed in a controlled environment with continuous monitoring of various cardiologic and pulmonary parameters, it is standardized and easily reproducible in different settings, and, in addition to VO_{2peak}, which certainly remains the most important parameter associated with exercise capacity, it provides several other direct and derived measures that can be used, in cases of limited aerobic reserve, to precisely identify possible deficits in the oxygen-transport system.[80,81]

Responses such as the VT, VE/VCO$_2$ slope, VE/VCO$_2$ at peak exercise, oscillatory ventilation, oxygen uptake on kinetics, rate of recovery of VO_2, and oxygen uptake efficiency slope have been used with greater frequency to classify functional limitations and to stratify risk in patients with heart disease. Many of these responses are expressions of ventilatory efficiency and reflect the various underlying pathophysiologic factors leading to inefficient breathing associated with heart failure or pulmonary disease.

Findings from the CPET have important clinical implications as it allows for the institution of specific treatments to optimize perioperative management (such as optimization of COPD treatment, management of ischemic heart disease, rehabilitation) to improve the overall status of the cardiopulmonary system and reduce surgical risk.

The ERS/ESTS functional guidelines emphasized the role of high-technology exercise testing. Ideally, all patients with an FEV_1 or DLCO (or both) of less than 80% of the predicted value and those with a history of cardiac disease should perform this test.[9]

The recent ACCP functional guidelines also emphasize this methodology.[10] A CPET is recommended for patients with lung cancer and candidates for lung resection with either a $ppoFEV_1$ or a ppoDLCO of less than 30% predicted, an altitude of less than 22 m reached on the Stair-Climbing Test, or a positive high-risk cardiac evaluation. This recommendation is based on several studies that showed the importance of VO_{2peak} in predicting cardiopulmonary complications and mortality in our specialty. The importance of maximum rate of oxygen consumption (VO_{2max}) in our specialty was first suggested by Eugene et al.[82] in 1982.

In that small study of 19 patients, the authors found that a VO_{2max} of less than 1000 mL was associated with a 75% mortality, whereas FEV_1 and forced vital capacity (FVC) had no predictive value in terms of postoperative complications. Subsequently, other small studies in the 1980s and early 1990s confirmed these findings.[83–85]

In 1995, Bolliger et al.[86] demonstrated that VO_{2max} had a better discriminatory ability when expressed as percentage of predicted value rather than as an absolute value. The authors found that the probability of complications was only 10% in patients with a VO_{2max} of greater than 75% of the predicted value, whereas it was as high as 90% in those with VO_{2max} below 40% of the predicted value.

The same group subsequently confirmed the importance of this parameter in a different group of patients.[87] They were able to develop a model predicting the risk of cardiopulmonary complications on the basis of the extent of resection and preoperative VO_{2max}. For instance, in a patient undergoing pneumonectomy with a VO_{2peak} of 50%, the risk of morbidity may be as high as 86%. In that series, the authors found that the morbidity rate was as high as 86% for patients with VO_{2peak} of lower than 60% of the predicted value, compared with only 12% for those with VO_{2peak} of greater than 90%.

In a large series involving more than 400 patients from the Cancer and Leukemia Group B national multicenter database, Loewen et al.[88] showed that patients with complications had a significantly lower VO_{2max} compared with patients without complications and confirmed the findings of the aforementioned studies.

Brunelli et al.,[89] in a recent study of more than 200 patients undergoing major anatomic lung resections with complete CPET evaluation before surgery, confirmed the safety threshold of 20 mL/kg/min (with a 0% rate of mortality and a 7% rate of cardiopulmonary morbidity) but found that values of VO_{2peak} below 12 mL/kg/min increased the risk of mortality. In such patients, the cardiopulmonary morbidity and mortality rates may be as high as 33% and 13%, respectively. Interestingly, in that large series, 43% of all patients had a preoperative VO_{2peak} below 15 mL/kg/min (with only 14% of patients having a VO_{2peak} of greater than 20 mL/kg/min), reflecting the case mix of patients who undergo modern thoracic surgery. These patients are generally elderly and unfit, with underlying cardiopulmonary comorbidities, and we should be ready to accept such levels of VO_{2peak} in our practices.

A recent meta-analysis confirmed the importance and the ability of VO_{2peak} to predict cardiopulmonary complications or mortality after pulmonary resection.[90] The authors of most studies generally agreed that a VO_{2max} value below 10 mL/kg/min to 15 mL/kg/min should be regarded as a high-risk threshold for lung resection and that values above 20 mL/kg/min are safe for any kind of resection, including pneumonectomy.

Similar to ppoFEV$_1$ and ppoDLCO a segmental estimation of VO_{2max} was suggested by Bolliger et al.,[27] who found that a value of ppoVO$_{2max}$ of less than 10 mL/kg/min (or 35% of the predicted value) was the only parameter that retrospectively identified all three patients who died in a subgroup of 25 patients at increased risk for postresectional complications.

In addition to VO_{2max}, CPET can provide several other direct and indirect measures, which can help to refine the preoperative risk stratification. Several authors have reported on such derived parameters (i.e., efficiency slope, oxygen pulse, VE/VCO$_2$ slope), which proved to be predictive of cardiac and pulmonary complications.[80,91,92]

ALGORITHMS

For practical reasons, published evidence on operability and functional assessment is often summarized in algorithms or flowcharts. Algorithms should be used as guides to standardize the preoperative clinical practice by minimizing variations and inappropriate exclusions. However, this schematic representation cannot capture the entire spectrum of patients, and exceptions may occur. Patients should always be evaluated individually.

The two most recent functional algorithms are those proposed by the ERS/ESTS joint task force on fitness for radical therapy and the ACCP lung cancer guidelines.[9,10] Both algorithms emphasize the importance of a preliminary cardiologic evaluation.

Patients with low cardiologic risk or with an optimized cardiologic treatment may proceed with the rest of the functional workup. Both algorithms recommend measurement of FEV$_1$ and DLCO in all patients. These two parameters must be expressed as percentages of predicted values.

In the ERS/ESTS flowchart (Fig. 26.1), patients without active cardiac problems and low cardiac risk and with both FEV$_1$ and DLCO greater than 80% of predicted values can be safely treated with the planned resection, including pneumonectomy. All other patients with an FEV$_1$ and/or DLCO below 80% of the predicted value should undergo an exercise test. Ideally, a formal CPET with VO_{2peak} measurement should be performed. However, in many settings, this test is not readily available because of logistic or organizational reasons. In these circumstances, a low-technology exercise test, preferably the Stair-Climbing Test, can be used as a screening test. Patients showing optimal performance on these tests (more than 22 m on the Stair-Climbing Test or more than 400 m on the Shuttle Walk Test) can proceed to surgery, whereas all other patients (those with <22 m on the Stair-Climbing Test or <400 m on the Shuttle Walk Test) should undergo a formal CPET to better define aerobic capacity.

In patients with borderline VO_{2peak} (between 10 mL/kg/min and 20 mL/kg/min or between 35% and 75% of predicted values), split lung function should be taken into consideration with estimation of ppoFEV$_1$ and ppoDLCO. Patients with borderline ergometric parameters and both ppoFEV$_1$ and ppoDLCO greater than 30% of the predicted value can proceed with the planned surgery. In all the others, ppoVO$_{2peak}$ should be estimated in a similar fashion as ppoFEV$_1$. If ppoVO$_{2peak}$ is lower than 10 mL/kg/min or 35% of the predicted value, the patient should be advised to choose alternative treatments as lobectomy or pneumonectomy is not recommended.

In the ACCP flowchart (Fig. 26.2), patients who are deemed to be at low cardiologic risk and who have ppoFEV$_1$ and ppoDLCO values that are both greater than 60% of predicted values are regarded as low risk for surgery (with a risk of mortality <1%). Patients with either a ppoFEV$_1$ or a ppoDLCO between 30% and 60% should perform a low-technology exercise test as a screening test. If the performance on the low-technology exercise test is satisfactory, the patient is regarded as being at moderate risk (morbidity and mortality rates may vary according to the values of split lung function, exercise tolerance, and extent of resection). A CPET is indicated only in cases in which the ppoFEV$_1$ or ppoDLCO values are lower than 30% or when the performance on the Stair-Climbing Test or Shuttle Walk Test is not satisfactory (i.e., an altitude of <22 m on the Stair-Climbing Test or a distance of <400 m on the Shuttle Walk Test). As in the European algorithm, VO_{2peak} values lower than 10 mL/kg/min or 35% of the predicted value indicate a high risk for major anatomic resection through thoracotomy; in such patients the risk of mortality may be higher than 10%, and considerable risk of severe cardiopulmonary morbidity and residual functional loss is expected. Conversely, VO_{2peak} values of greater than 20 mL/kg/min or 75% of predicted value indicate low risk.

SMOKING CESSATION

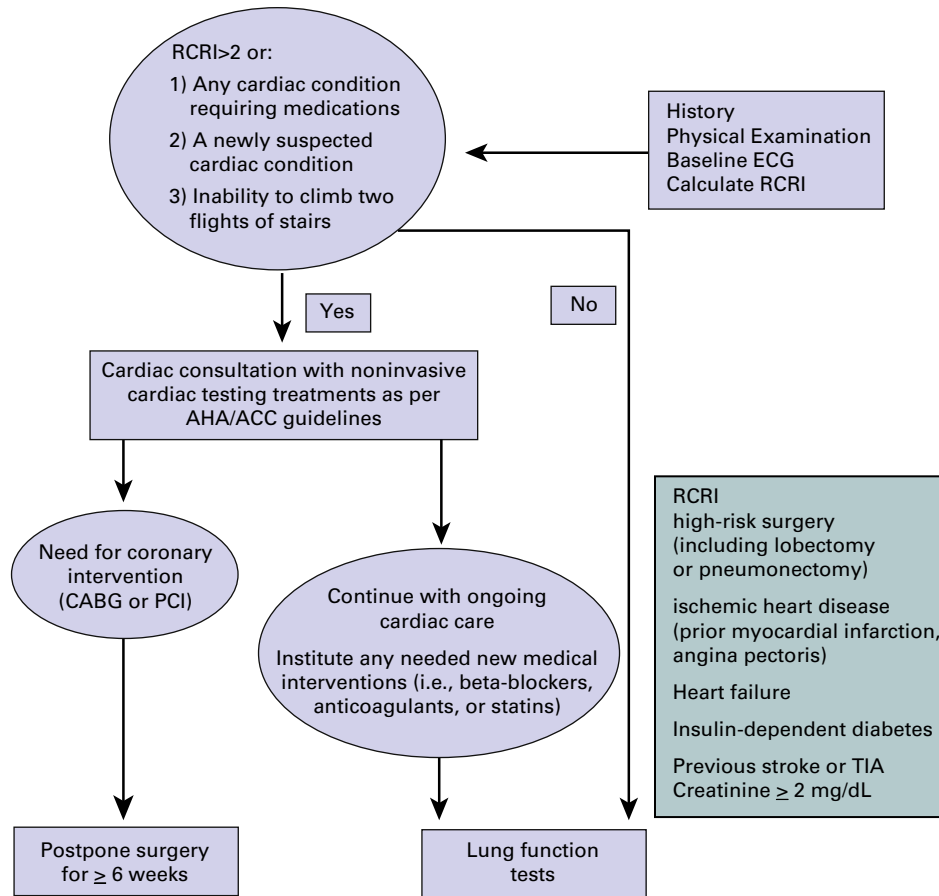
Although many patients with lung cancer stop smoking years before a tumor becomes symptomatic, a considerable number of patients are still current smokers at the time of diagnosis. Literature on whether stopping smoking preoperatively


Fig. 26.1. ERS/ESTS algorithm for preoperative functional evaluation. *AHA/ACC*, American Heart Association/American College of Cardiology; *CABG*, coronary artery bypass grafting; *ECG,* electrocardiogram; *ERS/ESTS*, European Respiratory Society/European Society of Thoracic Surgeons; *PCI*, percutaneous coronary intervention; *RCRI,* Revised Cardiac Risk Index; *TIA,* transient ischemic attack. *(Reproduced from Brunelli A, Charloux A, Bolliger CT, et al. improves outcome is far from robust, and the systematic review by Schmidt-Hansen et al.[93] did not lead to any firm conclusions. Retrospective studies have demonstrated a reduced number of pulmonary complications as well as a reduced rate of perioperative mortality for nonsmokers as compared with current and former smokers, with longer abstinence associated with a favorable trend.[94,95] The effect of smoking cessation might extend beyond the perioperative period as the quality of life in quitters is much better than in persistent smokers.[96] In a population of patients with lung cancer with a clear difference in histologic findings between first and second primary tumors, there was a trend for a much higher risk of developing a second primary tumor among those who continue to smoke.[97] Overall, physicians should encourage their patients to quit smoking prior to the operation and should emphasize that the earlier they quit, the better, as the effects of smoking cessation are immediate and long-lasting.

PULMONARY REHABILITATION

In general, there is growing evidence that preoperative conditioning is advantageous; however, these standard programs generally last 6 weeks to 12 weeks. Because it is necessary for patients with malignant disease to undergo surgery without delay, effective short-term preoperative pulmonary rehabilitation programs should be adopted. Data to support the routine use of pulmonary rehabilitation are not robust.[98] Patients in poor condition who are expected to have the highest risk of perioperative problems seem to benefit most from a short (4-week) training program.[98] This may as well have consequences for the patients who are preoperatively treated with chemotherapy and have a considerable risk of weight loss as well as deconditioning.

CONCLUSION

Patients with lung cancer often have several problems related to the harmful effects of smoking. It is therefore necessary to evaluate these patients in a timely and effective way to find out if there is a possibility for those staged with resectable disease. These evaluations should clarify the potential cardiopulmonary risks during and after the operation. For patients who are found to be operable, measures should be taken to prevent perioperative and postoperative complications as much as possible. Smoking cessation and rehabilitation are part of this risk reduction.

27 Results of Video-Assisted Techniques for Resection of Lung Cancer

Frank C. Detterbeck, Alberto Antonicelli, and Morihito Okada

SUMMARY OF KEY POINTS

- Many meta-analyses, outcomes and matched cohort studies demonstrate equal long-term outcomes for video-assisted thoracoscopic surgery (VATS) and open lobectomy.
- Matched comparisons generally demonstrate equal long-term survival for VATS versus open lobectomy for lung cancer, suggesting that the improved survival seen in unmatched studies is due to confounding factors.
- Many meta-analyses, outcomes, and matched cohort studies demonstrate similar operative mortality for VATS and open lobectomy.
- Pain, hospital length of stay, and complications are lower after VATS than after open lobectomy.
- There is no difference in the incidence of N2 nodal upstaging; the effect on N1 upstaging is unclear.
- The ability to deliver adjuvant chemotherapy may be better after VATS lobectomy.
- VATS lobectomy is associated with a learning curve of about 50 cases.

Over 100 years ago, Jacobaeus[1] first reported the diagnosis and treatment of pleural effusions using a thoracoscope. Since then, the application of thoracoscopy to pulmonary resection has advanced as a useful adjunct for surgeons, perhaps most prominently for wedge resection or pleural procedures. From the late 1980s to the 1990s, surgeons began using VATS for lobectomies to treat patients with early stage nonsmall cell lung cancer (NSCLC). In 1992, VATS simultaneously stapled lobectomy without rib spreading was reported by Lewis et al.[2] and with individual vessel and bronchial ligation was reported by Roviaro et al.[3] During the following year, the outcomes of VATS lobectomy were published by Walker et al.,[4] Coosemans et al.,[5] Kirby et al.,[6] and Hazelrigg et al.[7] The surgical approach has become far less invasive as the instrumentation has gradually improved over the past two decades and VATS has evolved into a basic and vital thoracic surgical technique.

However, the penetration of VATS anatomic resections (lobectomy and segmentectomy) has been slow to occur, and currently about 30% of anatomic resections in the United States are performed using VATS.[8–11] These VATS lobectomies in the United States are performed primarily by dedicated thoracic surgeons.[12] As reported in the database of the Society of Thoracic Surgeons (STS), which represents predominantly dedicated thoracic surgeons in the United States, the proportion of lobectomies done via VATS has increased from 19% in 2005 to 44% in 2009 and is currently 66%.[13] A similar increase from 20% to 54% from 2007 to 2011 has been reported in Denmark, which has a highly centralized health-care system.[14] Robust data about the overall proportion of lobectomies that are performed using VATS in Europe or Asia are not available, but estimates put this well below the penetration currently seen in the United States.[15]

DEFINITIONS

Video-assisted thoracoscopic surgery (VATS) is used for wedge resection, segmentectomy, lobectomy, pneumonectomy, sleeve lobectomy, lobectomy with chest wall resection, and extrapleural pneumonectomy.[16] The approaches vary substantially: reports on VATS lobectomy alone describe the use of one to six incisions from 4 cm to 10 cm in length, with and without rib spreading.[1,17,18] In general, however, VATS lobectomy is interpreted to mean an anatomic lobectomy with ligation of individual bronchi and vessels and lymph node dissection or sampling using a minimal number of ports without a retractor or rib spreading.

A clear definition of VATS lobectomy is needed. The Cancer and Leukemia Group B established a definition of VATS lobectomy for a prospective, multi-institutional trial, and this definition has been widely adopted.[19] A VATS lobectomy is defined as involving no rib spreading; maximum incisions of 8 cm; dissection of individual veins, arteries, and airways for the lobe in question; and node sampling or dissection identical to open thoracotomy.[19] This definition was endorsed by most of the 55 experts participating in the 20th Anniversary of VATS Lobectomy Conference: The Consensus Meeting, organized by the Scientific Secretariat and the International Scientific Committee of the International VATS Lobectomy Consensus Group.[20] However, several participants thought that a small retractor should be acceptable in specific circumstances, for example, when performing complex procedures such as bronchoplasty or when delivering a large specimen.

Some surgeons have suggested that VATS should include only procedures done exclusively with visualization on a monitor. This criterion should be abandoned for several reasons. The most important issues for patients with malignant diseases are the incisional trauma, achievement of curative surgery, and subsequent oncologic outcomes. Occasional viewing through a 4-cm, non–rib-spreading incision does not change the nature of the procedure. A hybrid VATS approach using both a monitor and direct vision without rib spreading or a robotic approach can provide a three-dimensional understanding of anatomy as well as magnified proximity visualization and would surely clinically facilitate complex procedures such as sleeve lobectomy or segmentectomy.[21–23]

Technical aspects of how to accomplish a VATS lobectomy are beyond the scope of this chapter and are the subject of surgical atlases. Styles vary in how surgeons perform different steps of the operation. The essential feature, however, is a hilar dissection and individual division of the vessels and bronchus of the lobe. Most often, these structures are divided using an endostapler, but ligation, division between clips, or sealing with energy devices is also feasible for smaller vessels.

Patient Selection

Patient selection ultimately depends on the surgeon's judgment about the ability to accomplish an oncologically appropriate resection of a given patient's tumor. However, some general guidance can be obtained from the opinions of experts at the

TABLE 27.1 Video-Assisted Thoracoscopic Surgery (VATS) Lobectomy Recommendations Derived From Consensus Statement of the International VATS Lobectomy Consensus Group[18]

INDICATIONS FOR VATS LOBECTOMY	
≤7 cm (T1, T2a, and T2b)	Recommended
N0 or N1 status	Recommended
Patients with previous thoracic surgery or pleurisy	Highly recommended
CONTRAINDICATIONS FOR VATS LOBECTOMY	
Chest wall involvement including rib(s)	Contraindicated
Central tumor invading hilar structure(s)	Contraindicated
FEV_1 <30%	Contraindicated
DLCO <30%	Contraindicated
PREOPERATIVE INVESTIGATIONS	
PET/CT and sampling of positive mediastinal lymph nodes	Highly recommended
Sampling of positive lymph nodes by EBUS/EUS	Recommended
VATS assessment at the time of surgery	Highly recommended
Total ipsilateral lymph node dissection in all patients	Recommended
INDICATIONS FOR CONVERSION TO OPEN THORACOTOMY	
Major bleeding	Highly recommended
Significant chest wall involvement	Recommended
Vascular sleeve	Highly recommended
Bronchial sleeve	Highly recommended
Bronchovascular sleeve	Highly recommended
TRAINING	
Number of cases to overcome steep learning curve: 50	Highly recommended
Resident case volume of a training center: >50/y	Recommended
Minimum case volume to maintain VATS skills: >20/y	Recommended
Proctoring should be necessary in all new VATS surgeons	Highly recommended
FUTURE DIRECTIONS	
Establishment of multi-institutional database	Recommended
Increased exposure of VATS lobectomy to trainees	Highly recommended
Establishment of standardized VATS lobectomy workshops	Highly recommended

Data taken from Yan T, Cao C, D'Amico TA, et al. Video-assisted thoracoscopic surgery lobectomy at 20 years: a consensus statement. *Eur J Cardiothorac Surg.* 2014;45(4):633–639.

CT, computed tomography; *DLCO,* diffusing capacity of the lungs for carbon monoxide; *EBUS,* endobronchial ultrasound; *EUS,* endoscopic ultrasound; *FEV₁,* forced expiratory volume in 1 second; *PET,* positron emission tomography.

recent Consensus Meeting (Table 27.1). Most of these experts consider VATS to be appropriate for stage I and II tumors unless there is substantial hilar involvement or the need for chest wall, bronchial, or vascular sleeve resection.

OUTCOMES: COMPARISON OF VATS AND OPEN LOBECTOMY

The scope of what can be successfully performed thoracoscopically includes pneumonectomy,[24,25] segmentectomy,[23,26] sleeve lobectomy,[21,27] and lobectomy with chest wall resection.[28] However, the literature is too limited for most of these procedures to define outcomes, and the results are confounded by patient selection, making assessment of the impact of the VATS approach per se difficult at best.

By contrast, the literature on VATS lobectomy for cancer is so abundant that we have chosen to focus our review on meta-analyses and large outcomes studies. Only a few randomized controlled trials were conducted; these were early in the VATS

experience and were small, underpowered studies. As the procedure matured and experience grew, increasing amounts of nonrandomized data showed that VATS lobectomy for cancer was safe, with outcomes similar to or better than those of open lobectomy. In the United States, the decision was made that a randomized controlled trial of VATS compared with open lobectomy would require a design to prove equivalence, which would necessitate too many patients and would not be worth the expense.[9] Hence, the strongest data come from large outcomes and propensity-matched studies and not randomized controlled trials.

To provide an evidence base for this chapter, a comprehensive literature search was carried out for studies comparing VATS with open lobectomy or segmentectomy for lung cancer. We included reports that involved a meta-analysis, a randomized controlled trial, a propensity-matched or otherwise case-matched study, or an outcomes study using a large multi-institutional database. We did not include reports of individual, single-institution comparative series without case matching. Two systematic reviews were not included because a quality assessment judged them to be poor, and they included studies that were otherwise already captured.[29,30] One meta-analysis was excluded because it focused only on three propensity-matched studies, which were already included individually.[31] Another was excluded because it used an erroneous code for VATS lobectomy.[32]

Short-Term Outcomes

The results of many studies have demonstrated that VATS lobectomy is a safe procedure (Table 27.2). These studies, including meta-analyses, propensity-matched series, case-matched series, and randomized controlled trials, demonstrate that the conversion rate from VATS to open procedure is about 5% to 10%. Most of these conversions resulted from oncologic or technical factors; bleeding was the reason for conversion in only a few studies. Furthermore, conversion from VATS to an open procedure is not associated with increased perioperative mortality or complications when compared with planned open thoracotomy.[30]

The studies included in this review (Table 27.2) almost universally show no significant difference in perioperative mortality between VATS and open lobectomy (Fig. 27.1).[9,10,14,33–54] Closer examination shows that, in fact, the trend to lower perioperative mortality rates with VATS is consistent. This lower mortality rate is true even among special populations of patients (e.g., older, frail, high pulmonary risk) in case-matched series. The length of hospital stay has been significantly lower for VATS resection in most studies (Fig. 27.2). The difference is approximately 1 day to 3 days, on average. Comparison between studies is difficult, however, because the average length of stay varies markedly, most likely reflecting differences in regional standards and the structure of the health-care system.

The overall rate of complications is also significantly lower in VATS resection in most studies (Table 27.2, Fig. 27.3).[10,33–35,37,39–47,50–54] Comparison of complications among studies is difficult because of the varying definitions of a complication and the degree of severity of complications that were counted. Certain specific relevant complications have been reported in some studies (Table 27.3).[10,34–45,50,52–55] A fairly consistent trend toward lower rates of pneumonia, prolonged air leak, arrhythmia, and need for postoperative mechanical ventilation has been demonstrated, with the difference being significant in less than half of the studies.

Some of the studies have included VATS resections performed with rib spreading. Comparisons of VATS resection done with and without rib spreading show lower rates of complications when rib spreading is avoided.[34,36] Specifically, avoidance of rib spreading is associated with significantly less pain,

shorter hospital stay, lower perioperative complications, and lower mortality rates.[34,56]

Postoperative pain is significantly less after VATS lobectomy than following open thoracotomy. In a 2007 meta-analysis of the available data, the pain level, analgesic dose, and frequency and duration of analgesic use over the first postoperative week were significantly lower after VATS lobectomy than after open lobectomy (p = 0.008 to 0.0001).[34] Pain, measured with a visual analog scale, was less with VATS throughout the first month, but by postoperative month 3, there was no difference (Fig. 27.4).[34]

Limited data show that VATS significantly improves the proportion of patients who are functioning independently and without limitations. The time to full mobility is significantly reduced, and patients are quicker to regain arm mobility.[57] Overall quality of life appears to be better for patients who have received VATS compared with those who received open lobectomy.[58] Pulmonary function tests at 1 year are better after VATS lobectomy.[34]

Lastly, older and frail patients seem to be better able to tolerate a VATS lobectomy.[47–49]

Long-Term Outcomes

Many series have reported long-term outcomes associated with VATS compared with open resection for lung cancer (Table 27.4).[9,14,33–36,38,41,43,48,55,59–63] In large meta-analyses, the 5-year survival is reported to be better following VATS resection, with most studies indicating a significant difference. However, this comparison is potentially confounded if patients with smaller, earlier stage tumors are more likely to be selected for a VATS resection. Some authors have tried to address this by focusing only on stage I NSCLC and have shown either better or equal survival after VATS resection (Fig. 27.5).[34,59,61] Others have addressed this by propensity matching or other ways of case matching. These comparisons have shown no difference in long-term outcomes, either for all matched patients

or for patients within a subset of stage I disease (Table 27.4). Outcomes studies have typically shown a long-term survival benefit for unadjusted results but no significant difference when the results are adjusted for prognostic factors.[14,50,64] It should be noted that these adjustments include structural and treatment factors such as center volume, center type, stage, staging tests, node dissection, and adjuvant therapy; however, patient-related and tumor-related factors (i.e., comorbidities, stage, histology) are usually not available in these databases. In large series (>500 patients) that include stage-specific outcomes after VATS, long-term survival rates for VATS have been similar stage-for-stage to the average rates for resected NSCLC in general.[65,66]

Many authors have examined the rate of either local or systemic recurrence. These studies have shown a fairly consistent trend to lower recurrences of both types in patients who have VATS resection, with about one-third of these demonstrating that the difference was significant (Table 27.4). However, these analyses have the disadvantage of not being matched or randomized. Nevertheless, consistent results are seen in randomized controlled trials, propensity-matched studies, and larger outcomes studies.[43,62,63] It has been suggested that better oncologic outcomes after VATS resection may be because VATS causes fewer inflammatory mediators in the early postoperative period,[53] but this suggestion remains speculative.

In summary, the data in aggregate demonstrate that survival after VATS resection is essentially the same as after open resection. Suggestions of possibly better outcomes are likely related to confounding factors because such differences generally disappear when propensity matching or adjustment for structural or treatment variables are made.

Specific Issues

Node Dissection/Staging N1 and N2

Data from a large number of unmatched, nonrandomized comparisons have shown no difference in mediastinal node staging between VATS and open lobectomy, specifically no difference in the number of nodes or the number of node stations sampled in a meta-analysis (14 studies, $p = 0.63$).[31] This issue has also been addressed in two randomized and several prospective trials, which showed no difference.[54,63,67,68] A propensity-matched study of the

National Cancer Database (NCDB) found that significantly more nodes were examined during VATS versus open resections (10.3 vs. 9.7, $p < 0.01$).[69] A systematic review and meta-analysis specifically addressing node staging found no difference between VATS and open procedures.[41] Although a difference in staging has been reported in some retrospective studies, the investigators of these studies have stated that the difference resulted from intentional omission of sampling of some node stations on clinical grounds, not because of technical limitations of the approach.[41,44]

In 2012, Boffa et al.[13] examined nodal upstaging in 11,531 patients with clinical stage I primary lung cancers who had lobectomy or segmentectomy from 2001 to 2010 in the STS database (7137 open procedures and 4394 VATS). There was no difference between VATS and thoracotomy in the rate of upstaging to N2 involvement, but there was a significantly lower rate of N1 upstaging in the VATS group. This difference was interpreted as suggesting that less attention is paid to assessing N1 nodes during VATS resection. A follow-up study was carried out by Licht et al.[14] using the Danish National Lung Cancer Registry. Although the number of dissected node stations was the same, VATS resulted in lowering of both N2 and N1 nodal upstaging (3.8% vs. 11.5%, $p < 0.001$ and 8.1% vs. 13.1%, $p < 0.001$, respectively) than did open lobectomy for clinical stage I NSCLC.[13] However, multivariate analysis showed no difference in survival, suggesting that nodal upstaging either did not matter or reflected confounding by unknown selection or recording factors.

Two recent studies, both using a propensity-matched analysis of T1,2N0M0 patients in the NCDB, came to conflicting conclusions.[69,11] One study found no difference in N1 or N2 upstaging (7.7 vs. 8.1 [N1] and 3.8 vs. 4.1 [N2], $p = 0.53$ in 9380 matched pairs of VATS/robotic vs. open patients, respectively),[69a] whereas the other found lower N1 and a trend to lower N2 upstaging (6.9 vs. 8.0, $p = 0.046$ [N1] and 3.2 vs. 3.9, $p = 0.098$ [N2] in 4437 matched pairs of VATS vs. open patients, respectively).[69] The reason for the discrepancy is unclear. There were only slight differences in factors included in the propensity matching and the years included (2010–2012[11] and 2010–2011[69]). There was no difference whatsoever in nodal upstaging between VATS and robotic procedures in the study that included robotic resections,[11] which has also been confirmed by others.[70] Other unmatched retrospective studies have suggested a lower rate of N1 and N2 upstaging via VATS or similar rates of N2 upstaging.[62,71,72]

It may be that the rate of nodal upstaging is a reflection of other factors and not actually the approach used. Boffa et al.[13] found that there was no difference in N1 upstaging by VATS versus open approaches when the analysis was restricted to sites that performed one or the other approach in most (≥80%) of their resections (8.7% vs. 8.7% in 989 VATS cases vs. 3668 open cases).[13] Medbery et al.[69] found no difference in N1 or N2 upstaging when the analysis was restricted to academic/teaching centers (10.5 vs. 12.2 VATS vs. open, $p = 0.084$ in 2008 matched pairs), although they did find an overall lower rate of N upstaging by VATS in an analysis restricted to cases that had seven or more nodes examined (12.1 vs. 14.0 VATS vs. open, $p = 0.031$ in 2825 matched pairs).[69] Finally, although the propensity-matched studies attempted to account for tumor characteristics such as T stage and size, none of the studies could account for factors such as whether the tumor was central versus peripheral, or mostly solid versus ground glass (characteristics that are known to affect the incidence of nodal involvement).

Taken together, the data suggest that there is little, if any, inherent difference in the ability to carry out intraoperative staging between VATS and open resections. There are some data suggesting the possibility of a lower rate of N1 node assessment with VATS, but the validity and impact of a rate difference, if any, are unclear.

Ability to Tolerate Adjuvant Chemotherapy

The ability of patients to receive adjuvant chemotherapy is improved following VATS lobectomy, as assessed in several studies.[67,73–77] Retrospective studies without adjustment for other patient characteristics have all shown a better ability to administer adjuvant chemotherapy after VATS resection. For example, in one study, the ability to deliver more than 75% of the planned dose was higher with VATS (89% vs. 71%).[67] Furthermore, chemotherapy toxicity appears to be reduced after a VATS resection.[67] However, in a registry study in which adjustments were made for comorbidities and other factors, VATS resection was not associated with better delivery of adjuvant chemotherapy (only age, comorbidities, and the N1 or N2 node status were associated with better delivery).[74]

A few authors have reported long-term outcomes for VATS compared with open resections in patients who were given adjuvant chemotherapy. Some findings have suggested that survival is better in the VATS group.[67,74] However, in a multivariate analysis of this issue in the Danish National Lung Cancer Registry, it appears that survival was statistically associated with comorbidity, pathology, and compliance but not with the surgical approach.[74]

Learning Curve

Without question, VATS lobectomy is associated with a learning curve, as are all surgical procedures. The experts at the VATS Consensus Meeting estimated that, in general, most surgeons become reasonably proficient and comfortable with the procedure after approximately 50 cases. This learning curve is consistent with the findings of several investigations that have also indicated 50 cases as a number that achieves a reasonable comfort level.[78–80] Furthermore, the results of studies suggest that training of thoracic surgical residents in VATS lobectomy can be accomplished safely.[79] According to a study by Boffa et al.,[64] most thoracic surgical trainees in the United States, especially those with a predominant focus on thoracic surgery, thought that their training had prepared them to perform VATS lobectomy.

Robotic Versus VATS Lobectomy

The rate of robotic lobectomy is still quite low, although the number of robotic lobectomies has increased significantly (10.4% of lobectomies in 2012 in the NCDB were performed using robotics).[11] Available matched or adjusted comparative studies suggest there is no major difference in outcomes of VATS versus robotic lobectomy.[11] Specifically, no difference was observed in 30-day mortality, length of stay, or nodal upstaging in propensity-matched comparisons (295 and 1938 matched pairs),[82] or in comparisons adjusted for patient and hospital characteristics.[83] Some studies have found no difference in total major or minor complications,[82,83] but Paul et al.[83] found a significantly higher rate of iatrogenic complications (accidental laceration or bleeding) that persisted after adjustment for patient and hospital characteristics (odds ratio, 2.64 [1.58–4.43]). The cost of robotic lobectomy appears to be higher than for VATS (by about $4500), even without accounting for the capital cost of the robot itself.[82,83]

DISCUSSION

VATS lobectomy was first described in the early 1990s, and an abundance of literature has been published on the subject. The data reviewed in this chapter demonstrate that VATS lobectomy is safe, is associated with lower rates of complications and mortality than open lobectomy, and results in equivalent long-term outcomes. Thus VATS lobectomy is well established and should be considered the standard of care from a patient perspective. Indeed, the 2013 lung cancer guidelines of the American College of Chest Physicians recommend a minimally invasive resection as the preferred method for resection of early stage NSCLC in experienced centers (evidence level, grade 2C).[84]

Some of the advantages of VATS are seen only transiently; for example, pain is nearly resolved at 3 months with either a VATS or open approach. However, other advantages, such as lower operative mortality rates, have long-term implications. Whether other potential advantages, such as long-term survival or the ability to deliver adjuvant chemotherapy, are attributable to the VATS approach or to patient selection is, as yet, unclear.

The appropriate place for VATS lobectomy from a societal perspective is more difficult to define. Many factors besides patient experience and outcomes play a role. The availability of equipment and expertise are important factors, as is the balance between material and personnel costs (e.g., How does an extra day in the hospital compare with an extra staple cartridge used in the surgical suite?). The structure of the health-care system and cultural norms of the society have a considerable influence on these factors, which will balance differently in specific settings.

Resistance to change may be one of the major factors inhibiting wider adoption, despite the data supporting the technique. Time is needed to fully assess a new technique, but surely 20 years and thousands of studies have provided sufficient assessment. The learning curve is inarguable, but certainly it can be overcome, as many centers have demonstrated. Reviewing the data and investing in learning a new technique are needed for greater adoption of VATS.

CONCLUSION

VATS lobectomy is well established and supported by a large body of literature. The evidence has been summarized in several meta-analyses, large-scale outcomes studies, many propensity-matched studies, and small randomized controlled trials. The propensity-matched studies and adjusted outcomes data generally demonstrate that short-term mortality and long-term survival rates are equivalent between VATS and open lobectomy. However, simple comparisons and meta-analyses demonstrate that VATS resections are associated with less morbidity, fewer complications, lower mortality rates, and decreased length of stay compared with thoracotomy. Therefore we conclude that lobectomy should be performed by VATS whenever possible.

28 Robotic Surgery: Techniques and Results for Resection of Lung Cancer

Ayesha Bryant, Benjamin Wei, Giulia Veronesi, and Robert Cerfolio

SUMMARY OF KEY POINTS

- Robotic surgery can be used for completely portal (no utility incision) or robotic-assisted (uses utility incision) techniques.
- Appropriate patient and port positioning are critical for a successful performance of robotic lobectomy.
- Perioperative morbidity and mortality for robotic lobectomy are comparable to that for video-assisted thoracoscopic surgical (VATS) lobectomy.
- Robotic lobectomy may have advantages in terms of surgeon ergonomics, mediastinal lymph node dissection, and intraoperative blood loss over VATS lobectomy.
- Robotic lobectomy can be done safely and is being increasingly used for anatomic pulmonary resections.

DEFINITIONS

A general thoracic operation is defined as any operative procedure for lesions or structures in the thorax, including but not limited to lesions or pathology in the mediastinum, pulmonary parenchyma, chest wall muscles or skeletal structures, diaphragm, or esophagus.

A robotic system is defined as any machine or mechanical device that uses a computer to translate human movements into the movement of robotic instruments. The robotic instruments or tools, not the surgeon's hands, interact with the patient's tissue.

A robotic thoracic operation is defined as a general thoracic operation that is minimally invasive (i.e., no rib spreading) and in which the surgeon's and assistant's views of the operative field are via a monitor rather than through an incision. Moreover, the procedure utilizes a robotic system for all or mostly all of the crucial aspects of the operation. For pulmonary resection, crucial surgical aspects include dissection and ligation of the pulmonary arteries and veins, dissection and removal of the mediastinal and hilar lymph nodes, and bagging of the specimen. For mediastinal operations, dissection and removal of the mediastinal lesion are robotically performed. For esophageal operations, dissection of the esophagus and/or the esophageal lesion, resection and/or bagging of the specimen, removal of the thoracic lymph nodes, and possibly anastomosis of the esophagus to the stomach or other chosen conduit are crucial tasks completed with the robotic system.

We have suggested a nomenclature that differentiates completely portal robotic operations (CPRs) from operations in which a utility incision is used, which are referred to as robotic-assisted operation or robotic-assisted thoracic surgery. Such a nomenclature specifies the number of robotic arms implemented and is defined as follows.

A CPR is defined as an operation that uses ports only (incisions that are only as large as the size of the trocars placed in them). In this case the air in the pleural space or chest cavity does not communicate with the ambient air in the operating room, carbon dioxide is used to insufflate the chest, and the only port incision that is larger than the trocars that go through them is one through which a specimen contained in a protective bag is removed.

A robotic-assisted operation is defined as a procedure in which a utility incision is used (defined as either an incision in the chest that may or may not have trocars or robotic arms placed through it or an incision that allows communication between the ambient air in the operating room and the pleural space), which does not involve spreading of the ribs, and in which carbon dioxide insufflation is used selectively (only as needed).

The number of robotic arms used during the operation is included in the nomenclature and is separated by a hyphen after the type of operation is specified. The abbreviation for the type of operation also includes a one-letter initial to indicate the specific procedure. For example, a CPR lobectomy using four arms is a CPRL-4, and a CPR segmentectomy using three arms is a CPRS-3 (Table 28.1).

HISTORY OF SURGICAL ROBOTICS

Industrial robots are mechanical arms that, working alone or in cooperation, perform precise, complex, repetitive tasks, and manipulations under computer control. Robot arms are increasingly flexible in terms of the objects they can work on and the tasks they perform, including capabilities that require visual and other sensing systems linked to powerful computers with artificial intelligence software.

Surgical robots also consist of mechanical arms that attach to surgical instruments. However, although computers filter and scale the movements and manipulations carried out by these arms, surgeons always directly control the arms. Robotic surgical systems have been in development since the 1980s.[1] Intuitive Surgical Inc. and Computer Motion Inc. emerged as the two main companies producing robotic systems for minimally invasive surgery in the first decade of the 21st century.[2] Intuitive Surgical's robot arms are controlled manually by the surgeon; Computer Motion's system employed voice control too. Both companies obtained limited approval from the US Food and Drug Administration (FDA) for their systems. The two companies merged in 2003. Several other companies in Europe and the United States are developing robotic surgical systems: most are intended for minimally invasive surgery, but others are being developed to perform open surgery or remote surgery.

The da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, CA, USA) is currently the only FDA-approved robotic system for lung surgery.[2] The surgeon sits at a console some distance from the patient, who is positioned on an operating table in close proximity to the robotic unit with its three or four robotic arms.[3–9] The robotic arms incorporate remote center technology, in which a fixed point in space is defined, and the surgical arms move around it to minimize stress on the thoracic wall during manipulations. The system's small

TABLE 28.1 Operative Characteristics for the Proposed Nomenclature System for General Thoracic Robotic Operations

	Completely Portal Robotic	Robotic Assisted
Suggested abbreviations	CPR	RA
Designation includes the number of robotic arms used	Yes (e.g., CPRL-4, completely portal robotic lobectomy using 4 arms)	Yes (e.g., RAL-4, robotic-assisted lobectomy using 4 arms)
Rib spreading	No	No
Access or utility incision made	No	Yes
Carbon dioxide insufflation used	Yes	Sometimes
Communication between pleural space air and ambient air in operating room	No	Yes
Trocars placed though all incisions	Yes	No
Incisions bigger than size of trocars used	No	Yes
Site of specimen removal	Usually over the anterior aspect of the tenth rib	Usually over the anterior aspect of the fourth rib

proprietary EndoWrist instruments, which are attached to the arms, are capable of performing a wide range of high-precision movements. The surgeon's hand movements with the so-called master instruments at the console control the EndoWrist instruments. These master instruments sense the surgeon's hand movements and translate them electronically into scaled-down micromovements to manipulate the small surgical instruments. Hand tremor is filtered out by a 6-Hz motion filter. The surgeon observes the operating field through console binoculars. The image comes from a maneuverable high-definition stereoscopic camera (endoscope) attached to one of the robot arms. The console screen can also display digital input from electrocardiography, computed tomography, and other imaging modalities. The Firefly Fluorescence Imaging (Intuitive Surgical, Inc) involves a camera head with laser-based illuminator to visualize vascular and lymph node flow in three dimensions after injection of fluorescent dye.

The console also has foot pedals that allow the surgeon to engage and disengage different instrument arms, reposition the master controls on the console without moving the instruments themselves, and activate electric cautery. A second optional console allows tandem surgery and training.

ROBOTIC LOBECTOMY: TECHNICAL ASPECTS

The number of robotic pulmonary resections continues to increase. The team learning curve for robotic surgery is steep; however, the learning curve for the typical thoracic surgeon may be less than that for VATS lobectomy, especially for lymph node dissection. This difference may be one reason why the popularity of robotic resection is increasing among surgeons. A review of the guidelines and pathways to team building and credentialing for robotic pulmonary resections follows.

Operating Room Configuration

As with any operation, planning each stage of the operation is crucial to ensure success. The robot adds anxiety to inexperienced robotic surgeons and anesthesiologists. Thus planning the room layout before the operation is essential and includes positioning the bedside cart, robot, nurses' table, monitors, and patient relative to the anesthesia equipment. The robot is driven in over the patient's head during lobectomy; thus precise planning and communication of the position of two monitors and the distance between the operating surgeon at the console and the scrub nurse and surgical assistant(s) at the patient's bedside are needed (Fig. 28.1).

Console

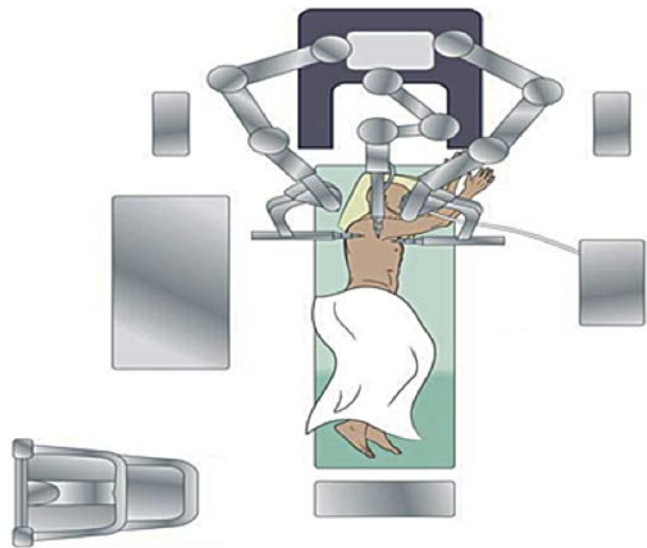
The surgeon's console should be positioned in such a way that good communication with the surgical team at the bedside can be established. The da Vinci Surgical System console contains a


Fig. 28.1. A potential universal room setup for all robotic operations, regardless of specialty.

microphone that amplifies the voice of the surgeon to the rest of the team. The presence of a second console permits easy exchange of control between surgeon, medical student, resident, or fellow for training purposes; this second console, if used, should be located fairly close to the primary console.

Robot/Bed

The approach of the robot to the patient's side should be clear of any obstacles. The robot is driven over the patient's head on a 15-degree angle to open up robotic arm 3 over the head and shoulder (Fig. 28.2). In addition, monitors are positioned so that the bedside assistants and scrub nurse have a clear view.

Depending on the size of the room and the arrangement of immobile structures within it, the patient's bed may need to be turned such that the patient's head is located well away from the ventilator and anesthesia console. A long extension for the endotracheal tubing should be used if necessary.

When the robot is set up, robotic arm 3 should be placed on the robot side opposite the side of the lobectomy (e.g., if performing a right lobectomy, robot arm 3 should be located on the robot's left when facing the robot).

Surgical Team

The surgical bedside assistant should be in position at the patient's ventral side (i.e., in front of the patient's abdomen
Fig. 28.2. The optimal angle for driving the robot over the patient's head to maximize the use of robotic arm 3 and prevent external collisions.

and chest), with a monitor on the opposite side. The scrub nurse should be in position with the instrument stand near or over the patient's feet, as in conventional thoracotomy or VATS.

Patient Positioning

The patient is placed in the supine position, general anesthesia is induced, and the patient is intubated with a left-sided double-lumen endotracheal tube. Proper placement of the double-lumen tube is assisted greatly by the use of a flexible pediatric bronchoscope and is crucial to a smooth operation because access to the patient's head and endotracheal tube will be limited by their positioning and the presence of the robot after docking.

After the double-lumen tube is secured, the patient is placed in the lateral decubitus position with the operative side up. An axillary roll is placed. We do not use an arm board; rather, we place the patient's back at the edge of the table, leaving space in front of the face to fold the arms and expose the axilla for port placement (Fig. 28.2). We have used this positioning for more than 17 years for our thoracotomies because when a four-arm robotic approach is used, robotic arm 3 can move on a plane that is below the bed and avoid conflicts with that arm and the operative bed itself. Padding should be used around the arms and head to prevent nerve damage during the surgery. We use large foam pads to protect the patient's head and arms. This easy, quick, and cost-effective technique requires no special equipment and is reproducible.

Port Placement/Docking

The ports are inserted in the seventh intercostal space over the top of the eighth rib for upper/middle lobectomy and in the eighth intercostal space over the top of the ninth rib for lower lobectomy (Fig. 28.3).

The ports are marked as follows: robotic arm 3, a 5-mm port is located 1 cm to 2 cm lateral from the spinous process of the vertebral body; robotic arm 2, an 8-mm port is located 10 cm medial to robotic arm 3; the camera port (we prefer a 12-mm camera) is located 9 cm medial to robotic arm 2; and robotic arm 1 (a 12-mm port) is placed directly above the diaphragm anteriorly. The assistant port (12 mm) is placed as low as possible in the chest, triangulated exactly halfway between the most anterior robotic port (which is robotic arm 1 in the right chest and robotic arm 2 in the left chest) and the camera port, and as
Fig. 28.3. (Right side). The optimal port placement for a completely portal robotic lobectomy using all four arms. The four ports are placed over the same rib: over the top of the ninth rib for lower lobectomy and over the top of the eighth rib for upper lobectomy. The 12-mm access port *(A)* is placed halfway between the camera port *(C)* and robotic arm 1 *(1)* for upper and lower lobes and between the camera and robotic arm 2 *(2)* for middle lobectomy. The port is placed as low as possible staying just above the diaphragm as carbon dioxide is insufflated to help push the diaphragm down. *3*, robotic arm 3; *MAL,* midaxillary line.

low as possible to remain just above the diaphragm, which is being pushed downward by the insufflating humidified carbon dioxide gas.

Sequence of Port Placement

A 5-mm port is placed first in the camera port position, and carbon dioxide insufflation is initiated at a pressure of 10 mmHg. We use humidified warm carbon dioxide. An intercostal nerve block with 0.25% bupivacaine with epinephrine (Marcaine) is then performed from ribs 3 to 8 by injecting a wheel of bupivacaine subpleurally under direct vision. Then the 5-mm thoracoscope is used to help assist the placement of all other ports, which are placed under direct vision. The camera port is placed first, robotic arm 3 is placed second, and
Fig. 28.4. (Left side). As in Fig. 28.3, but showing left side.

robotic arm 2 in the right chest and robotic arm 1 in the left are placed last.

The 5-mm camera is then moved to the port for robotic arm 2, and the two most anterior ports (robotic arm 1 in the right chest and robotic arm 2 in the left) and the access port are placed under direct vision using a seeking needle. Our techniques completely avoid all of the diaphragmatic fibers. The 5-mm camera port is then replaced by a 12-mm camera port. We use a zero-degree scope for the entire procedure to help prevent torquing of the intercostal nerve.

The port placement for left-sided lobectomy is a mirror image to that previously described (Fig. 28.4). The difference is that robotic arm 3 is next to robotic arm 1, rather than next to robotic arm 2. The numbering is different; however, the locations of the ports are the same.

The robot is moved at a 15-degree angle toward the patient's face off the long axis of the bed (Fig. 28.2). The robotic arms are docked to the ports, maximizing the amount of space between the arms to avoid collisions. Once the system is docked, the operating table cannot be moved.

The instruments used to start the surgery are an 8-mm Cadiere forceps in the left robotic arm, an 8-mm bipolar curved thoracic dissector in the right robotic arm, and a 5-mm thoracic grasper in robotic arm 3.

For their initial placement, robotic instruments should be inserted under direct vision during thoracic surgery. Once instruments are safely positioned, they can be quickly and safely inserted or changed for other instruments by properly using the memory feature of the robot, which automatically inserts any new instrument to a position that is exactly 1 cm proximal to the latest position. However, when this memory feature is used, the surgeon must ensure that no vital structures have moved into the path of the newly placed instrument. The most common structure to move is the lung.

The insertion of robotic instruments deserves special attention, as does the passing of vascular staplers around fragile structures such as the pulmonary artery and vein. Carefully orchestrated movements and clear communication are needed between the surgeon and the surgical bedside assistant, a resident, fellow, physician assistant, or nurse practitioner who acts as the surgeon's link to the patient. We have developed our own communication system between the bedside assistant and the surgeon to prevent iatrogenic injuries. This communication system uses the anvil of the stapler as the hour hand of a clock so that the degree of articulation can be quantified and communicated.

Mediastinal Lymph Node Dissection

The pleural surface is inspected before initiating node dissection and lobectomy to confirm that there are no metastatic lesions. We perform mediastinal lymph node dissection before lobectomy not only to evaluate the lymph nodes but also to access arterial and venous branches and the bronchus.

Right Side

The inferior pulmonary ligament is divided to gain access to station 9 lymph nodes, which are removed along with station 8 lymph nodes. Robotic arm 3 is used to retract the lower lobe medially and anteriorly to remove lymph nodes from station 7. Care is taken to control the two feeding arteries that make the subcarinal lymph node bloody. Robotic arm 3 is used to retract the upper lobe inferiorly, whereas robotic arms 1 and 2 are used to dissect lymph nodes at stations 2R and 4R, clearing the space between the superior vena cava anteriorly, the esophagus posteriorly, and the azygos vein inferiorly. Avoiding dissection too far superiorly can prevent injury to the right recurrent laryngeal nerve that wraps around the subclavian artery.

Left Side

The inferior pulmonary ligament is divided to facilitate removal of lymph nodes at station 9. The nodes in station 8 are then removed. Station 7 is accessed in the space between the inferior pulmonary vein and lower lobe bronchus, lateral to the esophagus. The lower lobe is retracted medially/anteriorly with robotic arm 3 during this process. Absence of the lower lobe facilitates dissection of lymph nodes at station 7 from the left. Because of enhanced magnification and 360-degree vision, the robot has a distinct advantage compared with VATS for the dissection of station 7 lymph nodes from the left chest. Lastly, robotic arm 3 is used to wrap around the left upper lobe and press the lobe inferiorly to allow dissection of stations 5 and 6 lymph nodes. Care should be taken while working in the aortopulmonary window to avoid injury to the left recurrent laryngeal nerve. Station 2L cannot typically be accessed during left-sided mediastinal lymph node dissection because of the presence of the aortic arch, but the 4L node is commonly removed.

General Concepts

In general, for a right-handed surgeon, a blunt instrument such as a Cadiere forceps is placed in robotic arm 2, which is always the left hand, and the right hand, which controls robotic arm 1, uses a thoracic dissector.

The stapler may be placed through one of three ports: the access port, robotic arm 1, or robotic arm 2. The current design of commercially available white or gray vascular staplers requires a 12-mm port; the green-loaded stapler commonly used for the bronchus requires a 15-mm port. We prefer to remove the trocar and leave it docked to the robotic arm and then place the stapler through the skin incision. We prefer to place a vessel loop under a vessel to be stapled to help elevate it while the stapler is passed beneath it.

We commonly use a prerolled sponge to absorb blood from the operative field or facilitate blunt dissection to improve visibility.

Removal of lymph nodes from surrounding structures should be done before stapling them in the interests of both ensuring an oncologically sound operation and facilitating isolation and division of structures.

Adhesions, if substantial, may be lysed via the assistant port using VATS techniques until safe placement of all the robotic instruments is permitted.

The order in which the structures are isolated and divided during lobectomy varies somewhat, depending on patient anatomy.

OUTCOMES

The outcomes after robotic surgery for lung cancer have been reported in several series[6,10–15] (Table 28.2).

Short-Term Results

Two studies showed that short operative times (132 min and 175 min, respectively) are possible as the experience of each surgeon grows.[11,12] Despite decreasing operative times, these two series also demonstrated extremely low operative mortality rates and outstanding mediastinal lymph node removal, and both used a completely portal technique that eliminated an access incision except at the end of the operation for extraction of the bagged specimen.

An updated series of 282 patients undergoing robotic lobectomy demonstrated an average blood loss of 20 mL, 0.5% rate of intraoperative/postoperative transfusion, 107-minute mean operative time, and median 2-day hospital length of stay with low rates of perioperative major morbidity (9.6%) and mortality (0.25% 30-day and 0.5% 90-day mortality).[16] Operative times have been shown to decrease with surgeon experience.[17]

Similarly, as detailed in Chapter 27, surgeons who used a VATS access incision also have reported outstanding results with a low 30-day mortality rate. The hospital length of stay for robotic surgery has been comparable to that for VATS lobectomy, ranging from a mean of 2 days to 5 days.

One study comparing results from 120 robotic lobectomies with those from VATS cases in the Society of Thoracic Surgeons database from 2009 to 2010 demonstrated lower postoperative blood transfusion rates (0.9% vs. 7.8%, $p = 0.002$), fewer air leaks greater than 5 days (5.2% vs. 10.8%, $p = 0.05$), decreased chest tube duration (3.2 days vs. 4.8 days, $p < 0.001$), and decreased length of stay (4.7 days vs. 7.3 days, $p < 0.001$) compared with open lobectomy, and trending in favor of robotic lobectomy over VATS.[18] Studies of the rate of nodal upstaging with robotic lobectomy versus VATS are conflicting, with some showing an advantage, whereas others have not.[19,20]

Long-Term Results

The success of oncologic procedures is measured by the 5-year survival rate. Because robotic anatomic pulmonary resection is relatively new, few studies have reported an actuarial 5-year survival rate. One study with a median follow-up of 27 months demonstrated 5-year survival of 91% for stage IA patients, 88% for stage IB patients, and 49% for stage II patients and a 43% 3-year survival for patients with stage IIIA disease.[20] A theoretical advantage of minimally invasive procedures is that they produce a lower level of inflammatory response and thus may improve 5-year survival. Further studies are needed and are ongoing.

CONCLUSION

The future of minimally invasive surgery will involve robotics. The use of robotic technology for the performance of anatomic lung resection is increasing.[13] Although there is currently only one robotic system for thoracic surgery, other prototypes are being explored. To maintain safe and effective robotic surgery, surgeons must continue to design evidence-based pathways to the credentialing of robotic surgical teams. Despite the small number of studies reported in the literature from several single centers and a handful of surgeons, the results show good intraoperative results with anatomic pulmonary resection and promising long-term survival rates. Further studies on the true cost to society (not solely to the hospital or patient) and the actual 5-year to 10-year survival rates for people with cancer treated robotically are needed. In addition, literature that evaluates the reproducibility of this type of robotic surgery across centers and its feasibility in impoverished or Third-World countries is also needed.

29 Extent of Surgical Resection for Stage I and II Lung Cancer

Hisao Asamura and Dominique Grunenwald

SUMMARY OF KEY POINTS

- With the realization that many more lung cancers are being detected, which may not only be indolent but also smaller than 2 cm, thoracic surgeons are considering sublobar resections in their practice.
- There are conflicting data from meta-analyses and large databases regarding the efficacy of segmentectomy or wedge resection compared with lobectomy.
- Despite promising data from propensity-matched trials of lobectomy compared with sublobar resection, the results of the Japanese and American randomized trials for management of the less than 2-cm nodule should define the proper resection for this population.

Present-day surgery for lung cancer with curative intent consists of resecting (removing) the proper extent of the lung parenchyma bearing the cancer lesion, along with the local–regional lymph nodes, which may contain cancer metastasis.[1] For resecting the lung parenchyma, the following surgical procedures may be performed, depending on the extent of the disease: pneumonectomy (removal of the entire lung on either side), bilobectomy (removal of two adjacent lobes), lobectomy (removal of a single lobe), segmentectomy (segmental resection, removal of a single segment or adjacent segments), and wedge or partial resection (removal of wedge-shaped parenchyma regardless of the bronchovascular anatomy). When the proximal portion of the bronchus is involved by the direct extension of the tumor or by lymph node metastasis at the hilum and the resected end of the bronchus with lobectomy or pneumonectomy cannot be tumor-free, a sleeve resection, which entails resection of the proximal portion of the bronchus and reconstruction, might be considered in conjunction with lobectomy (sleeve lobectomy) or pneumonectomy (sleeve pneumonectomy) to ensure a safe surgical margin. Sleeve resection enables tumor-free resection without sacrificing the noninvolved lung parenchyma.

With respect to the pulmonary hilum, these procedures can be divided into anatomic resection (pneumonectomy, bilobectomy, lobectomy, and segmentectomy) and nonanatomic resection (wedge resection). In anatomic resection, the extent of the pulmonary parenchyma for resection is determined by the extent of perfusion of the pulmonary vessels as well as by the extent of aeration of the bronchi, which are divided at the hilum. In nonanatomic resection, the extent of the parenchymal resection is determined solely by the location of the target lesion. Although segmentectomy and wedge resection are both referred to as sublobar resection, the technical characteristics of these two procedures are quite different (Fig. 29.1).

In this chapter, we discuss the proper selection of the mode of parenchymal lung resection, with particular focus on stage I and II lung cancer, from both oncologic and technical viewpoints. We also present an overview of the evolution of lung cancer surgery since the 1930s, when the only option available for surgical resection for lung cancer was pneumonectomy.

OVERVIEW OF THE EVOLUTION OF LUNG CANCER SURGERY

Historically, lung cancer surgery has evolved so as to minimize the extent of parenchymal resection (Fig. 29.2). Surgeons have been trying to achieve an optimal balance between radical surgery and surgery that preserves postoperative lung function. Kummel[2] presented the earliest report, published in 1911, of a pneumonectomy of the right side; the patient was a 40-year-old man who died on the sixth postoperative day. After a series of early postoperative deaths after pneumonectomy in the 1920s, Evarts Graham Churchill[3] in St. Louis, Missouri, reported the first successful pneumonectomy, using a tourniquet technique, on a 48-year-old male doctor with lung cancer in 1932. After this landmark operation, reports of successful pneumonectomies for lung cancer were presented by Rienhoff and Broyles,[4] Alexander,[5] Archibald,[6] Sauerbruch,[7] and Overholt.[8] In 1940, Overholt[9] reviewed 110 pneumonectomies, including his own 15 cases, for benign and malignant lung diseases and found a mortality rate of 65% for procedures performed for malignant disease. He noted that the operability of primary lung cancer was 25%. In the 1940s, pneumonectomy was established as the standard mode of pulmonary resection for lung cancer. Allison[10] performed pneumonectomy with intrapericardial ligation of the pulmonary vessels, and more importantly, adding local–regional lymph node dissection to pneumonectomy was proposed as radical surgery for lung cancer. Cahan and coworkers[11] called this procedure radical pneumonectomy, which indicated the combination of parenchymal resection and lymph node dissection.

In the 1950s and 1960s, lobectomy gradually replaced pneumonectomy. In 1950, Churchill et al.[12] reported that the 5-year survival rate with lobectomy (19%) was better than that with pneumonectomy (12%). Belcher[13] reported a 5-year survival rate after lobectomy of 61%, which was outstanding at that time. In 1960, Cahan[14] again defined radical lobectomy as an operation in which one or two lobes of an entire lung are excised in a block dissection, along with certain regional hilar and mediastinal lymphatics (Fig. 29.3). The extent of lymph node dissection was also defined according to the primary site of the lung cancer. Cahan analyzed the outcomes of 48 radical lobectomies for primary and metastatic lung cancers and concluded that survival for 5 or more years could be attributed in large part to radical lobectomy associated with more extensive lymphatic dissection. In the 1970s and 1980s, lobectomy was considered the standard mode of resection for primary lung cancer and pneumonectomy was no longer the standard approach.

Although lobectomy came to be considered the standard of care for primary lung cancer, lesser resections—segmentectomy and wedge resection—for peripheral lung cancer have always been reserved for patients who are not able to tolerate more extensive procedures such as lobectomy or pneumonectomy. Churchill and Belsey[15] originally introduced segmental resection in 1939 as segmental pneumonectomy for the treatment of benign lung diseases. This technique was later advocated for use in patients who had operable lung cancer and limited pulmonary reserve. In 1972, Le Roux[16] reported on 17 patients with peripheral tumors who had undergone segmental resection. In 1973, Jensik et al.[17]
Fig. 29.1. Anatomic and nonanatomic sublobar resections. suggested that anatomic pulmonary segmentectomy could be effectively applied to small primary lung cancers when the surgical margins were sufficient.

The results of some subsequent nonrandomized studies showed that excellent outcomes could be achieved with segmental resection for patients with early cancers. These reports stimulated a debate about the optimal resection technique for early-stage non-small cell lung cancer (NSCLC), which the Lung Cancer Study Group addressed in a prospective, randomized trial conducted with 247 patients with stage IA NSCLC.[18] The investigators examined postoperative prognosis and pulmonary function after limited pulmonary resection, including anatomic segmentectomy and nonanatomic wide wedge resection, or lobectomy. They found a 75% increase in the recurrence rate ($p = 0.02$) and a 30% increase in the overall death rate ($p = 0.08$) for limited resection. With regard to pulmonary function, the investigators judged the follow-up and reporting to be somewhat unreliable because study funding was terminated early. The authors concluded that limited resection did not confer improved perioperative morbidity, mortality, or late postoperative pulmonary function. Because of the higher rates of

death and local–regional recurrence associated with limited resection, lobectomy still must be considered the surgical procedure of choice for patients with peripheral T1 N0 NSCLC. Because this landmark trial is the only randomized trial in which limited resection was directly compared with lobectomy, the results are still considered valid.

In 2006 and 2011, Allen et al.[19] and Darling et al.[20] published results from a prospective, randomized trial—the American College of Surgery Oncology Group Z0030 study—designed to evaluate the prognostic significance of lymph node dissection in lung cancer. In this trial, systematic sampling was compared with lymph node dissection for N0 or nonhilar N1, T1, or T2 NSCLC (stage I and II). In short, the results of this study did not support a prognostic advantage of lymph node dissection over sampling. The authors concluded that if systematic and thorough presection sampling of the mediastinal and hilar lymph nodes is negative, mediastinal lymph node dissection does not improve survival for patients with early-stage NSCLC; the authors added that these results cannot be generalized to patients who have radiographic staging or higher-stage tumors.

On the basis of the results of these two important prospective studies, it is widely accepted that the present-day standard of care should be at least lobectomy with lymph node sampling or dissection for stage I and II lung cancer.

RESULTS OF SURGICAL RESECTION FOR STAGE I AND II LUNG CANCER

The outcome of surgery for stage I and II lung cancer has been best demonstrated in publications in 2006 and 2007 by the International Association for the Study of Lung Cancer (IASLC), with results based on the largest and latest global database.[21,22] In 1998, for the preparation of the forthcoming seventh edition of the *TNM Classification of Malignant Tumours* (published in 2009),[23] the IASLC established its Lung Cancer Staging Project. Data were contributed from 46 sources in more than 19 countries. Adequate data were available for 67,725 cases of NSCLC and 8088 cases of small cell lung cancer (SCLC) treated with all modalities of care between 1990 and 2000. In these studies, the survival rates for clinical (c) and pathologic (p) stage I and II NSCLC were given according to the seventh edition of the tumor, node, and metastasis (TNM) system. The 5-year survival rates were 50% for cIA, 43% for cIB, 36% for cIIA, and 25% for cIIB lung cancer. The corresponding 5-year survival rates for
Fig. 29.3. Radical lobectomy. (A) The extents of parenchymal resection (lobe) and (B) lymph node dissection are both determined by the location of the primary tumor. A, Right upper and middle lobe. B, Right middle and lower lobe. *(Reprinted with permission from Cahan WG. Radical lobectomy.* J Thorac Cardiovasc Surg. *1960;39:555–572.)*

pathologic stage lung cancer were 73% for pIA, 58% for pIB, 48% for pIIA, and 36% for pIIB. Current consensus is that postoperative adjuvant chemotherapy improves survival for patients with lung cancer of stage II or higher, as indicated by the results of a series of large-scale clinical trials in the late 1990s and early 2000s.[24–26] Although the IASLC database contained 349 cases of resected SCLC with pathologic TNM staging available, the survival data were given only for clinical stages. With regard to c-stage I and II, the 5-year survival rates were 38% for cIA, 21% for cIB, 38% for cIIA (only 8 patients), and 18% for cIIB.[27]

Detailed survival data for patients with resected lung cancer were reported in a series of Japanese lung cancer registry studies. A retrospective registry study has been performed three times for patients who had resections in 1994, 1999, and 2004.[28–30] The latest report was based on 11,663 patients with all histologic types who had resections in 2004 and for whom survival data were provided according to tumor classification with use of the seventh edition of the TNM classification.[30] Among these 11,663 patients, 243 (2.1%) had tumors with small cell histology. The 5-year survival rates for c-stage lung cancer were 82% for cIA, 66.1% for cIB, 54.5% for cIIA, and 46.4% for cIIB. The 5-year survival rates for p-stage lung cancer were 86.8% for pIA, 73.9% for pIB, 61.6% for pIIA, and 49.8% for pIIB.

A new classification of adenocarcinoma of the lung, which included earlier forms of adenocarcinoma, was published in 2011 to provide uniform terminology and diagnostic criteria.[31] In short, new concepts were introduced, such as adenocarcinoma in situ (AIS) and minimally invasive adenocarcinoma (MIA), for small solitary adenocarcinomas with either pure lepidic growth or predominant lepidic growth smaller than 5 mm to define patients who, if they were to undergo complete resection, would be expected to have 100% or near-100% disease-specific survival, respectively. By contrast, adenocarcinomas are also classified according to their predominant pattern, with comprehensive histologic subtyping as lepidic, acinar, papillary, or solid. Earlier forms such as AIS and MIA were recognized only after the advent of high-resolution computed tomography and the dissemination of computed tomography screening programs. In the Japanese Registry Study,[30] these early-stage lung cancers had been included with stage IA cancers, and the proportion of these cancers may be associated with a difference in survival, especially for stage IA disease. The surgical significance of these classifications has also been analyzed.[32] In studies published in 2011 and 2013, the prognosis of 545 radiographically determined noninvasive adenocarcinomas of the lung that showed ground-glass opacity (GGO) was described; a consolidation-to-tumor ratio of 0.25 or less in cT1a was used as a radiographic criterion of noninvasive cancer, and the lesion was resected using lobectomy.[33,34] The 5-year survival rates for noninvasive and invasive adenocarcinomas were 96.7% and 88.9%, respectively. This surgical outcome indicates the realistic possibility of lesser resections, such as segmentectomy and wedge resection, for early lung cancers.

POSSIBILITY OF SUBLOBAR, LIMITED RESECTION FOR STAGE I AND II LUNG CANCER

Technical and Pathologic Considerations

When we think of sublobar resection, especially segmental resection, as a possible radical resection for lung cancer, in which no tumor tissue must be left behind, we must consider several factors. In sublobar resection, the lung parenchyma must be transected and divided for the procedure to be complete, whereas in lobectomy, the fissure is divided to remove the entire lobe. Sublobar resection has some technical limitations associated with tumor size, location, histologic type, and node involvement. In particular, tumor size and location are closely related to the safe surgical margin in a radical resection.

Tumor size and local recurrence after sublobar resection have been studied extensively. Bando et al.[35] studied 74 patients who had sublobar resections and found that the local–regional recurrence rate was 2% for tumors less than 2 cm and 33% for tumors larger than 2 cm. Fernando et al.[36] and Okada et al.[37] also found that tumor size less than 2 cm was an independent, favorable predictor of a smaller chance of recurrence and better survival after sublobar resection. If we consider the distance

between the tumor and the surgical margin of the lung parenchyma, it is easy to understand why larger tumors have a greater chance of local recurrence (Fig. 29.4A). Another important factor is the location of the tumor in relation to the pleural surface and the hilum. A fundamental, geometric understanding of a lung segment is that the segment is fan-shaped, with the base on the pleural surface and the apex at the pulmonary hilum. Therefore, the distance between the tumor and the resection line is inevitably smaller for a tumor that is close to the hilum, even if the tumor is small (Fig. 29.4B). In general, even for a tumor diameter of 2 cm or less, segmentectomy or wedge resection should be performed only if the tumor is located in the outer third of the lung parenchyma. Other unfavorable factors for limited resection are an aggressive histology, such as SCLC, and lymph node involvement. These conditions indicate a higher likelihood of tumor spread in the lobe that contains the segment.

Oncologic Considerations

Limited, sublobar resection should be considered for lung cancer in the following three situations:

- T1 N0 M0 lung cancer in individuals with limited cardiopulmonary reserve, regardless of the type of lesion;

- early lung cancer with a predominantly GGO appearance (pathologic AIS or MIA);
- small but invasive lung cancers located in the periphery of the lung.

As noted earlier, considerable interest in sublobar resection arose in the 1970s and 1980s when the feasibility of limited resection for patients with a compromised cardiopulmonary reserve was demonstrated. At that time, the 5-year survival and recurrence rates for sublobar resection were considered inferior to the rates for lobectomy, and sublobar resection was restricted to patients with impaired cardiac function or substantial comorbidities that precluded conventional lobectomy. In fact, in 1994, Warren and Faber[38] demonstrated decreased survival and increased recurrence among 173 patients with stage I NSCLC who had sublobar resection or lobectomy. However, the results of single-institution retrospective investigations published between 1997 and 2004, in which the equivalency of sublobar resection to lobectomy for patients with limited cardiopulmonary reserve was evaluated, contradict earlier results and demonstrate that stage I disease portends a survival advantage regardless of the extent of surgical resection or the histologic subtype. Campione et al.[39] found no significant difference in survival between lobectomy and anatomic segmentectomy in a series of 121 patients with stage IA lung cancer. Other studies demonstrated similar
Fig. 29.4. Relationship between the tumor and the surgical margin. (A) For larger tumors, the distance between the tumor and the surgical margin becomes inevitably smaller. (B) When the tumor is located close to the pulmonary hilum, the distance between the tumor and the surgical margin also becomes smaller, despite the tumor size. *A,* Pulmonary artery; *B,* bronchus; *V,* pulmonary vein. *(Courtesy Hisao Asamura, MD.)*

results for segmentectomy and lobectomy.[40–50] The surgical indication of limited resection for patients with stage IA lung cancer with limited cardiopulmonary reserve is the reasonable treatment of choice.

As discussed previously, AIS (formerly bronchioloalveolar carcinoma) and MIA are novel concepts that indicate the noninvasive or minimally invasive nature of adenocarcinoma with the unique radiographic presentation of GGO. In a variety of retrospective Japanese studies, the use of limited resection for patients with nonsolid (pure) or part-solid (mixed) GGO tumors has been assessed. In each of these studies, patients with an AIS or an MIA had prolonged survival and lower recurrence after resection compared with patients with other subtypes of NSCLC. The use of sublobar resection for these early tumors was based on a clinical–pathologic study of the correlation between the degree of invasive growth (stromal invasion) and the prognosis. Sakurai et al.[51] classified 380 resected adenocarcinomas of 2 cm or less in diameter according to the degree of invasive growth (structural deformity and its location in the adenocarcinoma) and showed that 100% survival could be achieved for patients with AIS or MIA, despite the mode of pulmonary resection. On the basis of these clinical–pathologic observations, it would be reasonable to consider sublobar resection for AIS and MIA with GGO according to the location and size of the tumor.

The indication for sublobar resection must be considered from not only an oncologic but also an anatomic perspective. In the case of a tumor that is located deep inside the lung parenchyma, sublobar resection cannot ensure a safe surgical margin because the surgical margin is close to the hilar structures. As noted previously, the shortest distance between a tumor and the resected margin falls in the area close to the hilum. The tumor diameter also affects the distance to the surgical margin. Therefore as with segmentectomy or wedge resection, sublobar resection should be used only when the tumor is located in the outer third of the lung parenchyma and, preferably, is 2 cm or less in diameter. For tumors that are located in the inner two-thirds of the lung parenchyma or that are larger than 2 cm in diameter, lobectomy should still be selected, regardless of the tumor pathology.

However, for a histologically invasive lung cancer that is a small (≤2 cm, T1a), solitary nodule located in the periphery of the lung, the feasibility of limited, sublobar resection must be assessed from the perspective of the present day. Such an assessment would entail revision of the Lung Cancer Study Group study performed in the late 1980s.[18] Indeed, the present-day routine workup for patients with resectable lung cancer is different from the workup done in the 1980s. To investigate sublobar resection for early lung cancer, a few prospective studies are ongoing. As summarized by Iwata,[52] the role of sublobar resection has been explored in large databases such as Surveillance, Epidemiology, and End Results Program and the National Cancer Database (NCDB). Veluswamy et al.'s[53] analysis of 2008 adenocarcinomas and 1139 squamous cell carcinomas all less than 2 cm in patients older than 65 revealed that wedge was always inferior to other resections independent of histology; however, for adenocarcinoma, overall survival and lung cancer–specific survival of segmentectomy were equivalent to lobectomy, but not for squamous cell carcinoma. By contrast, Khullar et al.'s[54] and Speicher's et al.'s[55] analyses of clinical stage I patients in the NCDB revealed that overall survival was inferior for sublobar resections compared with lobectomy. These analyses, however, were limited in that only 290 of 987 propensity-matched patients in the NCDB could be analyzed for survival because survival was not available past 2006. Meta-analyses investigating the role of sublobar resections also failed to have consensus. In Cao et al.'s analysis of 54 studies,[56] intentional use of sublobar resections resulted in similar overall survival to lobes while this was not seen in cases where a sublobar resection was performed for compromised patients. The disease-free survival

always favored lobectomies. Bao et al.'s[57] survival analysis of 22 studies found equivalent overall survival between segmentectomy and lobectomy only for tumors smaller than 2 cm. Finally, in an analysis of 4564 lobectomies and 2287 sublobar resections, Taioli et al.[58] concluded that the high degree of heterogeneity of study design for these analyses might preclude useful conclusions using conventional meta-analyses to study these resections. Five propensity-matched studies with 69 to 312 matched sublobar and lobectomy patients with 3-year to 10-year overall survival data have been published.[59–63] Common matching parameters have included age, sex, and tumor size, and all studies found no differences in disease-free survival or overall survival comparing segmentectomy with lobectomy. Kodama et al.'s[63] study is notable in that it summarized 10-year intermediate end points from surgery revealing that freedom from local–regional recurrence for segmentectomy and lobectomy was 95.3% and 97%, respectively, and no differences in overall survival were recorded for 10-year survival (segmentectomy, 83.2%; lobectomy, 88%). With regard to the use of video-assisted thoracoscopic surgery (VATS) segmentectomy, two studies have revealed equal overall survival and disease-free survival for VATS segmentectomy compared with VATS lobectomy,[62,64] whereas Ghaly et al.[65] have reported no difference in disease-free survival or overall survival for 91 VATS segmentectomies compared with 102 open chest segmentectomies.

Randomized clinical trials with peripheral lung cancers no more than 2 cm in diameter as the target lesions are being conducted in the United States by the Cancer and Leukemia Group B (CALGB 140503; ClinicalTrials.gov identifier: NCT00499330)[38] and in Japan by the Japan Clinical Oncology Group and the West Japan Oncology Group (JCOG0802/WJOG4607L).[66] For the CALGB trial, the primary end point is disease-free survival and the secondary end points are overall survival, rate of local–regional and systemic recurrence, and pulmonary function; the estimated enrollment is 1258. For the Japanese trial, the end points are overall survival (primary) and postoperative pulmonary function (secondary), and the targeted accrual is 1100 patients (Fig. 29.5). If the prognosis for patients who have segmentectomy is not significantly inferior to that for patients who have lobectomy and if the postoperative pulmonary function is significantly better for patients who have segmentectomy, we can definitively conclude that the standard surgical modality for these early tumors should be segmentectomy.

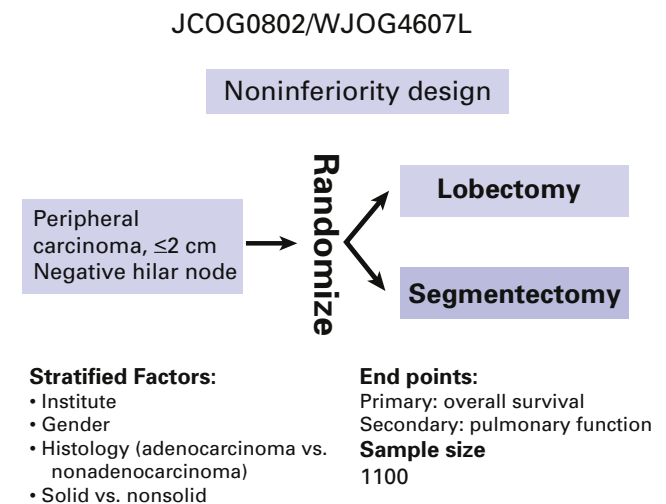
JCOG0802/WJOG4607L


Fig. 29.5. The design of JCOG0802/WJOG4607L, an ongoing phase III randomized trial comparing segmentectomy and lobectomy for small lung cancers (part-solid ground-glass opacities or solid tumors) that are 2 cm or less in diameter.

CONCLUSION

The present-day standard of care for lung cancer resection is still at least lobectomy with hilar and mediastinal lymph node sampling or dissection. It is reasonable to perform sublobar resection, such as segmentectomy and wedge resection, for patients with limited cardiopulmonary reserve. The use of sublobar resection may be justified for most early lung cancers with minimal or no invasive features located in the outer region of the lung parenchyma. The feasibility of sublobar resection for lung cancer with overt invasive features is under investigation, with particular focus on tumors 2 cm or less in diameter. The results of several ongoing trials are awaited. Lobectomy should be recognized as the standard mode of resection for appropriate patients.

30 Extended Resections for Lung Cancer: Chest Wall and Pancoast Tumors

Valerie W. Rusch and Paul E. Van Schil

SUMMARY OF KEY POINTS

Chest Wall:
- Invasion of parietal pleura and chest wall indicates T3; involvement of vertebral body indicates T4 chest wall tumor.
- Extensive resection required.
- Long-term survival possible postresection if:
  - No distant metastases
  - No mediastinal lymph node involvement
  - Complete (R0) resection.
- Systematic lymph node dissection should be performed as part of resection.
- Choice of prosthesis for chest wall reconstruction determined by size and location of chest wall defect.

Pancoast:
- Superior pulmonary sulcus: uppermost extent of costovertebral gutter.
- Challenging to treat due to involvement of adjacent vital structures, including brachial plexus, subclavian vessels, and spine.
- By definition, stage IIB or higher; mediastinal staging via endobronchial ultrasound or mediastinoscopy recommended.
- Induction chemoradiotherapy followed by surgical resection is the standard of care.
- Operative approaches:
  - Posterior (Paulson) approach
  - Modified posterolateral periscapular (Masaoka) approach
  - Anterior (Dartevelle/Spaggiari) transmanubrial approach.

CHEST WALL TUMORS

General Principles

Invasion of the parietal pleura or chest wall by a primary lung cancer is a relatively rare occurrence, reported in 5% to 8% of all cases of lung cancer.[1] Invasion of the parietal pleura and the chest wall suggests a T3 tumor, and involvement of the vertebral bodies suggests a T4 tumor. Tumors infiltrating the second or first rib and surrounding structures usually are considered to be superior sulcus or Pancoast tumors when neurologic symptoms are present.[1] Pancoast tumors are described in detail in the latter part of this chapter.

Extensive resection is required to remove tumors invading the chest wall. Although such tumors once were considered to have a dismal prognosis, many series have shown that long-term survival

may be possible when the patient has no distant metastases, no involvement of mediastinal nodes, and evidence of complete (R0) resection as demonstrated by histologically negative margins in the ribs as well as in the muscles and soft tissues of the chest wall. In addition, a thorough lymph node evaluation by means of either systematic node dissection or at least a lobe-specific node dissection related to the location of the primary tumor is required. A minimum of six lymph node stations must be removed, of which three must be located in the mediastinum and must include the subcarinal station.[7] According to the definition of complete resection as proposed by Rami-Porta et al.[2] there must be no extracapsular extension and the highest mediastinal lymph node must be negative. Complete (R0) resection can be challenging in cases of posterior tumors located near the costovertebral angle or involving vertebral bodies, and analysis of frozen sections is not feasible for tumors with osseous margins.

Staging

The goal of surgical treatment in cases of T3 and T4 lung cancers is to obtain an R0 resection. Surgical treatment may be part of a multimodality approach that includes induction chemotherapy or chemoradiation therapy to reduce the tumor volume and to optimize resection margins. A thorough preoperative evaluation is necessary. Functional operability depends on a detailed cardiopulmonary assessment as outlined by a working group of the ERS together with the ESTS.[3] T3 and T4 tumors require at least a lobectomy, but no specific criteria have been developed to determine whether a patient will tolerate a planned chest wall resection. Nevertheless, as it is clear that a chest wall resection may induce additional respiratory compromise, clinical judgment by an experienced thoracic surgeon and discussion of each individual case by a multidisciplinary tumor board are necessary when this procedure is anticipated. Published series report that mediastinal nodal involvement is a poor prognostic factor and that extensive surgery is not warranted when mediastinal lymph node metastases are present.[4,5]

Computed tomography (CT) of the chest with use of intravenous contrast medium is the preferred method for defining the extent of the primary tumor and evaluating the involvement of hilar and mediastinal lymph nodes (Fig. 30.1). Findings on CT images that are used to identify osseous or soft-tissue chest wall invasion include obliteration of the extrapleural fat plane, the length of tumor contact with the pleural surface, the angle of the tumor with the pleura, and clear evidence of chest wall invasion.[6] A combination of several criteria increases sensitivity.[4] For paravertebral and superior sulcus tumors, magnetic resonance imaging (MRI) of the chest is required to determine neural or vertebral involvement. Respiratory dynamic MRI has been shown to have a sensitivity of 100% and a specificity of 83% for determining chest wall invasion but has not been widely adopted.[7] Ultrasonography of the chest wall also may be helpful but does not show superior sulcus tumors.[8] Positron emission tomography (PET), preferably, integrated PET–CT, should be performed for every patient to evaluate local–regional extension and possible distant spread precluding surgical intervention.

The pathologic status of the mediastinal nodes should be confirmed before a large chest wall resection is planned.[9] Endobronchial ultrasound and endoscopic ultrasound with transbronchial or transesophageal biopsy are currently the procedures of choice. In selected cases, these procedures are supplemented with mediastinoscopy to reduce the false-negative rate as much as possible.

Surgical Resection

Depending on the location of the primary tumor and its extension into the chest wall, the incision is carefully chosen and may be centered on the anterior, lateral, or posterior chest wall. The thoracic cavity is entered away from the primary tumor, as every attempt should be made to obtain an en bloc resection with complete removal of the primary tumor together with the invaded chest wall to avoid any spillage of tumor cells in the pleural cavity.[10] Video-assisted thoracoscopic surgery may be helpful for initial evaluation.[11]

The precise margins to be obtained around the primary tumor have not been exactly determined, but most authors have agreed that at least 1 cm is required.[4] Once the pleural space has been entered, chest wall involvement is evaluated and a determination is made as to whether an extrapleural resection or a full-thickness chest wall resection is required. Stoelben and Ludwig[1] described four categories of chest wall involvement for determining the subsequent resection (Table 30.1). When the tumor easily detaches from the chest wall in the extrapleural plane by finger dissection, this usually indicates only inflammatory adhesions that do not require chest wall resection. Frozen section analysis of

Fig. 30.1. Coronal computed tomography image demonstrating large tumor invading the chest wall in a 58-year-old patient.

suspicious areas of the parietal pleura may clarify this. When the tumor is densely adherent or frankly invades the chest wall, rib resection is indicated. For anterior tumors, resection of part or all of the sternum may be needed. For posterior tumors, resection of transverse processes or vertebral bodies may be needed, and a spine surgeon (either an orthopedic surgeon or a neurosurgeon) should work collaboratively with the thoracic surgeon.[12] However, resection of these vertebral structures is infrequently seen outside the classic Pancoast (superior sulcus) position. To reduce trauma to the uninvolved extrathoracic muscles, rib resection can be performed from inside the chest with use of the technique described by Cerfolio et al.[13]

Lobectomy or bilobectomy is the procedure of choice for pulmonary resection. A pneumonectomy is necessary in some cases, but it is a high-risk procedure when combined with extensive chest wall resection and should be performed only in centers with extensive experience.[14]

Multiple techniques are available for reconstruction of the chest wall. No reconstruction is required for defects of 3 cm or less that are covered by the scapula. However, when the defect is located at the tip of the scapula, chest wall reconstruction is required to prevent entrapment of the scapula, which is a highly symptomatic complication that is associated with poor cosmetic results.[4] Polypropylene and polyglactin meshes, polytetrafluoroethylene patches, and the so-called Marlex mesh with methylmethacrylate (MMM) sandwich technique are options for the reconstruction of large defects.[15] Close cooperation with a plastic surgeon is required in situations in which soft-tissue reconstruction is needed to cover a chest wall prosthesis. Polytetrafluoroethylene is frequently used as the standard material. However, for large anterior or anterolateral defects, the MMM sandwich technique provides greater immediate chest wall stability (Figs. 30.2A and 30.2B) with the lowest risk of postoperative respiratory insufficiency.[16] A new moldable system composed of titanium with connecting bars and rib clips is useful for obtaining a rigid basis when reconstructing the chest wall.[17,18] This system is particularly useful for large defects associated with skin ulceration and infection, for which the MMM sandwich technique is contraindicated (Fig. 30.3A–B). Synthetic material should be covered by viable muscle or musculocutaneous flaps to reduce the risk of infection.

Results and Long-Term Survival

At experienced centers, the mortality and morbidity rates associated with these procedures have decreased. The mean postoperative mortality rate is about 6%, with the majority of deaths being caused by pulmonary complications and respiratory failure.[4] This finding underlines the importance of careful preoperative cardiorespiratory evaluation and discussion within a multidisciplinary team before the decision is made to proceed with an extensive resection. In addition to standard complications after thoracotomy, specific complications related to the chest wall resection include infection necessitating removal of the prosthetic material, herniation of the scapula, paradoxical respiration (flail chest), and, in cases involving dissection close to the spinal cord, paraplegia and leakage of cerebrospinal fluid.
TABLE 30.1 Intraoperative Categories of Chest Wall Involvement and Subsequent Resection[a]

Intraoperative Findings	T Status[b]	Procedure
Lung and tumor not fixed to chest wall	Not T3	Standard resection
Inflammatory adhesions between tumor and parietal pleura or previous inflammatory pleuritic	Not T3	Extrapleural resection
Tumor has penetrated visceral pleura to the parietal pleura	T3	Extrapleural lobectomy probably possible
Tumor has infiltrated soft-tissue or osseous chest wall	T3 or T4	Lung and chest wall resection

[b]Related to chest wall.

In selected cases, induction chemotherapy or chemoradiation therapy may be helpful for decreasing the tumor volume and limiting the subsequent chest wall resection, but such therapy has not been standard treatment except for Pancoast tumors. Adjuvant chemotherapy or radiotherapy also remains controversial, and no specific guidelines exist for patients who have chest wall resection. Radiotherapy may be indicated for patients with close or positive surgical margins, but no randomized evidence is available to support its routine use.

In most large series, the 5-year overall survival rate has been approximately 30% to 40%. Long-term survival depends on lymph node involvement and the completeness of resection. In 1999, in a large series of 334 chest wall resections, Downey et al.[19] showed that the 5-year survival rate was 32% for patients with apparently complete (R0) resections but only 4% for those with incomplete (R1 and R2) resections. These findings were confirmed in later studies.[4] In a large series of 531 patients with pT3 lung cancer, a relatively uniform prognosis was found for the different subgroups of T3 involvement.[20] For the 407 patients with chest wall involvement, the 5-year survival rate was 43%. In a comparative study involving the seventh edition of the tumor, node, metastasis classification system, the prognosis for 140 patients with T3 chest wall invasion was not significantly different from that for 28 patients with tumors measuring more than 7 cm in size without chest wall invasion.[21] In a multivariate analysis of 107 patients who had chest wall resection for the management of lung cancer invading the chest wall, the completeness of resection, tumor size, node status, depth of invasion, and completeness of adjuvant chemotherapy were independent prognostic factors.[22] In that series, the overall 5-year survival rate was 26%.

With regard to the extent of pulmonary resection, a recent series showed that pneumonectomy combined with chest wall resection is feasible for highly selected patients.[14] In that series of 34 patients, the mortality rate was 2.9%, the morbidity rate was 38%, and the overall 5-year survival rate was 47%. For patients with N0, N1, and N2 disease, the 5-year survival rates were 60%, 56%, and 17%, respectively. After complete (R0) resection, the rate of local recurrence is very low.[10] N2 involvement can be considered to be a marker for systemic disease, and most patients with N2 involvement will die of distant metastases.[1]

Quality of life after chest wall resection is important to consider, but published data are sparse. In a retrospective series of 51 patients who were treated with chest wall resection, quality of life was only moderately impaired.[23] Subjective parameters, including dyspnea, correlated well with quality of life, whereas objective measurements of pulmonary function did not.
Fig. 30.2. Intraoperative photographs made during reconstruction of a large anterior chest wall and sternal defect with use of a so-called MMM sandwich (Marlex mesh with methylmethacrylate) prosthesis (viewed from the foot of the operating room table). The prosthesis is secured to the remaining half of the sternum medially and to the ribs inferiorly and laterally. (A) The polypropylene mesh has been infiltrated with methylmethacrylate, with an area left open for tissue ingrowth, and (B) prior to closure of the incision, absorbable sutures are used to tack the overlying muscle flaps to the prosthesis to prevent the formation of a seroma.

PANCOAST TUMORS

Historical Background

Nonsmall cell lung cancer (NSCLC) of the superior sulcus, commonly termed Pancoast tumors, is challenging to treat because of its involvement of adjacent vital structures, including the brachial plexus, subclavian vessels, and spine. Originally described by a radiologist, Henry Pancoast, in 1932,[24] Pancoast tumors were thought to be uniformly fatal until the 1950s, when, on the basis of anecdotal experience, induction radiotherapy and resection were found to be curative.[25,26] During the next 40 years, this approach remained the standard of care, with advances limited to the development of novel surgical techniques for T4 tumors involving the subclavian vessels and spine.[27–29] However, complete resection was usually achieved in only 60% of patients, and the overall 5-year survival rate remained at about 30%, indicating a need for novel therapy.[30] During the 1990s, concurrent cisplatin-based chemotherapy and radiotherapy followed by resection was shown to be safe and effective for the management of some stage III NSCLC.[31] The findings of small studies suggested that this treatment might be appropriate for Pancoast tumors,[32] which led to a large North American trial, the results of which established the use of induction chemoradiation therapy followed by resection as the standard of care. Other studies subsequently corroborated the results of the North American trial (see Table 30.2).

Anatomic Definition

The original definition of a Pancoast tumor was a carcinoma of uncertain origin, arising in the extreme apex of the chest, that was associated with shoulder and arm pain, atrophy of the hand muscles, and Horner syndrome. Anatomically, the pulmonary sulcus is synonymous with the costovertebral gutter, which extends from the first rib to the diaphragm. The term superior pulmonary sulcus is used to describe the uppermost extent of this recess.[33,34] Unbeknown to Pancoast, the most accurate description of this type of tumor was reported in 1932 by Tobias, who recognized it as a peripheral lung cancer.[35]

This original definition has been expanded to include tumors that do not involve the brachial plexus or stellate ganglion. Tumors involving the chest wall at the level of the second rib or below do not meet the criteria for classification as Pancoast tumors. Chest wall involvement may be limited to invasion of the parietal pleura in the superior sulcus but typically extends to involve the upper ribs, vertebral bodies, subclavian vessels, nerve roots of the brachial plexus, or stellate ganglion.

The thoracic inlet can be divided into three compartments on the basis of the insertions of the anterior and middle scalene muscles on the first rib and the posterior scalene muscle on the second rib. The anterior compartment, located anterior to the anterior scalene muscle, contains the subclavian and internal jugular veins and the sternocleidomastoid and omohyoid muscles. The middle compartment, located between the anterior and middle scalene muscles, includes the subclavian artery, the trunks of the brachial plexus, and the phrenic nerve. The posterior compartment contains the nerve roots of the brachial plexus, the stellate ganglion, and the vertebral column.

Originally, Pancoast tumors were considered to be located only posteriorly. However, they also may be located anteriorly, with predominantly vascular involvement rather than neurologic or vertebral involvement. Surgeons should be adept at both anterior and posterior approaches, as a combined procedure may be necessary to obtain a complete resection.

Pretreatment Evaluation

The presence of a Pancoast syndrome is not always associated with NSCLC. Other diseases, including lymphoma, tuberculosis, and primary chest wall tumors, may be associated with an apical mass and chest wall involvement. Transthoracic needle biopsy should be performed to establish a diagnosis before treatment.

Pancoast tumors are, by definition, classified as stage IIB or higher and require an extent-of-disease evaluation before treatment is initiated, including contrast-enhanced CT of the chest and upper abdomen, whole-body PET, and MRI of the brain (Fig. 30.4A–B). Because Pancoast tumors with mediastinal node metastases (N2 or N3 disease) have a poor prognosis, mediastinal staging via either endobronchial ultrasound or mediastinoscopy should be considered.

MRI with use of intravenous contrast medium is the modality of choice for evaluating structures of the thoracic inlet, including the brachial plexus, subclavian vessels, spine, and neural foramina and is crucial for preoperative planning.[36] The extent of nerve root involvement must be assessed. Resection of the T1 nerve root usually does not cause motor function deficit, but resection of the C8 nerve root or lower trunk of the brachial plexus leads to loss of hand and arm function. A careful neurologic examination is informative and supplements MRI findings.[37] Pain extending along the ulnar aspect of the forearm and hand is consistent with T1 involvement. Weakness of the intrinsic muscles of the hand indicates involvement of the C8 nerve root or lower trunk of the brachial plexus. Resection of a Pancoast tumor should be planned jointly with a spine neurosurgeon to allow optimal patient selection and the best chance of complete resection.

Patients must be evaluated to determine whether they can tolerate combined-modality therapy. Performance status, renal function, and neurologic function must be adequate in order for the patient to receive platinum-based chemotherapy. Pulmonary function tests and, when necessary, cardiac stress tests are done to evaluate the ability of the patient to tolerate pulmonary resection.

Multimodality Treatment

The management of NSCLC of the superior sulcus during the past 70 years can be classified into four eras. Pancoast first described these tumors as "a peculiar neoplastic entity found in the upper portion of the pulmonary sulcus of the thorax . . . evidently epithelial in its histopathology, but its exact origin is uncertain."[24] During the ensuing 20 years, these tumors became
Fig. 30.4. Preoperative magnetic resonance imaging showing a T4 Pancoast tumor that has invaded the thoracic spine. After induction chemoradiation therapy, complete (R0) resection was achieved by means of combined posterior resection of the involved area of the spine and posterolateral thoracotomy to complete the lobectomy and chest wall resection. (A) The tumor has filled the superior sulcus but has not invaded the brachial plexus or subclavian vessels, and (B) the tumor has invaded and destroyed part of the vertebral body.

NS, not stated.

recognized as NSCLC but were considered inoperable and incurable. In 1956, Chardack and MacCallum[25] reported the case of a patient in whom a poorly differentiated squamous cell carcinoma was managed with en bloc resection of the right upper lobe, involved chest wall, and nerve roots, followed by adjuvant radiotherapy (65.28 Gy over 54 days). The patient was alive and disease-free 5 years later. In 1956, Shaw[38] reported on a patient with the typical Pancoast syndrome who was referred for palliative radiotherapy. After treatment with 3000 cGy of radiation, the pain resolved and the tumor decreased in size, so Shaw performed a radical resection similar to that described by Chardack and MacCallum. The complete resection and long-term survival that were achieved in that case prompted Shaw et al.[26] to test this treatment strategy in additional patients. In 1961, they reported excellent local control and longer-than-anticipated survival in a study of 18 patients who were treated with 3000 to 3500 cGy of radiation over 2 weeks, followed by complete en bloc resection of the involved lobe, chest wall, and nerve roots 1 month later.

After that report, induction radiation (3000 cGy in 10 fractions over 2 weeks) and en bloc resection via an extended posterolateral thoracotomy became the standard of care for superior sulcus NSCLC. For 30 years (the second era in the management of Pancoast tumors), the basic therapeutic strategy for these tumors remained unchanged. The findings of multiple series (Table 30.3) confirmed the original results reported by Shaw and Paulson but also identified adverse prognostic factors, including the presence of mediastinal node metastases (N2 disease), involvement of the spine or subclavian vessels (T4 disease), and incomplete (R1 or R2) surgical resection.[33,37,39–47] The largest published series, which included 225 patients who were treated at Memorial Sloan-Kettering Cancer Center between 1974 and 1988, confirmed the importance of these prognostic factors.[30,48] Although the operative mortality rate was low (4%), R0 resection was achieved for only 64% of T3 N0 tumors and 39% of T4 N0 tumors and local–regional recurrence was common.[30] The survival rate after lobectomy was better than that after limited pulmonary resection, and the addition of intraoperative brachytherapy to resection did not appear to improve the survival rate.[48] The overall 5-year survival rate was 46% for T3 N0 tumors, 13% for T4 N0 tumors, and 0% for N2 disease.[30] These results emphasized the need for new treatment strategies to improve both local control and overall survival.

During the late 1980s and the 1990s (the third era in the management of Pancoast tumors), several thoracic surgery groups developed novel approaches for the resection of tumors involving the spine and subclavian vessels. Dartevelle et al.[27] developed an

anterior transcervical approach for the management of tumors involving the subclavian vessels and reported a 5-year survival rate of 31%. This experience led to widespread acceptance of the anterior approach involving resection of the subclavian artery and graft reconstruction for the management of T4 tumors. Modifications of this approach included the development of a transmanubrial osteomuscular sparing approach that avoids clavicular resection or disarticulation, the addition of a posterior or anterolateral thoracotomy to facilitate exposure of the lung and spine, and the use of a hemiclamshell thoracotomy (anterior thoracotomy and partial median sternotomy).[49–52] For superior sulcus carcinomas involving the spine, groups from Memorial Sloan-Kettering Cancer Center, from MD Anderson Cancer Center, and from institutions in France developed techniques for multilevel vertebrectomy and spine reconstruction that were designed to be performed in conjunction with pulmonary resection. Such techniques were facilitated by improvements in the materials available for spine stabilization.[28,29,53–55] The development of techniques allowing for complete resection of these technically challenging groups of T4 tumors was an important advance in the surgical management of Pancoast tumors. However, the overall 5-year survival rate remained approximately 30%.

During this same time period, several studies were performed to evaluate the results of treatment with radiation only. The results of these studies are difficult to interpret because they were retrospective, they included small numbers of patients, the tumors were only clinically staged, and the treatment techniques were highly variable.[56–58] The 5-year survival rate ranged from 0% to 40%, depending on tumor stage, total radiation dose, and other prognostic factors such as weight loss. The results in terms of local control and survival appeared to be inferior to those reported after surgical treatment, but this difference reflects in part the patient population and the variable treatment techniques. The brain was a common site of disease progression.[58]

The success of combined-modality therapy for stage IIIa (N2) NSCLC during the 1980s and 1990s led directly to the development of a large multicenter North American phase II trial (SWOG 9416, INT 0160),[59] representing the fourth era in the management of Pancoast tumors. Induction chemoradiation therapy followed by resection is a logical treatment strategy for a group of tumors that present a formidable challenge in terms of local control. The induction regimen used in this trial had been tested in previous trials and was known to be feasible and effective in the multi-institutional setting.

This phase II study enrolled 111 eligible patients with mediastinoscopy-negative, clinical T3–4 N0–1 tumors of the superior sulcus.[59] Induction therapy consisted of two cycles of etoposide and cisplatin with 45 Gy of concurrent radiation. Patients with stable disease or tumor regression had thoracotomy and anatomic pulmonary resection followed by two additional cycles of postoperative chemotherapy. Of the 111 patients who were enrolled, 83 (75%) ultimately had thoracotomy. Induction therapy was well tolerated and had a significant ability to sterilize the primary tumor. One-third of the patients had a complete pathologic response and another one-third had minimal residual microscopic disease in the resected specimen. R0 resection was obtained for 91% of T3 tumors and 87% of T4 tumors.

Three additional observations from this study are important. First, the rate of postoperative complications was not significantly greater after induction chemoradiation therapy than with historical experience with radiation therapy. Second, CT imaging after induction therapy overstaged the disease in a significant proportion of patients; specifically, 55% of patients who had stable disease on CT had either a complete pathologic response or only residual microscopic disease. Lastly, as has been the experience with NSCLC in general, only a small proportion of patients (42%) were able to successfully complete the course of postoperative chemotherapy.

The final results of this trial were reported in 2007.[60] The 5-year survival rate was 44% for all patients and 54% for those who had a complete resection. The pathologic response, but not the tumor stage, predicted the overall survival rate. Relative to previous experience with induction radiotherapy, the pattern of relapse changed predominantly to one of distant failure rather than local recurrence.[44] The excellent results in this trial with respect to the response to induction treatment, the rate of operative mortality, the rates of R0 resection and local control, and the overall rate of long-term survival effectively established the treatment regimen as a new standard of care for both T3 and T4 tumors. Additional single-institution studies and a multicenter phase II trial from Japan demonstrated similar results.[32,61–67]

Accrual to the North American Pancoast tumor trial was completed within the planned time frame but required the efforts of 76 surgeons from all North American cooperative groups to enroll 111 eligible patients. This difficulty in accrual indicates that it may not be possible to complete future randomized phase III trials that include resection within an acceptable length of time for this uncommon NSCLC subset. This trial highlights several issues that could be studied in future trials. First, induction therapy regimens involving the use of more contemporary chemotherapy drug combinations may lead to even better outcomes, but these regimens would need to be no more toxic when combined with radiotherapy and surgery. The induction regimen theoretically also could be intensified by increasing the dose of radiation. Krasna et al.[68,69] reported on 23 patients who were treated with a median radiation dose of 59.4 Gy in combination with platinum-based chemotherapy before surgical resection. The pathologic complete response rate to induction therapy was 46%, and the overall 5-year survival rate was 49%, results that were not clearly superior to those of the INT 0160 trial. Second, this trial emphasized the difficulty of delivering cisplatin-based therapy postoperatively to this group of patients. Lastly, the high risk of brain metastases in this trial was similar to that reported in other combined-modality trials for patients with locally advanced NSCLC.

Technical Approaches to Resection

Posterior (Paulson) Approach

The patient is placed in the lateral decubitus position and rotated slightly anteriorly, and the chest is entered via a posterolateral thoracotomy. The pleural cavity is examined to determine resectability, and then the incision is carried superiorly, midway between the scapula and the spinous processes, to the seventh cervical vertebra, dividing the trapezius and rhomboid muscles. Exposure is obtained by placing the upper blade of the rib-spreading retractor under the scapula and the lower blade on the chest wall or by elevating the scapula with an internal mammary retractor (Fig. 30.5). The scalene muscles are detached from the first and second ribs.

The chest wall resection is then performed. The anterior border of the resection specimen is divided, allowing for a 4-cm margin from the tumor. After anterior division of the first rib, dissection is carried posteriorly in the subperiosteal plane to the T1 transverse process. The erector spinae muscle is retracted away from the thoracic spine, exposing the costovertebral angle. Although the ribs can be disarticulated from the transverse processes of the vertebral bodies, resection of the transverse processes along with the heads of the involved ribs is the best way to achieve a complete (R0) resection. This part of the operation is best performed by a spine surgeon or neurosurgeon. To prevent leakage of cerebrospinal fluid, the intercostal nerves are ligated with vascular clips. The posterior resection is carried to the first rib, and the T1 nerve root is ligated and divided if it is encased in tumor. Resection of the T1 nerve root can result in some weakness of the intrinsic muscles of the hand, although the hand
Fig. 30.5. Intraoperative photograph made during exposure for the resection of a Pancoast tumor. The incision (performed with use of the hook approach as described by Masaoka et al.)[79] follows the contours of the scapula, which is then elevated away from the chest wall with an internal artery retractor. The entire chest wall, including the first and second ribs, is well exposed. The erector spinae muscle has been mobilized and retracted posteriorly with use of so-called fish hooks, exposing the costovertebral junction in preparation for en bloc resection of the involved rib heads and transverse processes.

Fig. 30.6. Intraoperative photograph showing a rod-and-screw system, similar to the type used for the correction of scoliosis, that was inserted for spine stabilization after the resection of a T4 Pancoast tumor involving several vertebral bodies.

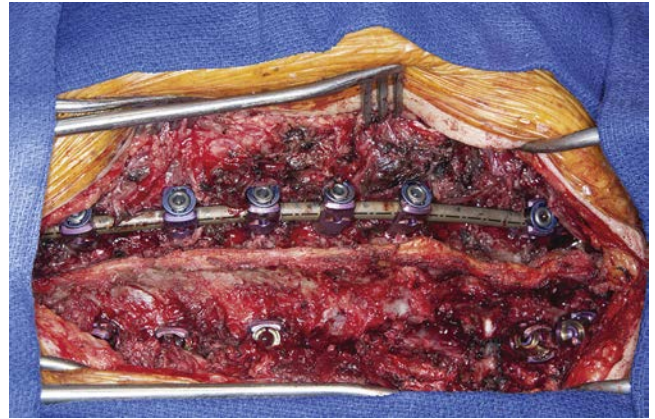
usually remains functional. Resection of the C8 nerve root and/ or lower trunk of the brachial plexus results in permanent paralysis of the intrinsic muscles of the hand. If frozen-section analysis demonstrates no residual viable tumor involving the nerve roots, the nerve roots can be spared.

After the chest wall resection, the specimen is allowed to drop into the chest cavity and the lobectomy and mediastinal lymph node dissection are performed. Chest wall reconstruction is unnecessary if the chest wall defect is small and is limited to the upper three ribs. If a defect is present at the scapular tip, chest wall reconstruction is performed with use of a 2-mm-thick Gore-Tex patch (W.L. Gore and Associates, Flagstaff, AZ, USA). The thoracotomy incision is then closed.

Resection of Vertebral Body and Epidural Tumors

Tumors involving the vertebral body and posterior elements of the spine and extensive epidural tumors are resected via a posterior approach with use of posterior cervicothoracic spinal fixation (performed by a spine neurosurgeon) followed by anterior resection and reconstruction. The patient is placed in the prone position, and a midline incision is performed. Resection of the involved area of the spine is accomplished with a high-speed drill. A multilevel rhizotomy of the involved nerve roots is performed, and the chest wall is disarticulated from the vertebral bodies. Posterior segmental fixation is performed with a single screw-and-rod system similar to the type used for the correction of pediatric scoliosis (Fig. 30.6). Through a posterolateral thoracotomy, the chest wall resection and reconstruction and the lobectomy are then completed.

Anterior Approaches

Masaoka et al.[70] were the first to describe the use of an anterior approach for the resection of tumors involving the structures of


the thoracic inlet. With this technique, the patient is placed in the supine position and a partial median sternotomy is extended into the anterior fourth intercostal space as well as to a transverse incision at the base of the neck (a so-called trap door incision). The neck strap muscles are divided, the anterior chest wall is retracted, and the pleural cavity is opened to expose the vascular and nerve structures of the thoracic inlet. The scalene muscles are divided, and the lung and chest wall resections are performed.

Subsequently, Masaoka et al.[71] described a modification of the posterior approach for Pancoast tumors (the so-called hook approach) because resection of the transverse processes and the heads of the ribs was difficult through the anterior approach. A long curved periscapular skin incision, extending from the level of the seventh cervical vertebra around to the midclavicular line and ending anteriorly above the nipple, is performed. Tilting the operating table and moving the arm affords complete exposure of the entire thoracic inlet and allows resection and reconstruction of the subclavian vessels (Fig. 30.7A).

Dartevelle et al.[27] was the first to describe a transclavicular approach to the thoracic inlet. The patient is placed in the supine position with the neck hyperextended and the head turned away from the involved side. An incision is made along the anterior border of the sternocleidomastoid muscle and is extended horizontally, below and parallel to the clavicle at the level of the second intercostal space, to the deltopectoral groove (Fig. 30.7B).[27,72] Next, the pectoralis major muscle is dissected away from the clavicle, and a myocutaneous flap is folded back, exposing the thoracic inlet. The scalene fat pad and the medial half of the clavicle are excised. The distal parts of the internal, external, and anterior jugular veins are divided to expose the subclavian and innominate veins. If the subclavian vein is involved, it is resected.

The anterior scalene muscle is divided, the phrenic nerve is preserved, and the subclavian artery is mobilized. If the subclavian artery is involved, it is resected and reconstructed, usually with a polytetrafluoroethylene vascular graft.

The middle scalene muscle is divided above its insertion on the first rib. The C8 and T1 nerve roots are identified and are dissected up to the confluence of the lower trunk of the brachial plexus. The ipsilateral prevertebral muscles are resected along with the paravertebral sympathetic chain and stellate ganglion and the T1 nerve root.

The chest wall resection is then performed. The first rib is divided at the costochondral junction anteriorly. The second rib is divided at its midpoint, the dissection is carried along the superior border of the third rib to the costovertebral angle, and the ribs are disarticulated from the transverse processes.
Fig. 30.7. (A) Illustration depicting the trans-scapular (hook) approach for the resection of a Pancoast tumor. The anterior part of the incision can be brought into the midaxillary line rather than the midclavicular line. This incision provides the exposure shown in Fig. 30.5. (B) Illustration depicting the transclavicular approach as described by Dartevelle et al.[26] for the resection of a Pancoast tumor involving the subclavian vessels.

Through this cavity, an upper lobectomy is performed and the cervical incision is closed. If exposure is inadequate, the anterior incision is closed and the resection is completed via a posterolateral thoracotomy.

The transclavicular approach, which includes resection of the medial half of the clavicle, has been the subject of concern because of its functional and aesthetic consequences. Grunenwald and Spaggiari[49] described a transmanubrial osteomuscular sparing approach that avoids division or disarticulation of the clavicle. An L-shaped cervicotomy is performed as described by Dartevelle et al.[27] The manubrium is exposed and divided via an L-shaped incision, with the sternoclavicular articulation being left intact. The first costal cartilage is resected, permitting mobilization of an osteomuscular flap that is progressively elevated.[73] Additional refinements of this approach were reported by Spaggiari and Pastorino[50] and Klima et al.[74] Pancoast tumors invading the anterior structures of the thoracic inlet can now be completely resected because of the development of approaches that allow exposure to critical neurovascular structures. These approaches have been summarized by Macchiarini.[75]

CONCLUSION

Resection of a lung cancer tumor invading the chest wall is a major procedure that should be performed by experienced surgeons, preferably at high-volume centers. Multidisciplinary care is necessary to determine the optimal diagnostic and therapeutic strategy for each individual patient. Good long-term results can be achieved after R0 resection in the absence of mediastinal lymph node involvement. Prospective studies are required to determine the precise role of induction and adjuvant therapy, especially for larger tumors and in cases of R1 resection.

Superior sulcus NSCLCs pose a therapeutic challenge because of their proximity to numerous vital structures. During the past 40 years, the development of effective combined-modality therapy and of novel surgical approaches has dramatically improved the rates of local control and overall survival for patients with these tumors. Future studies are needed to address the continuing problems of systemic relapse after surgery, especially in the brain.

31 Extended Resections for Lung Cancer: Bronchovascular Sleeve Resections

Shun-ichi Watanabe

SUMMARY OF KEY POINTS

- Bronchovascular sleeve resection is an essential technique for general thoracic surgeons to preserve as much as possible the patient's lung function and quality of life after pulmonary resection.
- Previous reports suggested that the incidence rates of bronchopleural fistula and surgical mortality after sleeve lobectomy and sleeve pneumonectomy were 3% and 2.5%, and 5.5% and 20.9%, respectively.
- In the tissue-healing process of the anastomotic site after bronchial sleeve resection, previous reports suggested that the blood flow in the bronchial arteries proximal to the anastomosis comes from the aorta, but the blood flow distal to the anastomosis comes from the pulmonary artery.
- There are controversies in techniques of bronchial sleeve resections regarding suturing methods, suturing layers, types of anastomosis, types of sleeve resection, and the necessity of wrapping the anastomosis.
- There are controversies in techniques of pulmonary artery angioplasty regarding types of resection, types of reconstruction, order of reconstruction in a double sleeve resection, and the necessity of anticoagulant therapy.

Bronchoplastic and angioplastic procedures are essential techniques in general thoracic surgery. When performing lung cancer operations, thoracic surgeons sometimes encounter situations that require these techniques; therefore thoracic surgeons should know how to perform these procedures. This chapter describes the history of, and strategy and techniques for, bronchoplastic and angioplastic surgical procedures.

HISTORY AND SURGICAL OUTCOMES OF BRONCHOVASCULAR SLEEVE RESECTION

Bronchial Sleeve Resection

The first bronchoplastic surgical procedure was described by Bigger in 1932.[1] The patient was a 14-year-old boy with a tumor in the left main bronchus, and the tumor was removed with an incision in the bronchus. Postoperative examination of the pathologic specimen indicated that the resected tumor was malignant. Therefore a week after the surgical procedure, a left pneumonectomy was done. However, the patient died of infectious pericarditis after these repeated thoracotomy procedures. The first bronchial sleeve resection was performed by Thomas in 1947.[2] The patient was a young man who was awaiting a commission in the Royal Air Force. An adenoma on the right upper lobe bronchus was detected at clinical examination, and the tumor was found to be occluding the right main bronchus. A sleeve resection and an end-to-end anastomosis of the right main bronchus were performed. The patient

was able to serve as an Air Force pilot in active flying duties after this lung-preserving operation.

In 1959, Johnston and Jones[3] described the first successful sleeve lobectomy for primary lung cancer, a procedure that had been performed by Allison in 1952. In 1955, Paulson and Shaw[4] named this procedure a "bronchoplastic surgery." In the 1970s and 1980s, Jensik et al.,[5] Bennett and Smith,[6] and Faber et al.[7] reported on case series of patients who had sleeve lobectomies. The first report of a carinal resection was made by Mathey et al.[8] in 1966, and in 1978, Grillo[9] reported success with 38 cases.

The results of bronchoplastic procedures have been reported in several studies (Table 31.1).[10–20] In most of these reports, 5-year survival rates were 40% to 50% and mortality rates were relatively low, ranging from 0% to 7.5%. Tedder et al.[10] reviewed the results of 1915 bronchoplastic procedures for primary lung cancer that were performed over 12 years, starting in 1979. According to that report, the incidence rates of bronchopleural fistula, bronchovascular fistula, and surgical mortality after sleeve lobectomy and sleeve pneumonectomy procedures were 3% and 10.1%, 2.5% and 2.9%, and 5.5% and 20.9%, respectively.

Pulmonary Artery Angioplasty

Gundersen[21] published the first report of a pulmonary artery sleeve resection in 1967. That report described two cases of successful pulmonary artery sleeve resection and end-to-end anastomosis. After the publication of these results, many successful cases were reported.[22,23] More recently, an increasing number of studies have described the results of concurrent bronchoplasty and pulmonary artery angioplasty procedures (Table 31.2).[13,16,17,24–27] For example, Rendina et al.[17] reported on 40 cases of concurrent procedures. The 5-year survival rate was 38.6%, which was equivalent to the 5-year survival rate of 38.7% recorded for 80 cases of only bronchoplastic surgical procedures.[17]

HEALING OF THE ANASTOMOTIC SITE AFTER BRONCHIAL SLEEVE RESECTION

Ishihara et al.[28] detailed the results obtained in animal models regarding the tissue-healing process of the anastomotic site after bronchial sleeve resection. He injected silicone rubber of different colors into the bronchial artery and pulmonary artery after a sleeve lobectomy. The results confirmed that the blood flow in the bronchial arteries proximal to the anastomosis came from the aorta, but the blood flow distal to the anastomosis came from the pulmonary artery (Fig. 31.1). Inui et al.[29] evaluated bronchial blood flow by laser Doppler velocimetry in dogs. Their results suggested that the bronchial mucosal blood flow was reduced when the peribronchial tissue was detached, and blood flow was restored by dressing the anastomosis with the greater omentum.[29]

According to some reports, systemic administration of small doses of steroids after the bronchoplastic procedure prevented an inflammatory reaction and edema in the tissue around the anastomotic site.[30,31] Consequently, this treatment was believed to improve blood flow and promote healing of the anastomosis. However, Inui et al.[29] suggested that treatment with steroids did

Fig. 31.1. Stereomicroscopic view of the bronchial circulation at the anastomosis site. The bronchial arteries were perfused with different colors of silicone rubber. Bronchial arteries proximal to the anastomosis are filled with orange silicone rubber, which was injected into the aorta. Bronchial arteries distal to the anastomosis are filled with yellow silicone rubber, which was injected into the pulmonary artery. *(Reprinted with permission from Ishihara T, Nemoto E, Kikuchi K, Kato R, Kobayashi K. Does pleural bronchial wrapping improve wound healing in right sleeve lobectomy?* J Thorac Cardiovasc Surg. *1985;89(5):665–672.)*

not improve blood flow at the anastomotic site in animal models as evaluated by laser Doppler velocimetry. Rendina et al.[30] reported that treatment with steroids in the clinical setting substantially decreased the incidence of postoperative morbidity and shortened the postoperative intensive care unit and hospital stays. The patients in that study received postoperative aerosol steroid inhalation three times per day and intravenous injections of 10 mg methylprednisolone twice a day.

SURGICAL TECHNIQUES AND CONTROVERSIES REGARDING BRONCHIAL SLEEVE RESECTIONS

Suturing Method: Interrupted or Continuous?

The first question for the optimal selection of a suturing method is whether an interrupted or continuous suture should be used. It is generally thought that a continuous suture allows less blood flow at the anastomotic site than an interrupted suture. Reduced blood flow could lead to anastomotic dehiscence or stenosis; therefore the interrupted suture has been adopted in many institutions. However, Kutlu and Goldstraw[14] and Aigner et al.[32] reported good results with a continuous suture technique. Bayram et al.[33] found no pathologic differences in the healing process between dogs treated with interrupted and continuous sutures.

The greatest concern about a continuous suture technique is that if part of an anastomosis develops dehiscence, the defect might propagate over the whole anastomosis. This possibility may explain why many thoracic surgeons are reluctant to adopt the continuous suture technique. Hamad et al.[34] reported a new bronchial anastomosis technique, which uses three running sutures. They showed that this technique could be performed easily and quickly with few knots, and it minimized the risk of a whole anastomosis dehiscence, even after difficult sleeve resections.

The advantage of a continuous suture is that it is technically easier than an interrupted suture, particularly for a mini-thoracotomy procedure. The innovation of absorbable monofilament sutures made continuous suture techniques easy and safe. Nevertheless, the advantage of the interrupted suture is that it maintains good blood flow at the anastomosis. Furthermore, if a partial dehiscence occurs, the whole anastomosis would not be compromised. The disadvantage of the interrupted suture is that tying several posterior sutures with knots on the outside of the anastomosis is technically difficult. However, current advances have made it possible to place several posterior suture knots on the inside of an anastomosis, which should be more convenient and technically easier to perform. When absorbable monofilament sutures are used in this procedure, airway complications can be avoided because the knots are readily absorbed, provoke little tissue reaction, and create minimal bronchial obstruction.

Suturing Layers: Through-and-Through or Submucosal Suture?

Two methods are used for suturing the cartilaginous portion of the bronchus. One method is to place the suture outside the mucosal layer, for the so-called submucosal suture; the other method is to pierce through the whole wall of the bronchus, for the so-called through-and-through suture. Paulson and Shaw[4] demonstrated the effectiveness of the submucosal suture using interrupted fine cotton or cable-wire sutures. Rendina et al.[35] also recommended using the submucosal suture with the aid of magnifying loupes. However, no evidence has supported the usefulness of the submucosal suture; thus in many institutions, the whole-wall suture has been performed with use of an absorbable monofilament thread. This method is preferred for two reasons. First, the submucosal suture is technically more difficult than the whole-wall suture. Second, the monofilament absorbable suture is unlikely to develop anastomotic complications from infection associated with the thread. This type of infection may occur with either a submucosal suture or a through-and-through suture and may result in collection of sputum and anastomotic stenosis.

Type of Anastomosis: Telescope or End-To-End?

Two methods are used for creating a bronchial anastomosis: the telescope and the end-to-end methods. The telescope anastomosis is currently used when a large-caliber mismatch is present
Fig. 31.2. Endoscopic view of a bronchial anastomosis after a wedge sleeve resection of the right upper lobe. The wedge sleeve resection caused a deformation to develop in the airway mucosa *(asterisk)*, which may cause sputum retention at the anastomotic site.

between the bronchial ends.[36] This method does not require a tissue wrapping for the anastomosis, and many good results have been reported to date, particularly in lung transplantation procedures. However, some transplant surgeons have reported disadvantages of the telescope anastomosis. The primary disadvantage is that the retrograde collateral blood flow from the pulmonary artery of the residual lung may be insufficient at the overlapping edges of the distal bronchus; therefore this method may lead to necrosis and stenosis at the anastomosis. The mortality rate for patients with stenosis after a telescope anastomosis is reportedly 2% to 3%.[37] Aigner et al.[32] reported that the incidence of anastomotic complications associated with the telescope technique was 30% in the early 1990s. Converting to the end-to-end bronchial anastomosis markedly reduced the complication rate to less than 4%.[32] Rabinov et al.[38] suggested that the "reverse telescope" anastomosis technique greatly reduced the incidence of anastomotic stenosis.

Type of Sleeve Resection: Wedge or Conventional?

When the tumor invades a very small area of the central bronchial wall or when it is considered to be a low-grade malignant tumor that requires only a small surgical margin, a wedge sleeve resection can be performed instead of a conventional sleeve resection. The wedge resection maintains the blood flow of the bronchial anastomosis because a small area of the bronchial wall remains connected. However, this procedure may cause a deformed airway to develop, which may result in sputum retention at the anastomotic site (Fig. 31.2). Moreover, tension at the anastomosis may become excessive. In such cases, it is recommended to convert to the conventional sleeve resection. Rendina et al.[35] suggested that a sleeve resection is always preferable to a wedge sleeve resection because the latter procedure caused a number of complications as a result of excessive tension.

Bronchial Anastomosis: Wrap or No Wrap?

Several tissues may be used as an autologous material for wrapping the bronchial anastomosis, including the pericardial fat pad, the intercostal muscle, and the parietal pleura, among others. Wrapping the bronchial anastomosis may cover the small
Fig. 31.3. Illustration of a patch reconstruction after a tangential resection of the pulmonary artery. The advantage of the patch reconstruction is that the suture line of the pulmonary artery does not touch the bronchial anastomosis; this is advantageous particularly after a left upper bronchovascular sleeve resection.

dehiscence site and prevent the formation of a bronchopleural fistula. This procedure also prevents erosion at the surface of the pulmonary artery adjacent to the anastomosis, thereby preventing the development of a bronchovascular fistula. No clear evidence indicates that wrapping the bronchial anastomosis promotes angiogenesis around the anastomosis.[28,29]

SURGICAL TECHNIQUES AND CONTROVERSIES REGARDING PULMONARY ARTERY ANGIOPLASTY

Pulmonary Artery Resections and Reconstructions: Tangential Resection or Sleeve Resection?

Tangential Resection

The tangential resection is performed when the tumor invades part of the pulmonary artery. A direct running suture of the resected pulmonary artery wall may cause stenosis and thromboembolism in the pulmonary artery; therefore direct running suture should be applied only when the tumor invades a small area of the pulmonary artery. Cerfolio and Bryant[39] suggested that when a direct suture is estimated to reduce the pulmonary artery diameter by 20% to 30%, a sleeve resection of the pulmonary artery should be performed instead of a direct suture in order to prevent stenosis and occlusion of the pulmonary artery. When the resected area of the pulmonary artery is too large for a direct suture but not large enough for a sleeve resection (i.e., <50% of the arterial wall), a patch reconstruction should be applied. The advantage of a patch reconstruction compared with a sleeve resection of the pulmonary artery is that the suture line of the pulmonary artery does not touch the bronchial anastomosis; this is advantageous, particularly after a left upper bronchovascular sleeve resection (Fig. 31.3).

Autologous pericardium is the preferred material for a pulmonary artery patch because of its many advantages. The autologous pericardial patch can be taken readily from the pericardial sac,

anterior to the phrenic nerve. The autologous pericardial patch shrinks substantially immediately after excision. Thus care must be taken to obtain a piece of the pericardium that appears much wider than the size of the pulmonary artery defect. The patch is sutured to the pulmonary artery with continuous 5-0 or 6-0 nonabsorbable monofilament sutures.[17,39] The edge of the autologous pericardium also tends to recoil during suturing. Therefore several sutures should be placed around the edge of the recoiled pericardial patch prior to the running suture in order to ensure that the pericardium remains flat and to make suturing easy (Fig. 31.3). Bovine pericardium is stiffer than autologous pericardium, so using bovine pericardium can eliminate the recoiling problem, but bovine pericardium is expensive.

Sleeve Resection

Compared with a direct suture, a sleeve resection of the pulmonary artery is associated with a lower incidence of stenosis and, consequently, a lower frequency of thromboembolism. An end-to-end anastomosis is typically performed with a 5-0 or 6-0 monofilament nonabsorbable suture. A sleeve resection of the pulmonary artery is usually performed along with a sleeve resection of the bronchus; therefore tension at the pulmonary artery anastomosis is minimal. However, when a bronchial sleeve resection is not required, a pulmonary artery sleeve resection should be performed with a conduit interposition reconstruction. A synthetic or autologous graft is used as the material for the conduit, and a 2-cm section should be sufficient for the length of the conduit. Rendina et al.[40] reported that the autologous conduit could be prepared from a section of the pericardium. A conduit is constructed by wrapping the pericardium around a 28-F chest tube and then suturing the sides longitudinally with a 6-0 monofilament nonabsorbable suture. Cerezo et al.[41] described a new method for reconstruction of an autologous pulmonary artery conduit; they used a pulmonary vein graft collected from the resected lung.

Which Should Be Reconstructed First in a Double Sleeve Resection: The Bronchial or Vascular Anastomosis?

Much controversy has focused on the order of reconstruction in a double sleeve resection. Rendina et al.[40] suggested that the vascular reconstruction should be performed before the bronchial anastomosis because it reduces the time that the pulmonary artery must be clamped. However, other authors have noted that it is preferable to perform the bronchial anastomosis before the vascular anastomosis.[42] Two reasons are cited for the latter preference. First, once the pulmonary artery is reconstructed, it is difficult to perform the bronchial anastomosis because it requires retracting the pulmonary artery, which may cause a thromboembolism or dehiscence at the pulmonary artery anastomosis. Second, inflation of the lung after a bronchial anastomosis allows the surgeon to check the tension and detect kinking at the pulmonary artery anastomosis.

Postoperative Anticoagulant Therapy: Necessary or Unnecessary?

Controversy persists regarding the use of postoperative anticoagulant therapy. Rendina et al.[35] administered a dose of heparin (3000 U, single venous injection) before the anastomosis and a subcutaneous injection of heparin (15,000 U/day) for 7 days to 10 days after surgical procedures. Cerfolio and Bryant[39] suggested that only a small dose of heparin (1500 U, single venous injection) should be used before the anastomosis to avoid the risk of postoperative bleeding. At the National Cancer Center Hospital in Tokyo, we do not administer heparin either during or after surgical procedures, and we have not found any cases of thromboembolism of the pulmonary artery.

CONCLUSION

Bronchovascular sleeve resection is an indispensable surgical technique for thoracic surgeons. This technique is performed to preserve the patient's lung function and quality of life after the operation; thus special care must be taken to avoid postoperative morbidity and mortality. Thoracic surgeons can optimize outcomes by understanding the essential techniques and controversies involved in this procedure.

32 Multiple Nodules: Management of Synchronous and Metachronous Lung Cancers

Jessica S. Donington

SUMMARY OF KEY POINTS

- Multiple primary lung cancers (MPLCs) are increasing in incidence as imaging accuracies improve and resections are better tolerated.
- Differentiating MPLCs from intrathoracic metastatic disease is challenging and based primarily on clinical judgment.
- Molecular analysis for tumor clonality has the potential to increase accuracy of differentiation between MPLCs and intrathoracic metastatic disease.
- Complete resection is the treatment of choice for MPLCs, but preservation of pulmonary parenchyma is essential and therefore the use of sublobar resections is common.
- Survival rates following complete resection of synchronous MPLCs are reported as between 35% and 75% with prognosis being decreased in those with N1 and N2 involvement.
- Metachronous MPLCs are almost always diagnosed at an early stage in asymptomatic patients as part of surveillance imaging. Survival following resection is typically 40% and determined by the stage of the second cancer.
- Stereotactic body radiotherapy is an attractive treatment alternative for early stage MPLC because of its ability to preserve pulmonary parenchyma.

The concept of MPLCs was introduced by Beyreunther in 1924,[1] but remained a rarity for many decades. From 1960 to 1990 only sporadic case series were reported,[2–6] but it was not until the integration of computed tomography (CT) scanning into lung cancer care that the true magnitude was appreciated. Today, rapid improvements in imaging accuracy, decreased mortality associated with lung cancer resections, increased use of CT scans for routine postoperative surveillance, and integration of mutational analysis for resected cancers are all contributing to a growing cohort of MPLC. Whether presenting as synchronous or metachronous tumors, one of the greatest challenges is differentiating MPLCs from intrathoracic metastatic disease. The first step in that distinction is appropriately recognizing the frequency of MPLCs in the modern era. Rates of less than 5% of all nonsmall cell lung cancers (NSCLCs) from older series are now believed to greatly underestimate the true incidence of MPLCs.[7] High-resolution CT scans also allow for the detection of ground-glass opacities, which are not evident on standard chest x-ray or early generation CT scans. These precancerous lesions and early stage adenocarcinomas have a lepidic growth pattern with a predilection for indolence and multiplicity. Risk factors and prognosis for multifocal adenocarcinomas are different from traditional MPLCs reported in older series. The management and treatment decisions for MPLCs follow the same general principles used for other early stage NSCLCs with special consideration for the preservation of pulmonary parenchyma and vigilant posttreatment surveillance.

DIFFERENTIATING MPLCs FROM METASTATIC DISEASE

Patients with multiple nodules at the time of NSCLC diagnosis or a new pulmonary nodule following successful treatment of an early stage NSCLC pose a significant clinical challenge due to the lack of clear criteria that differentiate intrapulmonary metastasis from MPLC. The most widely referenced definition is from 1975, from Martini and Melamed.[8] It is applied most appropriately to metachronous tumors, or to those that have already been resected or found at autopsy, and relies heavily on cell type (i.e., adenocarcinoma or squamous cell carcinoma). Further factors used to refine the criteria include origin in an area of carcinoma in situ, lack of carcinoma in common lymphatics, and lack of extrathoracic metastasis (Table 32.1).[9] This definition is becoming outdated in an era when mutational and molecular analysis can differentiate tumors on a genetic basis.

Some investigators have suggested that individual adenocarcinomas can be distinguished based on differences in the proportion of histologic subtypes (i.e., lepidic, papillary, acinar, micropapillary).[10,11] By contrast, other investigators report that mutational and molecular analysis of somatic changes in tumor DNA can better discriminate between MPLC and metastatic disease. Mutational analysis of the epidermal growth factor receptor and K-ras mutations can be used to differentiate between metastatic and second primary adenocarcinomas of the lung.[11–13] The utility of this approach is limited by the facts that this type of analysis is only relevant to adenocarcinomas, not all adenocarcinomas harbor these mutations, and expression can be heterogeneous throughout the tumor. Cytogenetic profiles can be used to evaluate the clonal relationship between tumors.[14,15] Genomic DNA copy number alterations are key events in tumor development and array comparative genomic hybridization can distinguish between clonal tumors (metastasis) and MPLCs.[12,16] Investigators from the Massachusetts General Hospital reported on 68 patients with multiple resected adenocarcinomas whose tumors were classified as MPLC or metastasis by a comprehensive histologic profiling, including profiling using SNaPshot multiplex polymerase chain reaction. In their study, the 3-year survival rate was significantly improved in patients classified as MPLC by molecular profiling, but not by histologic profiling, indicating improved accuracy with molecular analysis.[17] Although this molecular profiling appears to be more precise than histologic profiling, it is time consuming, expensive, and requires large amounts of genomic DNA. Molecular analysis may not currently be reasonable for use on a case-by-case basis, but it is helping to redefine the frequency and clinical characteristics associated with MPLCs.

Clinical judgment remains critically important in these cases, with biopsy typically having only a small and supplemental role.[18] Patients are generally placed into management categories based on the appearance, location of nodules, and the presence of nodal or extra thoracic metastatic disease. Biopsies are often difficult and typically not helpful in differentiating metastasis and second primaries without molecular analysis because the majority of MPLCs are of the same histology.

TABLE 32.1 Criteria From Martini and Melamed[8] for Multiple Primary Lung Cancers

Metachronous	**DIFFERENT HISTOLOGY**	
	Same histology if	Prolonged interval between tumors (typically >2 years)

		Different lobes with:
		• no cancer in shared lymph node basins
		• no extrathoracic metastasis

MPLCs in the Lung Cancer Staging System

The previous editions of the tumor, node, and metastasis (TNM) classification for lung cancer have been somewhat vague with respect to the classification of lung cancer with multiple pulmonary sites of involvement, which has resulted in marked variability in how these tumors are classified.[19,20] The creation of homogeneous groups is a goal of cancer staging, but this task is challenging when lung cancer occurs in different pulmonary sites, and the individual cancers exhibit distinct patterns of biologic behavior, recurrence, and survival. In previous lung cancer staging systems, there has been a lack of clarity regarding these distinct patterns of disease as well as ambiguity about how to best apply stage classification.

Definitions have evolved over time for multiple intrathoracic sites of lung cancer in the TNM system. Prior to 1993, all separate tumor nodules were classified as M1. They were then defined as T4 if in a different lobe. In 1997, separate tumor nodules were classified as T4 if in the same lobe and M1 if in a different lobe (ipsilateral or contralateral). In 2010, separate nodules were reclassified as T3 for a same lobe, as T4 if in a different ipsilateral lobe, and as M1 if in a contralateral lobe.[19,20] However, none of these definitions addressed the concept of variability in appearance and behavior of these additional sites of disease. Furthermore, the seventh edition contained only an elusive mention of ground-glass or lepidic lesions (GG/L) and predated the classification of adenocarcinoma histologic subtypes.[21,22]

In the eighth edition of TNM classification, four distinct disease patterns were identified for lung cancers with multiple sites of pulmonary involvement and clear instructions were provided on how to apply the TNM classifications to each pattern of disease.[23] The four disease patterns include: (1) synchronous primary lung cancers, (2) multiple GG/L nodules, (3) solid primary lung cancer with one or more separate solid tumor nodule(s) of the same histologic type, and (4) pneumonic type of lung cancer, a diffuse form that is radiologically similar to pneumonia. The radiographic and pathologic features of each of these four disease categories are outlined in Table 32.2. Second primary lung cancers and GG/L are each recognized as variants of MPLCs. In patients with second primary cancers, each tumor is staged with a unique TNM. GG/L cases are also viewed as independent tumors, but are more interrelated with a strong predilection for multiplicity and lack of lymphatic involvement and are therefore recommended to be staged with the T based on the highest T lesion and "#/m" indicating multiplicity and a single N and M designation. Solid tumors with separate solid nodules and pneumonic lung cancer are not variants of MPLC, but are rather variants of advanced intrathoracic spread of a single tumor and are therefore staged as T3 if spread is limited to a single lobe, T4 if spread is to a single lung, and M1 if bilateral.[24]

Synchronous Primary Lung Cancers

The improved resolution of CT imaging has led to increased rates of NSCLC patients presenting with multiple nodules at initial diagnosis. The definitions for synchronous MPLC remain ambiguous, even though treatment algorithms and prognosis are dramatically different from those for patients with multiple nodules from the same tumor. Prognosis for these patients is not as good as those who present with a single primary tumor, but far better than those with widely metastatic disease. Most feel that classifying all of these as intrathoracic metastatic disease greatly "over stages" a significant number of patients with synchronous primary early stage tumors, and denying local therapy may miss the potential for cure. The lack of uniformity for precise identification and definitions for synchronous primary NSCLC has resulted in a paucity of large series of homogeneously treated patients.

Patient Evaluation

Recent trials support an aggressive approach to the treatment of patients with more than one nodule suspicious for early stage NSCLC with the understanding that these may represent MPLC, but a thorough preoperative assessment is essential to rule out metastatic disease and assure the patient has adequate cardiopulmonary reserve to tolerate local therapy for both cancers. Preoperative assessment includes routine pulmonary function tests because these patients may require multiple resections, CT scan of the chest, and whole-body positron emission tomography (PET). Additional tests considered essential include brain imaging by magnetic resonance imaging (MRI) or CT and pathologic mediastinal staging, even in cases of CT-negative and PET-negative mediastinal nodes.[18] Every attempt should be made to exclude the possibility that this may represent intrathoracic metastatic disease prior to local intervention.

Surgical Resection and Outcome

Once two nodules are deemed to be synchronous early stage MPLCs, careful planning is needed to adequately treat each while preserving pulmonary parenchyma. The vast majority of large series of synchronous MPLCs involve patients who undergo resection of both cancers.[18] Five-year survival for resected patients ranges from 16% to 76% but is improved in more recent series and in those with a predominance of multifocal adenocarcinoma, which has a more indolent behavior (Table 32.3).[10,25–34] A 2013 meta-analysis specifically looked at prognostic factors and outcomes of resections for synchronous MPLCs.[35] The authors specifically attempted to exclude carcinoid tumors and pure adenocarcinoma in situ from the analysis, because of their indolent nature. Tumors were considered synchronous if they occurred within 2 years of initial resection. Four hundred and sixty-seven patients were analyzed from six different studies conducted from 1983 to 2011,[10,25,30,36–38] which coincides with the integration of CT scanning into NSCLC care. The majority of patients (67%) had the same histology in both tumors. Between 16% and 78% of patients were treated with at least one sublobar resection, and half of the tumors were unilateral. Two tumors were seen in most patients, but 11% had three or more. Median overall survival was 52 months, far more in line with survival for early stage than metastatic NSCLC. Risk factors for poor outcome included male gender, increasing age, nodal involvement, and unilateral tumors, with N2 involvement being the strongest predictor of poor outcome. Those patients with favorable status with regard to these four prognostic factors

TABLE 32.2 Schematic Summary of Patterns of Disease and TNM Classification of Patients With Lung Cancer With Multiple Pulmonary Sites of Involvement

Eighth Edition Staging Category	Multiple Primary Lung Cancer		Single Lung Cancer With Intrathoracic Spread	
	Second Primary Lung Cancer	Multifocal GG/L Nodules	Separate Tumor Nodule	Pneumonic Type of Lung Cancer
Imaging Features	≥2 distinct masses with imaging characteristic of lung cancer (e.g., spiculated)	Multiple ground-glass or part-solid nodules	Typical lung cancer (e.g., solid, spiculated) with separate solid nodule	Patchy areas of ground glass and consolidation
Pathologic Features	Different histotype or different morphology by comprehensive histologic assessment	Adenocarcinomas with prominent lepidic component (typically varying degrees of AIS, MIA, and LPA)	Distinct masses with the same morphology by comprehensive histologic assessment	Same histology throughout (most often invasive mucinous adenocarcinoma)
Staging	Separate cTNM and pTNM for each cancer	T based on highest T lesion with "#/m" indicating multiplicity; single N and M	Location of separate nodule relative to primary site determines if T3, T4, or M1a; single N and M	T based on size if in single lobe, T4 or M1a if in different ipsilateral or contralateral lobe; single N and M

AIS, adenocarcinoma in situ; *GG/L,* ground glass/lepidic; *LPA,* lepidic predominant adenocarcinoma; *MIA,* minimally invasive adenocarcinoma; *TNM,* tumor, node, and metastasis.

(gender, age, lymph nodes, and laterality) had a 5-year survival of 82% in a pooled survival estimate from the six trials compared with only 43% for those with any poor prognostic risk factors.[35] Factors such as lung function, tumor size, and adjuvant therapies were not included in the analysis.

A consistent finding throughout the literature is that approximately one-third of synchronous MPLCs are detected incidentally at the time of resection.[2,10,35,39–41] Frozen section is typically not informative in these circumstances because histology is typically the same. An R0 resection is recommended, and this typically requires a sublobar resection for one or both of the lesions. If an R0 resection is not possible, a diagnostic biopsy is recommended to help direct further care.[18] Hilar and mediastinal lymph node evaluation is essential for these patients. As with other early stage NSCLC patients, there is a risk of a false-negative result on preoperative evaluation and N2 involvement is strongly associated with poor prognosis.

Metachronous Primary Lung Cancers

Incidence

Similar to synchronous MPLCs, the definition for metachronous tumors remains somewhat ambiguous. Increases in the incidence of metachronous MPLC in recent literature can be attributed to (1) more patients presenting with early stage NSCLC, (2) more patients surviving treatment for early stage NSCLC, and (3) increased use of CT scans as part of routine postoperative surveillance. Series of resected NSCLC patients prior to the year 2000 typically reported rates of 0.5% to 3.2% in resected patients.[42–45] Large series from 2001 and 2002 reported rates of 4.1% and 4.6%, and a 2013 report of 1294 patients from the Memorial Sloan Kettering Cancer Center (MSKCC) found 7% incidence of second primary lung cancers.[39,46,47] Although this was substantially higher than that reported by previous series, it is important to note that this is lower than the rate of recurrence within the same population (20%). In the MSKCC series, the rate of tumor recurrence following resection begins to decrease after 4 years, whereas the rate of a second primary NSCLC increased steadily over time, going from a rate of 3/100 person-years in the first 2 postoperative years to 6/100 person-years 5 years from resection. Most series report an average interval of 30 months to 50 months between initial and subsequent tumors (Table 32.4).[40,46,48–50]

The majority of second primary NSCLCs (93%) in the MSKCC series were detected by scheduled surveillance CT scan.

The augmented rate of MPLCs in this series is attributed to the increased use of routine postoperative surveillance scans. Patients received on average 1.9 CT scans in year 1 and 1.5 scans in year 2, which decreased to 0.8 scans/year through year 7. A 2010 analysis of the Surveillance, Epidemiology, and End Results (SEER) database found only 1.5% incidence of second primary NSCLC, but only 25% of resected early stage NSCLC patients in SEER receive any postoperative surveillance by CT.[51] Differences in the incidence of MPLC in the SEER and MSKCC are likely related to the decreased use of postoperative CT surveillance in the SEER population.

Similar to synchronous tumors, approximately two-thirds of metachronous MPLCs are of the same histology,[2,3,25,40,41,45,52] but that histology is changing over time. Squamous cell carcinomas were once the most common, but adenocarcinoma is reported more frequently in modern series.[47] This shift in histology may impact prognosis, as multifocal adenocarcinomas are thought to have a more indolent course, predilection toward multiplicity, and excellent survival following resection.[9]

Evaluation

Patients suspected of having a metachronous MPLC require careful evaluation to rule out the possibility of recurrent disease. Whole-body PET and brain MRI are considered essential, but the role for invasive mediastinal staging is less clear. The use of mediastinoscopy and the extent of systematic mediastinal lymph node evaluation used for the initial NSCLC may limit the ability to perform invasive mediastinal staging for the subsequent cancer. Endobronchial ultrasound with biopsy is an attractive alternative in a patient who has previously undergone mediastinoscopy, but accuracy is decreased in this setting.

Surgical Resection and Outcome

Almost all cases (75% to 90%) of metachronous MPLCs are detected at an early stage, and treatment therefore centers on local strategies with the grand majority undergoing surgery. Sublobar reactions are common, being used in approximately 40%, and this appears unchanged between older and more recent series. Survival following resection is approximately 40% at 5 years, somewhat disappointing for early stage NSCLC, but much better than would be expected for metastatic disease (Table 32.4).[25,40,46,48–50] Stage of the second tumor is the most consistent predictor of survival. Survival rates are improved in patients undergoing resection of metachronous multifocal GG/Ls.[9]

Metachronous Tumors Following Pneumonectomy

Development of subsequent lung cancer in the remaining lung after a pneumonectomy poses a unique treatment problem, and surgery is often considered contraindicated. There are a limited number of small series documenting feasibility of resection of second primary lung cancer following pneumonectomy,[53–56] but overall information on this select group of patients is limited. The largest series from the Mayo Clinic reports on 14 patients over a 20-year period.[57] Similar to other series of metachronous MPLC, the overwhelming majority of subsequent tumors were found in asymptomatic patients on routine surveillance CT scans and all were stage I. The 1-year, 3-year, and 5-year survival rates after resection for metachronous MPLC were 86%, 71%, and 50%, respectively. Wedge resection was the preferred mode of resection, with improved short- and long-term outcomes compared with more extensive procedures.[57]

Stereotactic Body Radiotherapy

Stereotactic body radiotherapy (SBRT) is an emerging option for patients with MPLC. SBRT for synchronous MPLC has been

investigated in multiple small, single-institution retrospective series. Many patients in these series are treated with resection of one focus and SBRT of the other, but several report SBRT for both foci (Table 32.5).[58–61] The largest series to date is from the Netherlands, where 62 patients with synchronous NSCLCs were treated.[62] Fifty-six had SBRT to both lesions and six underwent resection for one tumor and SBRT for the other. There were no grade 4 or 5 adverse events; primary tumor control was 84% at 2 years, and 2-year overall survival was 56%. An exploratory analysis between unilateral and bilateral tumors noted no differences in toxicity, but a significant decrease in local and regional control for unilateral MPLCs.

SBRT is particularly attractive in this setting of metachronous MPLC because these are almost always diagnosed at an early stage and there is an increased need to preserve pulmonary parenchyma. Multiple small series studies on SBRT for metachronous MPLC reported excellent local control and 2-year overall survival rates similar to those of surgery (Table 32.6).[59,62,63] In a retrospective series of 48 metachronous MPLCs treated at Washington University, the 2-year overall survival rate was

68%; in comparison 15 synchronous MPLCs treated over the same period had a 2-year survival of only 27.5%.[59] The largest reported series of SBRT for metachronous MPLC is from the Netherlands, with 107 patients treated between 2003 and 2013.[62] The majority had an anatomic resection for their initial NSCLC, and median interval between tumors was 48 months. At 2 years, local control was 89% and overall survival 60%, which were very similar to early survival results for single primary NSCLC.

A growing body of evidence suggests that SBRT is also a safe and effective treatment option in selected patients with metachronous MPLC following pneumonectomy (Table 32.7).[64–67] Testolin et al.[64] reported a series of 12 patients treated for MPLC after pneumonectomy for NSCLC. All patients completed the planned treatment with 2-year disease-free survival and overall survival rates of 36.1% and 80%. Haasbeek et al.[67] reported on SBRT in 15 postpneumonectomy patients, with a disease-free survival and overall survival of 91% and 80.8%. Pathologic confirmation of disease is challenging in this population due to fear of pneumothorax with single lung and is therefore frequently deferred.

EVIDENCE-BASED PRACTICE GUIDELINES

Both the American College of Chest Physicians and the European Society for Medical Oncology address MPLCs in their most recent evidence-based guidelines. In the European Society for Medical Oncology guidelines for treatment of metastatic NSCLC, it is recommended that solitary oligometastatic disease to the contralateral lung in most cases should be considered as a second primary tumor and treated if possible with surgery or definitive radiation.[68]

The most recent lung cancer guidelines from the American College of Chest Physicians address MPLCs under the "Special Treatment Issues" heading. The guideline details the importance of a multidisciplinary approach to the evaluation and management of patients with two intrathoracic foci of NSCLC.[18] The guidelines also recommend that diagnosis of MPLC can be based on the judgment of a multidisciplinary team and that clinical expertise best defines care with biopsy providing only supplemental information. The guidelines go on to recommend invasive mediastinal staging and extrathoracic imaging with whole-body PET and brain MRI for those patients being considered for

curative resection. The final recommendation is that tumors found incidentally in a different lobe at the time of surgery should be resected if the patient has adequate pulmonary reserve and there is no evidence for mediastinal node involvement.[18]

Upcoming guidelines from the American Society for Radiation Oncology for the use of SBRT in NSCLC also address MPLCs. Similar to other society recommendations, they encourage a multidisciplinary approach and thorough pretreatment staging to help differentiate MPLC from intrathoracic metastasis. SBRT is recommended as a curative treatment option for patients with synchronous and metachronous MPLCs with equivalent rates of local control, toxicity, and overall survival compared with single NSCLCs treated with SBRT.

CONCLUSION

Patients with lesions suspicious for MPLCs pose a challenge to the thoracic oncologic community. The discrimination between multiple independent primaries and intrathoracic metastatic disease is currently based on nonspecific criteria including location, size, timing, CT appearance, and evidence for nodal or metastatic disease. We are moving into an era where that determination can be made far more precisely based on molecular analysis of tumor clonal relationships and DNA alternations. As imaging technologies improve, resection becomes less invasive, and CT screening and surveillance become more widely integrated, the incidence of MPLCs should continue to rise. Thus an increased understanding of the biology of MPLC is required to help identify these patients for cancer prevention strategies and to better define treatment algorithms and prognosis. Clinicians require increased guidance as to which tumors can be treated by conservative local measures (observation, sublobar resection, SBRT) and which are responsible for the poor 5-year survival rates reported through the literature.

33 Surgical Management of Patients Considered Marginally Resectable

Hiran C. Fernando and Paul De Leyn

SUMMARY OF KEY POINTS

- Up to 25% of patients with stage I nonsmall cell lung cancer are considered medically inoperable or high risk for surgery.
- Therapies such as stereotactic body radiation therapy or ablation offer a less invasive alternative to surgery for marginally resectable patients.
- Guidelines have been developed to determine fitness for lung cancer surgery (see text).
- Guidelines to determine optimal therapy (e.g., surgery vs. stereotactic body radiation therapy/ablation) are not well established.
- The American College of Chest Physicians has determined that patients with a forced expiratory volume in 1 second or percentage of lung diffusion capacity for carbon monoxide less than 40% are at an increased risk for resection.
- The American College of Surgeons Oncology Group has defined criteria for patients considered to be high-risk for lobectomy but who are still candidates for sublobar resection or nonoperative therapy.
- Resection is still feasible in such patients defined as high risk.
- Sublobar resection can be undertaken with low mortality by experienced surgeons.
- Sublobar resection does not result in significant declines in pulmonary function in high-risk patients.
- Evaluation in a multidisciplinary setting that includes an experienced thoracic surgeon is recommended when determining therapy for marginally resectable patients.

The standard treatment of stage I nonsmall cell lung cancer (NSCLC) is lobectomy with systematic node dissection. Unfortunately, up to 25% of patients with stage I NSCLC are considered to be medically inoperable or are at high risk for surgery.[1] The increasing use of computed tomography (CT) screening often results in the detection of small tumors. This increase in the number of people with small tumors raises the following question: "What is the appropriate extent of pulmonary resection, particularly in older patients or in patients who, for other reasons, have marginally resectable disease?" The role of sublobar resection is further challenged by the introduction of new techniques associated with low rates of mortality and morbidity, such as stereotactic ablative radiotherapy (SABR) and radiofrequency ablation (RFA).

WHICH PATIENTS ARE CONSIDERED MARGINALLY RESECTABLE?

Respiratory failure and pulmonary complications represent the most substantial risks following lung resection, and preprocedure risk assessment is based primarily on pulmonary function. Algorithms for differentiating risk levels for patients who are candidates for lung resection have been published.[2] These guidelines provide general cutoffs for additional assessment and suggest threshold values to differentiate low-risk patients from high-risk patients. Cardiac evaluation and lung function testing—including lung diffusion capacity for carbon monoxide (DLCO)—are recommended for every patient who is to have pulmonary resection. Most centers use predictive postoperative forced expiratory volume in 1 second (FEV_1) and DLCO. If both values are higher than 30%, resection may still be feasible. According to the American College of Chest Physicians guidelines on the physiologic evaluation of patients for pulmonary resection,[3] patients with an estimated postoperative FEV_1 or DLCO of less than 40% are considered to be at increased risk for postoperative complications. The American College of Surgeons Oncology Group (ACOSOG) has initiated two studies in high-risk patients who have had sublobar resection and patients who are medically inoperable and are treated with RFA.[4,5] Although the same physiologic criteria were used for both studies (Table 33.1), an important factor is that a credentialed surgeon evaluated patients and deemed each patient to be either a poor candidate for lobectomy but a candidate for a more limited resection or a potential candidate for RFA because the patient was medically inoperable. Criteria that define marginally resectable as contrasted with unresectable are not standardized, and clinical evaluation by an experienced surgeon is essential. Ideally, the cases of all patients who are considered to have marginally resectable disease should be reviewed at a multidisciplinary meeting with an experienced thoracic surgeon participating in the discussion. In some cases of heterogeneous emphysema, pulmonary function may even improve after resection when the tumor is in the most emphysematous zone. This improvement is demonstrated by the results of lung volume–reduction surgery, and patients with this type of disease should not be denied the benefits of a curative lung resection.

It is difficult to know how many patients with stage I NSCLC are considered marginally resectable; however, we can get an estimate from some large database studies, such as those using data from the Surveillance, Epidemiology, and End Results (SEER) database. In one study involving 14,555 patients with stage I and II lung cancer, approximately 30% of patients aged 75 years or older were not offered surgery, compared with 8% of patients younger than 65 years.[6] It is unclear how many of these patients were not surgical candidates, and how many, if evaluated by an experienced surgeon, would have been offered sublobar resection. In another analysis of data from the SEER database, 10,761 patients with stage IA NSCLC had resection, with sublobar resection performed in 2234 (20.7%) of these patients.[7]

ROLE OF SUBLOBAR RESECTION IN THE TREATMENT OF NONSMALL CELL LUNG CANCER

The use of segmentectomy for treatment of lung cancer was initially described in 1973, when Jensik et al.[8] reported on patients who had segmental resection for lung cancer, thereby questioning the standard of lobectomy at that time. The only prospective

TABLE 33.1 Major and Minor Eligibility Criteria in the American College of Surgeons Oncology Group Z4032 Trial[a]

Major Criteria	Minor Criteria
FEV_1 ≤50% DLCO ≤50%	FEV_1, 51% to 60% DLCO, 51% to 60% Age ≥75 years Pulmonary hypertension (defined as pulmonary artery systolic pressure >40 mmHg) Poor left ventricular function (defined as an ejection fraction ≤40%) Resting or exercise arterial pO_2 ≤55 mmHg or SpO_2 ≤88% pCO_2 >45mmHg Modified Medical Research Council Dyspnea Scale score ≥3

[a]Eligible patients had to meet one major criterion or two minor criteria.[4]
DLCO, lung diffusion capacity for carbon monoxide; *FEV₁*, forced expiratory volume in 1 second; *pCO₂*, partial pressure of carbon dioxide; *pO₂*, partial pressure of oxygen; *SpO₂*, peripheral capillary oxygen saturation.

study comparing sublobar resection with lobar resection for the treatment of NSCLC is the Lung Cancer Study Group (LCSG) trial.[9] In this study, 122 patients were randomly assigned to limited resection (segmentectomy [67%] or wedge resection) and 125 patients to lobectomy. A threefold increase in local recurrence was associated with lobectomy, as was a trend suggesting a survival benefit (p = 0.088). Since the early 2000s, a large body of literature consisting of single-institution studies has demonstrated equivalent rates of regional recurrence and survival for segmentectomy and lobectomy for small (≤2 cm) node-negative tumors.[10–15] In an effort to increase the level of evidence to support limited resection for these small tumors, two prospective randomized studies are ongoing: one in the United States and Canada, with an expected enrollment of 1258 patients over 5 years (CALGB 140503; ClinicalTrials.gov identifier: NCT00499330); and the other in Japan, with an accrual of 1100 patients over 3 years (JCOG0802/WJOG4607L). Inclusion criteria in both trials are peripheral small (≤2.0 cm) NSCLC, excluding noninvasive lung cancer on CT (pure ground-glass opacity [GGO]). Until the data in these ongoing randomized trials are mature, it is recommended that, for standard-risk patients with operable disease, anatomic segmentectomy should be reserved for pure GGO lesions or partly solid lesions (<25%) smaller than 2 cm, located in the peripheral third of the lung. These pure GGO lesions are known to be noninvasive and are associated with no spread to the nodes. When segmentectomy is performed, the tumor should be situated in the central aspect of a typical pulmonary segment and the T1a N0 M0 status should be confirmed by examination of an intraoperative frozen section of N1 and N2 nodes. In addition, the surgeon should always resect all intersegmental lymph nodes to ensure they are tumor free. Otherwise, the procedure should be converted to a lobectomy. In patients considered marginally resectable, sublobar resection can be performed more liberally. To decrease rates of local recurrence, this procedure is combined with intraoperative brachytherapy at some centers.[16]

Sublobar resection can be performed by anatomic segmentectomy or wedge resection. In the case of wedge resection, the intersegmental and interlobar lymph nodes are usually not removed, and the margin between the staple line and the tumor is more likely to be smaller, especially in central lesions. In the LCSG trial, segmentectomy was associated with a decreased risk of recurrence in the involved lobe compared with wedge resection.[9] The superiority of segmentectomy over wedge resection for non-GGO lesions has been demonstrated in multiple studies. In one study of SEER data for patients with stage IA NSCLC, the survival associated with segmentectomy was compared with the survival associated with wedge resection. After adjusting for

propensity scores, overall and lung cancer-specific survival rates were significantly better after segmentectomy (hazard ratio, 0.80 [95% confidence interval, 0.69–0.93] and hazard ratio, 0.72 [95% confidence interval, 0.59–0.88], respectively).[17]

IMPACT OF SUBLOBAR RESECTION ON LUNG FUNCTION AND MORBIDITY

In the LCSG trial, pulmonary function tests were measured preoperatively and at 6-month intervals.[9] At 6 months, the changes from baseline for FEV_1, forced vital capacity, and maximum voluntary ventilation were significantly better in patients who had sublobar resection than in patients who had lobar resection. At 12 months to 18 months, only the FEV_1 was significantly better for patients who had sublobar resection compared with lobectomy. DLCO was not routinely measured in the LCSG trial. Keenan et al.[18] analyzed pulmonary function tests from 147 patients who underwent lobectomy and 54 patients who underwent segmentectomy. One year after lobectomy, there were significant decreases from the preoperative values for forced vital capacity, FEV_1, maximal voluntary ventilation, and DLCO capacity in patients who received lobectomy. However, the lung volume did not change substantially after segmentectomy. The only significant change after segmentectomy was in DLCO. The preoperative pulmonary function in patients who underwent segmentectomy was significantly reduced compared with that in patients who underwent lobectomy (FEV_1, 75.1% vs. 55.3%; p < 0.001). A 2009 study demonstrated that a substantial decline in postoperative function after lung resection is less likely among patients with low FEV_1.[19] In this study, investigators compared the outcomes for patients older than 75 years with stage I NSCLC who received segmentectomy (78 patients) or lobectomy (106 patients). The 30-day operative mortality rate was 1.3% for segmentectomy and 4.7% for lobectomy. Patients who received segmentectomy had fewer major complications (11.5% vs. 25.5%; p = 0.02). The 5-year overall and disease-free survival rates were equivalent.

The role of brachytherapy in marginally resectable (≤3 cm) stage I NSCLC treated by sublobar resection was evaluated in a multicenter randomized trial (Z4032). In a preliminary report from this trial, multivariable regression analysis showed no significant impact of brachytherapy, video-assisted thoracoscopic surgery (VATS), or thoracotomy on 3-month FEV_1, DLCO, or dyspnea score.[20] A 10% change in FEV_1 or DLCO was regarded as clinically meaningful. The FEV_1 decreased by 10% in 22% of patients who received sublobar resection of the lower lobe compared with 9% of patients who received sublobar resection of the upper lobe (p = 0.04; odds ratio, 2.79). An updated analysis of this study was recently reported.[21] Pulmonary function tests were obtained at baseline, 3 months, 12 months, and 24 months after therapy. This updated analysis only included 69 patients who had measurement at all four time points. The median change from baseline for FEV_1% was +2%, +1%, and +1% at 3 months, 12 months, and 24 months, respectively. The median change from baseline for DLCO% was –1%, –2%, and –2% at the same time points, respectively. A decline of 10% or more was seen after lower lobe resections at 3 months, but was not seen at 12 months or 24 months. A decline of 10% or more in DLCO was seen after thoracotomy at 3 months but not at 12 months or 24 months.

This trial also demonstrated that sublobar resection was associated with a 30-day and 90-day mortality of 1.4% and 2.7%, respectively.[22] Grade 3 or higher complications occurred in 27.9% of patients. Segmental resections were more likely to be associated with grade 3 or higher adverse events (41.5%) compared with wedge resections (29.7%). DLCO less than the median of 46% was also associated with a greater risk of grade 3 or higher toxicity.

A recent study evaluated the ACOSOG criteria in 490 stage I lung cancer patients undergoing resection at their institution.[23]

Patients were divided into high risk and low risk based on the inclusion criteria from Z4032, with 180/490 patients defined as high risk. No differences in postoperative mortality were seen between high-risk and standard-risk patients, however, length of stay was longer in the high-risk groups. Major (15.6% vs. 6.7%) and minor (48.3% vs. 22.3%) morbidity were also significantly increased in the high-risk groups. Three-year survival was 59% for high-risk and 76% for standard-risk patients. This study not only supports the classification used in the ACOSOG studies, but also underscores the continued role of surgery for these patients with no differences in mortality and acceptable 3-year survival.

VIDEO-ASSISTED THORACOSCOPIC SURGERY

Segmentectomy can also be routinely performed with minimally invasive surgical techniques.[24] In one single-institution series, 225 segmental resections were performed for stage I NSCLC patients (104 VATS and 121 open procedures).[25] There were no deaths among the patients who had VATS; however, two patients (1.6%) who had an open procedure died. Compared with open segmentectomy, VATS segmentectomy was associated with a shorter hospital stay (5 days vs. 7 days) and a lower rate of pulmonary complications (15.4% vs. 29.8%). The operative time, estimated blood loss, mortality rate, recurrence rate, or survival rate did not differ between the two groups. In a later series published by the same group, data on 785 patients who had segmentectomy or lobectomy were reviewed.[26] Among patients with stage IA NSCLC, there were no differences in time to recurrence and overall recurrence between the two procedures.

SUBLOBAR RESECTION VERSUS OTHER LOCAL THERAPIES

Although surgical resection remains the standard of care for early stage lung cancer, new techniques, including sublobar resection, SABR, and RFA, are now available for local therapy for high-risk patients with stage I NSCLC. These techniques are associated with lower procedure-related morbidity and mortality rates but increased rates of locoregional recurrence compared with lobectomy. One advantage of surgical resection is that lymph nodes can be removed and evaluated to confirm histology. Surgical and anesthetic techniques continue to improve, requiring updates to current guidelines. The identification of patients who are at high risk for lobectomy remains a complex clinical decision, and therefore the cases of such patients should be discussed by a multidisciplinary team.[27]

In many retrospective studies, selection bias has been demonstrated. An example of this bias was seen in a study by Crabtree et al.,[28] in which data for 462 patients who received surgery were compared with 76 patients who received SABR. Patients had a clinical stage IA/B NSCLC that was determined by the results of CT and positron emission tomography. In an unmatched comparison, the overall 5-year survival was 55% for patients who received surgery and the 3-year survival was 32% for patients who received SABR. After final pathologic examination, disease was upstaged in 35% of the patients who had surgery, with 13.8% of patients found to have N1 disease and 3.5% to have N2 disease. In the remaining 17.7% of patients, the T stage was upstaged from T1 to T2–T4. The analysis showed that patients who had surgery were younger, had lower comorbidity scores, and had better pulmonary function compared with the patients who received SABR. When a propensity analysis was used, the rates of local recurrence and disease-specific survival were similar for both groups of patients. The investigators matched 57 high-risk surgical patients to 57 patients who received SABR and found that the operative mortality rate for the high-risk surgical group was 7.0%, with no treatment-related deaths associated with SABR. In the matched comparison of this subgroup, there were no differences between surgery and SABR in terms of freedom from local recurrence (88% vs. 90%), disease-free survival (77% vs. 86%), and overall survival (54% vs. 38%) at 3 years.

In another study, the risk factors from three cooperative group trials involved RFA or SABR for patients who were medically inoperable and sublobar resection for patients who were deemed marginally operable.[29] The lowest values for DLCO were found among patients who received RFA. On initial evaluation, the 30-day rate of grade 3 or higher adverse events was higher for patients who had sublobar resection than for patients who received SABR. Nevertheless, in a propensity-matched comparison, there was no difference in grade 3 or higher adverse events at 30 days. These findings support the need for randomized trials to better compare these therapies.

Optimization of Oncologic Outcomes With Sublobar Resection

Because a better margin is more likely to be achieved when segmentectomy is performed, oncologic outcomes are likely to be improved by the preferential use of segmentectomy instead of wedge resection and by paying close attention to ensure an adequate surgical margin is achieved. Ideally, lymph node dissection or sampling should be done, and, as stated earlier, intersegmental lymph nodes are more likely to be removed with a segmental resection. In the Z4032 study, segmentectomy was associated with higher lymph node counts and, not surprisingly, higher rates of node upstaging.[30]

More recent data have supported the superior results with segmentectomy compared with wedge resection in the LCSG trial.[9] An analysis of data from the SEER database also demonstrated superior results for patients treated with segmental resection compared with wedge resection, even in tumors that were 2 cm or smaller.[17]

A strict definition for an adequate margin in sublobar resections remains unresolved, but a margin distance of 1 cm or more than the maximum tumor diameter is generally recommended.[31] To prevent local relapse, some institutions have used adjuvant intraoperative brachytherapy in conjunction with sublobar resection. Initial results from retrospective studies have suggested that this technique is effective in reducing rates of local recurrence.[16,32,33] Subsequently, the results of a prospective randomized study were reported.[4] There was no decrease in local recurrence rates associated with brachytherapy among patients with stage I NSCLC (≤3 cm in maximum diameter), which may have been a result of participating surgeons paying closer attention to margins. Only 6.6% of patients had positive results on cytologic examination of a sample taken from the staple line following resection, and it was in this group that the strongest trend favoring the use of brachytherapy was demonstrated. Three-year survival following resection was 70.8% in this group of patients with marginally resectable disease.

CONCLUSION

Sublobar resection should be considered the standard of care for patients with NSCLC who are deemed marginally resectable. Oncologic outcomes are improved with wide surgical margins, which are easier to achieve when segmental resection is performed. In addition, lymph node dissection or sampling should be done if resection is planned. Removal of lymph nodes will likely lead to a higher incidence of node upstaging, but will also help in identifying patients who are appropriate candidates for adjuvant chemotherapy. This added information would not be possible with alternative therapies such as SABR or RFA. Despite initial enthusiasm, adjuvant brachytherapy does not appear to offer oncologic advantages when applied routinely; however, brachytherapy may be useful for patients in whom the surgical margin will likely be close, and perhaps for patients with larger tumors, for whom sublobar resection is thought to be the best therapeutic option.

34   Technical Requirements for Lung Cancer Radiotherapy

Fiona Hegi, Todd Atwood, Paul Keall, and Billy W. Loo, Jr.

SUMMARY OF KEY POINTS

- Radiotherapy plays a central role in the treatment of lung cancer for patients in both the palliative and curative settings.
- Major advances in the technologic aspects of both radiotherapy and medical imaging have dramatically increased the accuracy and precision of treatment, resulting in less toxic and more curative treatment.
- In the developed world, the minimum standard for curative intent radiotherapy is linear accelerator-based three-dimensional (3-D) conformal radiotherapy with computed tomography (CT)-based computerized planning. Other technologies, such as cobalt teletherapy with two-dimensional (2-D) planning, may still be appropriate in low-resource settings.
- New approaches to radiotherapy treatment integrate information from multiple imaging sources, together with information about respiratory motion, and utilize sophisticated computerized approaches to planning to accurately model conformal dose distribution in the patient.
- Increased precision of treatment has permitted safe dose escalation for both early stage lung cancer and pulmonary metastases through stereotactic approaches, as well as making curative treatment easier to safely deliver for locally advanced lung cancer patients.
- Ongoing technologic developments in particle therapy and image guidance systems may further benefit lung cancer patients by increasing the precision of treatment and reducing the low-dose wash seen in current intensity-modulated planning approaches.
- The rapid evolution of radiotherapy technology means that ongoing education is required to maintain an up-to-date understanding of the imaging, planning, and delivery processes of modern radiotherapy in order to optimize the use of technology for lung cancer patients.

Radiotherapy plays a key role in the treatment of lung cancer potentially at any stage of the disease. Because lung cancer is predominantly in advanced stages at the time of diagnosis,[1] perhaps the largest overall clinical impact of radiotherapy has been in palliation of symptomatic sites. Even so, radiotherapy can be used with curative intent for a larger proportion of patients than can any other treatment modality. Major advances in the technologic aspects of both radiotherapy and medical imaging since the mid-1990s have dramatically increased the accuracy and precision of tumor targeting and treatment delivery, translating into less toxic and more curative treatment for both more advanced and earlier stage disease than has historically been treated with

radiotherapy treatment.[2] By contrast, radiotherapy generally requires a substantial technologic infrastructure, and lack of this infrastructure has been a barrier to access for patients in much of the world. It is estimated that in low-income to middle-income countries where over one-half of the global burden of cancer arises, only 25% of patients who would benefit from radiotherapy have access to it, and more than 20 countries have no access to radiotherapy at all.[3,4]

Sophistication of radiotherapy technology ranges from relatively simple to highly complex. Radiotherapy that is purely palliative in intent can result in substantial symptom relief, such as reduction of pain, airway or vascular obstruction, and hemoptysis, using relatively low doses of radiation that are tolerable even when delivered to relatively large volumes of the body.[5] In this application, highly accurate tumor localization and precise dose sculpting are less critical than simply having access to expeditious treatment with radiotherapy, and basic equipment is generally adequate. Conversely, obtaining the highest chance of local tumor control and cure with radiotherapy requires the most accurate possible determination of the tumor extent and spatial distribution and the delivery of highly dose-intensive radiation to all macroscopic tumor deposits without exceeding the tolerances of critical and sometimes sensitive normal organs.

The latter requires exquisite shaping of the radiation dose in space while ensuring highly accurate delivery to cover the entire tumor while minimizing any unnecessary radiation dose to the surrounding normal tissues. The technologies enabling such advanced radiotherapy continue to evolve rapidly and include multimodality imaging, such as x-ray CT, positron emission tomography (PET), and magnetic resonance imaging (MRI); technologies to characterize and manage tumor and organ motion, such as four-dimensional (4-D) imaging and multiple approaches to control, mitigate, or compensate for respiratory motion; advanced linear accelerator technologies, including multidirectional-shaped or intensity-modulated beams; computerized radiation planning and optimization; and particle beams with more favorable physical and/or biologic properties than conventional high-energy x-rays.

Multiple professional societies and expert panels have published guidelines on the management of lung cancer, with several providing recommendations specifically on radiotherapy techniques (see following list). In the developed world, the minimum technical standard for curative-intent lung cancer radiotherapy is considered to be linear accelerator-based 3-D conformal radiotherapy with CT-based computerized planning. This chapter will primarily focus on this technology as the base as well as on more advanced technologies. Nevertheless, we recognize that, for decades, curative radiotherapy has been accomplished with more basic technologies that may still be the best available in more-limited-resource settings. In such settings, an expert panel of the International Atomic Energy Agency has identified the baseline level of technology as cobalt megavoltage therapy with 2-D planning.[6]

In this chapter, we summarize the technologies of lung cancer radiotherapy and their use, technical requirements and quality assurance, and challenges and future directions.

Annotated List of Resources From Expert Organizations on the Treatment of Lung Cancer, Including Clinical and Technical Aspects of Radiotherapy

National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology: Nonsmall cell lung cancer (NSCLC) [http://www.nccn.org]
Guidelines that serve as a statement of evidence and consensus of the authors regarding their views of currently accepted approaches to the treatment of NSCLC.

NCCN Clinical Practice Guidelines in Oncology: Small cell lung cancer (SCLC) [http://www.nccn.org]
Guidelines that serve as a statement of evidence and consensus of the authors regarding their views of currently accepted approaches to treatment of SCLC.

American College of Chest Physicians (ACCP) Evidence-Based Clinical Practice Guidelines: Treatment of stage I and II NSCLC [Howington et al. *Chest*. 2013(5 Suppl):e278S–313S]
Collection of recommendations that address the diagnosis and management of stages I and II NSCLC.

ACCP Evidence-Based Clinical Practice Guidelines: Treatment of stage III NSCLC [Ramnath et al. *Chest*. 2013;143(5 Suppl):e314S–340S]
Collection of recommendations that address the diagnosis and management of stage III NSCLC.

ACCP Evidence-Based Clinical Practice Guidelines: Treatment of SCLC [Jett et al. *Chest*. 2013;143(5 Suppl):e400S–419S]
Collection of recommendations that address the diagnosis and management of SCLC.

ACR Appropriateness Criteria: Radiation therapy for SCLC [Kong et al. *Am J Clin Oncol*. 2013;36(2):206–213]
Report focused on developing acceptable medical practice guidelines for SCLC used by the Agency for Healthcare Research and Quality (AHRQ), as designed by the Institutes of Medicine (IOM).

ACR Appropriateness Criteria: Nonsurgical treatment for NSCLC: poor performance status or palliative intent [Rosenzweig et al. *J Am Coll Radiol*. 2013;10(9):654–664]
Report focused on developing acceptable medical practice guidelines for NSCLC used by AHRQ, as designed by the IOM.

European Society for Medical Oncology (ESMO) Clinical Practice Guidelines: early-stage and locally advanced NSCLC [Vansteenkiste et al. *Ann Oncol*. 2013;24 (Suppl 6):vi89–vi98]
European guidance document on the diagnosis, staging, and management of early and locally advanced NSCLC.

ESMO Clinical Practice Guidelines: SCLC [Früh et al. *Ann Oncol*. 2013;24 (Suppl 6):vi99–vi105]
European guidance document on the diagnosis, staging, and management of SCLC.

American Association of Physicists in Medicine (AAPM) Task Group (TG) 179: Quality assurance for image-guided radiation therapy (IGRT) utilizing computed tomography (CT)-based technologies [Bissonnette et al. *Med Phys*. 2012;39(4):1946–1963]
Report that provides consensus recommendations for quality-assurance protocols that ensure patient safety and patient treatment fidelity for CT-based IGRT systems, allowing for the widespread management of geometric variations in patient setup and internal organ motion.

ACR and ASTRO Practice Guideline: Intensity-modulated radiation therapy (IMRT) [Hartford et al. *Am J Clin Oncol*. 2012;35(6):612–617]
Guidance document designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients, with a focus on IMRT.

American Society for Radiation Oncology (ASTRO) Evidence-Based Clinical Practice Guideline: Palliative thoracic radiotherapy in lung cancer [Rodrigues et al. *Pract Radiat Oncol*. 2011;1(2):60–71]
Guidance document that provides information on the use of external beam radiotherapy, endobronchial brachytherapy, and concurrent chemotherapy in the setting of palliative thoracic treatment of lung cancer, based on available evidence complemented by expert opinion.

ASTRO and ACR Practice Guidelines: IGRT [Potters et al. *Int J Radiat Oncol Biol Phys*. 2011;76(2):319–325]
Guidance document designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients, with a focus on IGRT.

ACR and ASTRO Practice Guideline: 3-D external-beam radiation planning and conformal therapy (2011) [http://www.acr.org/guidelines]
Guidance document designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients, with a focus on 3-D conformal radiation therapy.

AAPM TG 101: Stereotactic ablative radiation therapy (SABR) [Benedict et al. *Med Phys*. 2010;37(8):4078–4101]
Report that outlines the best practice guidelines for SABR.

ASTRO and American College of Radiology (ACR) Practice Guideline: Performance of SABR [Potters et al. *Int J Radiat Oncol Biol Phys*. 2010;76(2):326–332]
Guidance document designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients with a focus on SABR.

ACR Appropriateness Criteria: Nonsurgical treatment for NSCLC: good performance status/definitive intent [Gewanter et al. *Curr Probl Cancer*. 2010;34(3):228–249]
Report focused on developing acceptable medical practice guidelines for NSCLC used by the AHRQ, as designed by the IOM.

ACR Appropriateness Criteria: Induction and adjuvant therapy for stage N2 non-small cell lung cancer [Gopal et al. *Int J Radiat Oncol Biol Phys*. 2010;78(4):969–974]
Report focused on developing acceptable medical practice guidelines for NSCLC adjuvant therapy used by the AHRQ, as designed by the IOM.

ACR Technical Standard: Performance of radiation oncology physics for external-beam therapy (2010) [http://www.acr.org/guidelines]
Technical guidance document that is designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients by outlining the role of radiation physics for external beam therapy.

AAPM TG 142: Quality assurance of medical accelerators [Klein et al. *Med Phys*. 2009;36(9):4197–4212]
Report that provides a comprehensive overview of the necessary quality assurance for a successful radiation oncology program.

ACR Technical Standard: Medical physics performance monitoring of IGRT (2009) [http://www.acr.org/guidelines]
Technical guidance document designed to serve as an educational tool to assist practitioners in providing appropriate radiation oncology care for patients, with a focus on monitoring IGRT.

ACR Practice Guideline: Radiation oncology (2009) [http://www.acr.org/guidelines]
Guidance document designed to serve as an educational tool to assist practitioners in providing overall appropriate radiation oncology care for patients.

AAPM TG 104: Role of in-room kilovoltage x-ray imaging for patient setup and target localization (2009) [https://www.aapm.org/pubs/reports/]
Report that includes a review of image-guided processes in the clinical setting and strategies for effective modification of these processes based on clinical data.

AAPM TG 75: Management of imaging dose during IGRT [Murphy et al. *Med Phys*. 2007;34(10):4041–4063]
Report that compiles an overview of image-guided techniques and their associated radiation dose levels, identifies ways to reduce the total imaging dose without sacrificing essential imaging information, and recommends optimization strategies.

RADIOTHERAPY EQUIPMENT

Imaging and Simulation Systems

Imaging and simulation systems for radiotherapy have evolved rapidly since their introduction in the early 1950s. Dedicated radiotherapy simulators initially consisted of diagnostic x-ray tubes simply mounted to replicate radiotherapy treatment geometries. Over time, simulator improvements were iteratively introduced to provide more information for 2-D, and eventually 3-D and 4-D, target localization and treatment planning. In the developed world, a combination of 3-D simulation systems, such as x-ray CT, PET, and MRI, has become the standard of care for modern lung cancer staging and radiotherapy. As simulation and imaging systems have become more sophisticated, high-quality diagnostic and functional information has become readily available, leading to more accurate lung tumor localization, treatment planning, and treatment delivery.[7]

2-D Simulation

Conventional 2-D simulators consist of a diagnostic x-ray tube that is able to image in both static and fluoroscopic modes, while reproducing the radiation properties and geometric movements of the radiotherapy treatment unit. Although the information from a conventional simulator is inherently 2-D, acquiring images at orthogonal angles can produce simplified 3-D information. It is possible to design treatment fields that encompass the target volume and spare normal tissues using 2-D simulation, but the process is typically limited to simplified or palliative lung cancer cases where more complex imaging techniques are not necessary or not available. The major disadvantage of conventional simulation is the lack of true 3-D information. This technique does not provide enough information for lung cancer treatments requiring complex beam geometries and sophisticated dose distributions.

Computed Tomography

CT simulators have become the standard of care for radiotherapy in the developed world. CT imaging data provide a complete 3-D view of the patient's anatomy, allowing for more accurate delineation of the tumor and the surrounding normal tissues. In addition, the CT data inherently include the associated tissue density information, which is a necessity for 3-D radiotherapy treatment planning.

Dedicated CT simulators are based on diagnostic CT scanners, with a few modifications. CT simulators typically include a laser alignment system as a reference for patient positioning, a 3-D imaging workstation for image visualization and manipulation, a larger bore size to accommodate patient immobilization devices, and a flat tabletop to replicate the radiotherapy treatment unit couch. CT data sets can be reconstructed in any orientation to provide coronal or sagittal slices of the anatomy, and digitally reconstructed radiographs can be created from CT data sets to resemble planar x-ray images from any angle or orientation. These characteristics allow for treatment geometries to be visualized that are possible on the treatment unit, but not possible on a conventional 2-D simulator.

Modern CT simulators are also capable of acquiring 4-D data. Four-dimensional CT simulation allows for the tumor to be evaluated at multiple time points in the respiratory cycle and for the most beneficial respiratory phase to be selected for treatment planning and delivery. The combination of these CT imaging advancements provides a simulation technique that allows for more accurate tumor localization, treatment visualization, and subsequent treatment delivery.[8]

Positron Emission Tomography

Combined PET/CT simulators are becoming increasingly common in radiation oncology departments worldwide. In the developed world, ^{18}F-2-deoxy-D-glucose (FDG)-PET–CT scans are consistently being used to provide detailed anatomic information combined with functional metabolic information for patients with lung cancer. PET–CT images have been shown to be effective for selecting patients with unresectable lung cancer for definitive radiotherapy, lung cancer staging, and delineating lung cancer target volumes.[8,9]

Combined PET–CT simulators include all of the radiotherapy-specific additions described in the previous section, with an

additional PET detector ring integrated into the simulator housing. Although PET images alone are able to provide the same useful metabolic information, combined PET–CT simulation systems mitigate image registration issues that arise when PET and CT images are acquired separately for tumor localization and treatment planning. Newer PET–CT simulators also include 4-D imaging capabilities. Like 4-D CT simulation, 4-D PET–CT allows for tumor metabolism to be evaluated at multiple time points in the respiratory cycle.

Magnetic Resonance Imaging

The use of MRI in radiation oncology is becoming increasingly common. MRI offers a way to combine high-quality anatomic and functional information, without the use of ionizing radiation. As a whole, MRI is capable of generating anatomic images with excellent soft-tissue contrast and functional images that demonstrate perfusion, diffusion, and chemical information.

MRI is often used in lung cancer radiotherapy when high soft-tissue contrast information is needed to delineate the tumor from surrounding tissues or when tumor respiratory motion analysis would benefit from images with a very high temporal and spatial resolution.[10] Although the inherent density in CT data is currently considered to be the standard for radiotherapy treatment planning, MRI units are increasingly being installed in radiation oncology departments to complement PET–CT simulators. In addition, many MRI vendors now offer larger bore sizes to accommodate patient immobilization devices and a flat tabletop to resemble other imaging modalities and the treatment unit. However, because MRI units are not integrated into CT simulators, proper image registration is necessary when MR images are used to delineate lung tumors.

Immobilization

Lung cancer immobilization devices are designed to reproduce the patient position from the time of simulation to the completion of radiotherapy. Ideal immobilization techniques and devices are able to comfortably secure the patient in an optimal position for simulation and therapy, while minimizing intrafraction motion, limiting beam attenuation, and not interfering with patient localization systems.

Immobilization systems for lung cancer radiotherapy commonly include polyurethane foam casts or evacuated vacuum bags/cushions placed underneath the patient's thorax, combined with a device to help position the patient's arms overhead. Additional pads and wedges are often added to make the patient more comfortable and increase the overall positioning reproducibility. With the rise of hypofractionated lung cancer regimens, additional abdominal compression techniques have also been used to further decrease the allowable respiratory tumor motion during simulation and the subsequent radiotherapy treatments.[11]

Treatment Planning Systems

Modern radiotherapy treatment planning systems are an integral part of the successful treatment of cancer with radiation. Treatment planning systems provide a set of computerized tools that allow the radiation oncologist, medical physicist, and treatment planner to create and visualize radiotherapy treatments, given the imaging data available. Early treatment planning systems relied solely on 2-D simulation techniques for tumor localization and treatment beam arrangement. In these systems, orthogonal pairs of 2-D images could be used to infer 3-D information for tumor localization, but treatment visualization was restricted to the available imaging planes, and dose distributions did not accurately reflect variations in tissue density.

As imaging systems and dose-calculation algorithms have advanced, so have treatment planning system capabilities. Current 3-D treatment planning systems are able to superimpose radiotherapy treatment beams on 3-D image sets with any geometry or orientation, allowing the use of a so-called beam's eye view technique to visualize the radiation beam in conjunction with the relevant patient anatomy. Furthermore, images from multiple imaging modalities can be rigidly registered to the treatment planning CT, and additional anatomic and functional information can be examined with respect to the treatment plan. Many treatment planning systems are now incorporating deformable image registration algorithms as well to accommodate the increased use of MR and PET imaging in radiotherapy. Current treatment planning systems are also able to integrate 4-D image data into the treatment planning process. Sophisticated treatment planning systems provide tools to analyze the extent of tumor motion throughout the respiratory cycle. This analysis allows the radiation oncologist to determine the optimal treatment phases for each individual tumor, while evaluating the dose distributions for any portion of the respiratory-gated treatment. 4-D treatment planning system functionality is especially beneficial for lung cancer radiotherapy.

Modern treatment planning systems also include advanced tools for treatment plan optimization and analysis. Treatment planners and medical physicists can easily adjust beam angles and weighting factors for conventional forward-calculated plans, whereas optimization parameters and associated weightings can easily be altered for inverse planning tasks. These treatment planning system capabilities streamline the overall treatment planning process. In addition, advanced treatment planning system analysis tools, such as dose–volume histograms, provide a more thorough investigation of the dose delivered to the radiotherapy target and the surrounding normal tissues. The combination of these advanced treatment planning system tools allows for accurate and efficient treatment planning for lung tumors and other cancers.

Target and Normal Tissue Delineation

Computerized 3-D treatment planning requires the identification of the spatial extent of both where the radiation dose needs to be deposited and what regions should be spared. The delineation of the target(s) and normal organs, also known as contouring, is generally made on 3-D images acquired during the simulation process, most often CT. At present, this process is primarily performed manually by an expert human observer, who draws the structures on cross-sectional image slices. However, computer software tools are often used to automate portions of this process with rapidly increasing sophistication.

Medical imaging technologies have advanced over time to provide increasingly exquisite detail that improves the accuracy of target and normal tissue delineation. The addition of metabolic imaging, particularly FDG-PET, provides increased sensitivity and specificity to guide the inclusion or exclusion of targets in the treatment volume. Nevertheless, it is important to understand the uncertainties in contouring and account for them in the treatment plan. The International Commission on Radiation Units and Measurements (ICRU) has developed a nomenclature for contouring that incorporates these concepts in the context of 3-D treatment planning and intensity-modulated radiation therapy (IMRT).[12,13] In brief, within this paradigm, the gross tumor volume refers to the extent of macroscopic tumor (i.e., visible on imaging or physical examination), whereas the clinical target volume refers to the regions at highest risk for microscopic tumor involvement. Uncertainties in the target definition are addressed by defining a larger volume that incorporates margins around these target volumes, and it is this planning target volume to which the radiation dose is

prescribed. The margins used to form the planning target volume include an internal margin to account for physiologic target motion, such as respiratory motion, and a set up margin to account for uncertainties in patient-positioning reproducibility, machine calibration, and other technical factors.

In order to optimize the treatment plan, in addition to ensuring adequate dose coverage of the targets, doses to the normal organs at risk of injury must be constrained, which requires contouring the normal organs at highest risk of injury by radiation. In the thorax, these organs generally include the lungs, esophagus, spinal cord, heart, and potentially other organs depending on the anatomic extent of the treatment volume and the dosing regimen. Atlases for standardized, consensus-based contouring for thoracic radiation therapy are useful references.[14] In addition, guidelines for normal organ dose constraints, based on a combination of clinical data, expert consensus, and constraints associated with acceptable toxicity in clinical trials are summarized in the National Comprehensive Cancer Network Guidelines for nonsmall cell lung cancer and quantitative analysis of normal tissue effects in the clinic reports.[15–19]

Dose Calculation for Lung Cancer Radiotherapy

In lung cancer radiotherapy, the transport of radiation originates in the therapy device and ends with energy deposition in the patient and beyond. There are many different types of interactions of photons and electrons, and the likelihood and characteristics of these interactions depend on the particle type, particle energy, and the material or tissue that the particles are passing through. These interactions are covered in detail in medical physics texts such as texts by Khan,[20] Johns and Cunningham,[21] and Metcalfe et al.[22] The complexity of radiation transport is exacerbated in lung cancer radiotherapy, where the density of lung tissue is approximately one-quarter of that of most other soft tissues and can range from a density very close to air in emphysematous regions to near that of soft tissue in high-density lung. Adding to this complexity are the sharp tissue density boundaries between the lung and chest wall or abdomen, lung and mediastinum, and the lung and lung tumor.

Independent of the complexity of radiation transport in lung cancer radiotherapy, a method to estimate the dose is needed for each patient's course of treatment. As imaging technology and computational power have advanced, so has the ability of dose-calculation algorithms to account for the complexity of radiation transport, resulting in algorithms in general use today having fewer and smaller errors than those of the past. Accurate radiation transport simulations of photons and electrons in lung cancer radiotherapy and the subsequent dose calculations are challenging, particularly in the following anatomic regions:

- In the lungs where the photon range and electrons set in motion by the photons will travel 3 to 10 times as far as the same particles in the rest of the soft tissue in the body due to the lower density of the lungs
- At the lung–tumor boundary lateral to the beam where there is lateral disequilibrium as more charged particles from the tumor enter the lung than vice versa resulting in a dose gradient
- At the lung–tumor boundary proximal to the beam where there is a rebuild-up of dose due to the step-up in density from the lung to the tumor
- At the tumor–lung boundary distal to the beam where there is a reduction of dose due to the step-down in density from the tumor to the lung
- Near the trachea and the main bronchi where the density inside the airways is typically 1/1000 of the density of soft tissue, and therefore there is very little attenuation of the photons and electrons
- At the chest wall and lung interface where the density changes can cause dose buildup and build-down

Knowledge of dose in the regions is important, both for the tumor where local control is related to dose and for normal tissue toxicity,[23] as pneumonitis,[16] rib fractures,[24] and other sequelae are side effects of radiation therapy. In particular, in the case of stereotactic ablative radiotherapy (SABR), in which often small treatment fields are used to treat tumors surrounded by low-density lung tissue, there is evidence that less accurate dose calculation may adversely impact treatment outcomes.[25,26]

The complexity of dose-calculation algorithms in general is higher for higher beam energies, smaller field sizes, lower density regions, and the use of IMRT or volumetric modulated radiation therapy (VMAT). Dose-calculation algorithm accuracy is also limited by the quality of the input data that are used to generate the beam models and heterogeneity corrections. Therefore both the measured beam data and the patient anatomy,[27] typically determined from CT,[28] are important parameters influencing the overall accuracy.

Dose-calculation algorithms have evolved since the 1960s to include more physics and to model the interactions of radiotherapy beams with human tissue in a more natural manner that reflects the known interaction and transport processes. The American Association of Physicists in Medicine (AAPM) Task Group 76 report on respiratory motion management recommends "that the most accurate dose calculation available be used."[29]

These algorithms can be grouped into several classes: photon transport correction methods, superposition/convolution methods, Monte Carlo methods, and finite-element methods.

Photon Transport Correction Methods

The first dose-calculation algorithms used in radiotherapy accounted for variations in tissue density by correcting for the photon transport. These algorithms, such as effective depth, effective tissue-to-air ratio, and Batho power law, account well for body surface changes and source-skin distance changes; however, in the lung, the dose relative to a homogeneous calculation assuming water only would be increased. For small fields, due to the increase in electron range, the dose to the lung actually decreases relative to a homogeneous calculation and therefore homogenous (no correction) algorithms often were used. These uses of these algorithms are declining, and if any of the following algorithms are clinically commissioned and available, they should be used.

Superposition/Convolution Methods

In superposition algorithms, the primary photon interactions from the treatment beam are determined very accurately by ray tracing. From the photon interaction sites, the dose deposited by electrons set in motion by the primary photons is computed by scaling energy deposition kernels based on the density path length between the interaction site and the deposition site. The energy deposition kernels are normally computed via Monte Carlo methods by forcing photons to interact at a point in water. The dose from the interaction of scattered photons is also computed in a similar manner. Superposition algorithms accurately account for photon transport, and account for electron transport in variable density tissue. The accuracy of superposition algorithms can be reduced at boundaries with large density differences, such as the lung–chest wall, lung–tumor, and lung–mediastinum boundaries. Given other uncertainties in lung cancer radiotherapy, such as target delineation and motion, the superposition algorithm should be sufficiently accurate for most clinical purposes.

Monte Carlo Methods

Considered the most accurate dose-calculation algorithms available, Monte Carlo methods explicitly model the transport of photons and electrons from the treatment head and into the patient using physics principles based on our understanding of the interactions of particles with matter, including quantum mechanics. Monte Carlo methods are clinically available; however, there are still many uncertainties with Monte Carlo, including the model of the specific linear accelerator used, the modeling of the patient anatomy, and the statistical uncertainty inherent in Monte Carlo calculations. A comprehensive guideline for those clinicians planning to use Monte Carlo dose-calculation methods is the AAPM Task Group 105 report.[30]

Finite-Element Methods

Another more recent class of dose-calculation algorithms uses finite-element methods to propagate radiation beams in patients. The incident particle fluence is discretized into spatial, energy, and angular distributions. This particle fluence is then propagated through the absorbing media in a grid, accounting for the attenuation and scattering of particles. This method yields results similar to those with Monte Carlo calculations.[31]

Many treatment planning systems have, at a minimum, a superposition-class algorithm as the most accurately available option. Often treatment planning systems will have more than one algorithm and use a faster algorithm; for example, the multiple iterations required for IMRT optimization. For the final dose calculation, the most accurate algorithm available should be used. The most accurate algorithm will yield the best estimate of dose to the patient that will guide the plan review process and alert the clinician to high-dose or low-dose areas of concern that need to be monitored or, in some cases, require plan modifications. The more accurate algorithm also improves the quality of data used for dose reporting and outcome analysis. A useful summary, still relevant to many algorithms in use today, is from Fogliata et al.,[32] who compared the performance of seven algorithms from four treatment planning system vendors with Monte Carlo calculations in consistent geometries. They found that as the complexity of the model of particle transport increased, so did the improved match to the Monte Carlo–calculated result, particularly with larger variations in density and higher energies.

Treatment Delivery Systems

Linear Accelerator

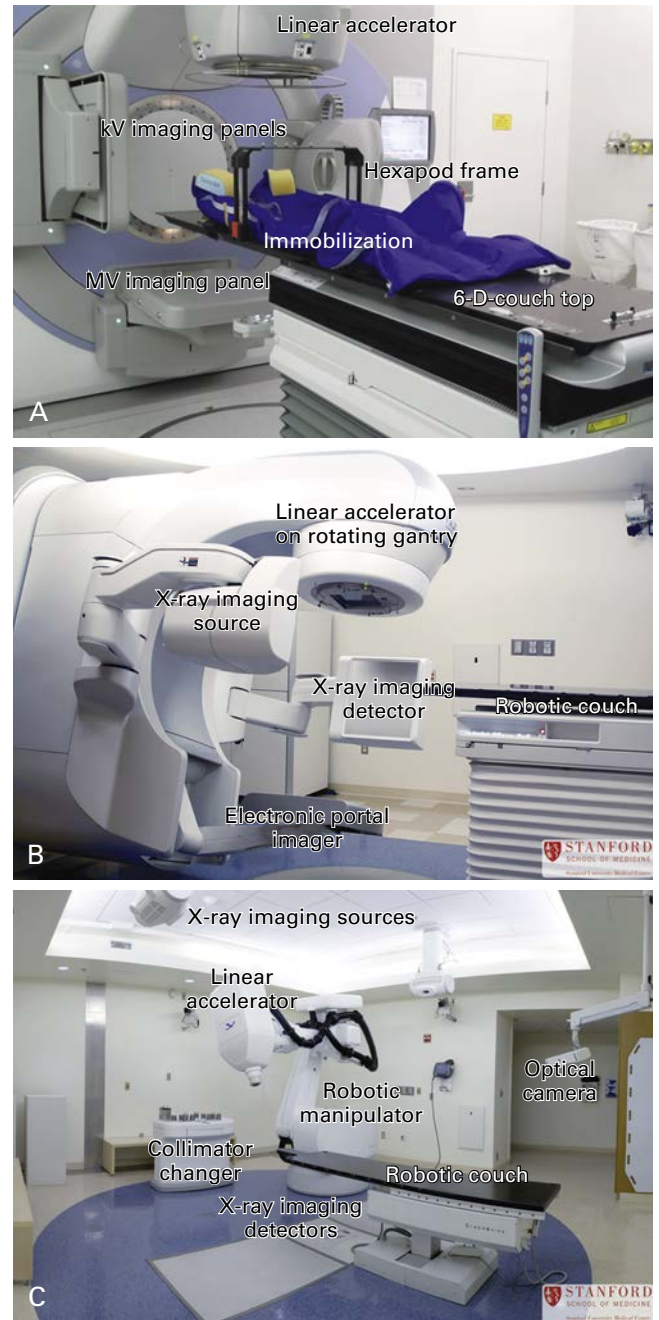
Most lung cancer radiotherapy in the developed world is delivered by linear accelerators (linacs). 4-Megavoltage (4-MV) linacs with onboard kilovoltage (kV) or MV planar imaging panels and CT planning are standard in most radiotherapy departments and are sufficient to deliver 3-D conformal radiotherapy for most patients with lung cancer. Developments in beam modulation by multileaf collimators have led to the implementation of increasingly sophisticated techniques in lung cancer radiotherapy, such as IMRT and VMAT, and the integration of image guidance technology, such as cone-beam CT and optical image guidance systems, has led to the development of sophisticated radiotherapy delivery systems that can deliver radiotherapy to moving targets with high precision. Modulated techniques that deliver precisely sculpted radiotherapy fields are attractive because they can reduce the exposure of normal tissue to radiation dose but are more complex to deliver due to the increased risk of geographically missing the radiotherapy target. In situations where the tumor is small and highly mobile, or during SABR where very large radiotherapy doses are delivered over


Fig. 34.1. Examples of modern image-guided linear accelerator radiation therapy systems. (A and B) The most common systems in clinical use have a C-arm configuration and may be used for conventionally fractionated radiation therapy as well as stereotactic ablative radiotherapy (with appropriate technical implementation). Barber, Nepean Cancer Care Centre, Penrith, Australia.)*

a short period using highly conformal radiotherapy fields, the use of more sophisticated radiotherapy delivery systems may be advantageous.

The most common linear accelerator systems have a C-arm geometry in which an open gantry rotates in a circular motion and the radiation beam is directed toward the isocenter of the gantry perpendicular to its axis of rotation (Fig. 34.1). Noncoplanar

beam arrangements are possible by combining gantry rotation with rotations of the patient couch. Imaging systems may be mounted on the gantry to provide rotating views to produce cone-beam CT images or in fixed configurations in the treatment room. Descriptions of some commercially available linacs with novel configurations of linac heads with image guidance systems follow.

The CyberKnife (Accuray, Sunnyvale, CA, USA) is a dedicated stereotactic radiotherapy system and has a 6-MV linac mounted on a robotic arm.[33,34] The robotic arm permits treatment with six degrees of freedom, and the CyberKnife is equipped with a number of image guidance systems that permit tracking of mobile radiotherapy targets. Two orthogonal kV imaging systems can image bony anatomy or fiducial markers before every one to few beams, and respiratory motion can be monitored by either external optical sensors or by assessing the motion of fiducials within a lung tumor.[35,36] Markerless tracking based on direct visualization of lung tumors is also possible for selected peripherally located lung tumors. The CyberKnife uses a nonisocentric planning technique, in which a large number of planning nodes are assigned to a treatment volume, and each node can receive a modulated beamlet given in six degrees of freedom, resulting in dose distributions that are precisely sculpted to the shape of the radiotherapy target volume. With tight dose conformity and high levels of accuracy, the CyberKnife system lends itself to stereotactic radiotherapy approaches in which extremely high doses are delivered to small moving targets within the lung parenchyma.[37,38]

TomoTherapy (TomoTherapy Inc., Madison, WI, USA) machines have a linac mounted in a CT-based ring gantry, allowing the delivery of a fan-shaped radiotherapy beam as the linac head rotates around the patient. An MV CT is incorporated to allow the acquisition of MV CT images for image guidance. TomoTherapy is capable of rapidly delivering long, precisely shaped radiotherapy fields without the need for junctions between fields.[39]

Cobalt Therapy Systems

Cobalt-based radiotherapy delivery systems are in widespread use throughout the developing world.[4] These permit the delivery of MV radiotherapy beams, with less complex quality assurance and maintenance than linear accelerators.

There have been developments in cobalt technology, which allow the delivery of sophisticated radiotherapy plans in combination with image-guided radiotherapy. The ViewRay (ViewRay Inc., Oakwood Village, OH, USA) system has three Cobalt-60 heads with multileaf collimators mounted in a rotating gantry. This is combined with a split-magnet MRI system, which allows the acquisition of MR images during radiotherapy beam delivery. These images can be used to assess the accuracy of radiotherapy beam delivery to the target or to facilitate real-time adaptation of the radiotherapy treatment plan.

Hadron Therapy Systems

Proton therapy is the most common form of hadron therapy. Protons are positively charged particles that are accelerated to very high energies (70 MeV to 250 MeV) by cyclotrons or synchrotrons, then transported through a series of vacuum tubes and magnets into treatment delivery rooms where they are delivered through a snout (collimator) that shapes the proton beam.[40] The main advantage of proton beams is that the beams deposit most of their energy abruptly in a confined spatial extent, reducing the incidental irradiation of surrounding tissues for a given dose to the target. Proton-beam delivery systems have evolved from fixed gantries with a single beam to rotating gantries that can deliver multiple proton beams capable of delivering radiotherapy plans

of high precision and complexity. The size and expense of proton therapy systems have limited their widespread availability. However, a large number of proton radiotherapy facilities are under development with many lung cancer clinical trials for proton therapy ongoing at the time of publication.[41]

TREATMENT DELIVERY FOR NONSMALL CELL LUNG CANCER

The evolution of radiotherapy treatment techniques for nonsmall cell lung cancer has been largely driven by innovations in our ability to image the tumor during the planning process and increasingly accurate image verification techniques during treatment delivery. The use of 3-D CT-based planning is now commonplace in many departments, permitting the development of more refined dosimetric assessments, such as using dose–volume histograms and volumetric analyses to analyze the relationship between dosimetry and toxicity. In turn, incorporation of this knowledge has led to a search for greater conformity with the development of 3-D conformal radiotherapy and the increasing use of IMRT and VMAT.

2-D Planning Simulation

2-D planning is based on landmarks, which are palpable externally, or visible on planar simulation films. 2-D planning does not permit the assessment of doses to individual internal organs, and the ability to predict toxicity or to ensure accuracy of treatment delivery is limited in comparison with 3-D conformal radiotherapy. The process of 2-D planning follows.

- *Image acquisition:* Planar images of the lung tumor are acquired using a simulator. The degree of respiratory excursion can be assessed to some extent on the planar images, which may be used as a guide to choosing an appropriate field size.
- *Patient contour acquisition:* An external surrogate, such as a strip of lead, is used to acquire an external patient contour at the level of the tumor.
- *Planning:* The external patient contour and the size and approximate position of the tumor are mapped, and a cross-sectional representation of the patient is constructed. The isodoses of the fields that have been selected are then mapped onto this cross section, allowing calculation by hand of the monitor units required to deliver the dose.

Conformal Radiotherapy: 3-D Conformal Radiotherapy, IMRT, and VMAT

The introduction of 3-D CT-based planning was a tremendous innovation in radiotherapy planning, permitting for the first time the 3-D visualization of tumors and organs at risk. The information from CT could be used for more accurate planning of lung radiotherapy for patients, based on the electron-density information provided by CT. The relationship between doses to the lung and pulmonary toxicity began to be explored, which permitted the development of 3-D conformal radiotherapy and eventually the introduction of IMRT and VMAT. In the contemporary practice of lung radiotherapy, the planning CT may be fused with functional imaging such as PET or MRI to facilitate accurate delineation of the tumor.

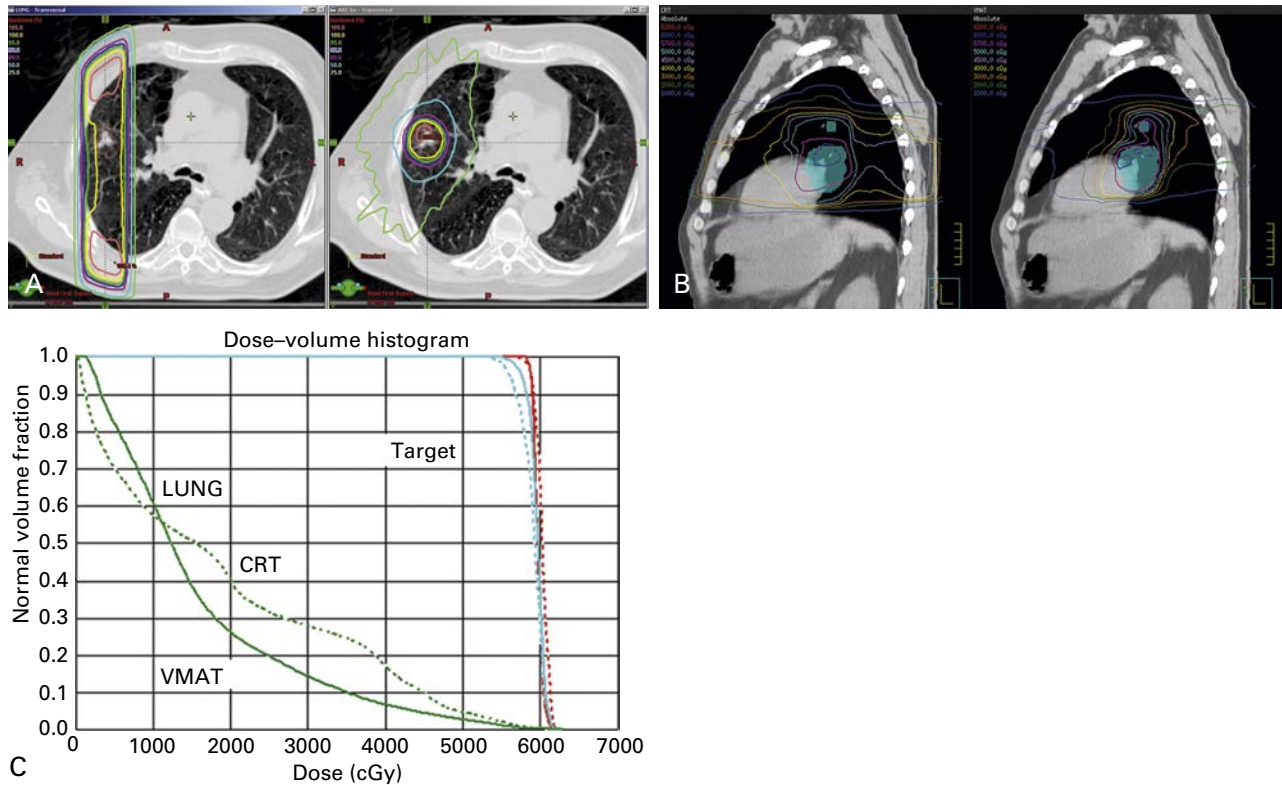
Planning concepts have developed in parallel with the dissemination of CT technology. The planning concepts for 3-D conformal radiotherapy were defined in ICRU 50 and 62.[12,42] The concepts of gross tumor volume, clinical target volume, and planning target volume were defined, and adequate coverage of the planning target volume specified that the planning target volume required coverage between 95% and 107% of the prescribed dose.


Fig. 34.2. (A) Comparison of conventional anterior–posterior postage stamp fields for medically inoperable early stage lung cancer (left) with an arc-based stereotactic ablative radiotherapy (SABR) plan (right). In the conventional plan, the highest doses are in normal tissues, preventing the use of ablative doses, whereas the conformal SABR plan minimizes normal tissue irradiation and permits ablative treatment of the tumor. *(Courtesy B.W. Loo, Stanford, CA.)* (B) Comparison of 3-D conformal radiotherapy (left) and volumetric modulated arc therapy (VMAT; right) plans for locally advanced lung cancer. Conformity of the high-dose region (95% isodose in *steel pink*) is improved with VMAT compared with 3-D conformal radiotherapy, with smaller amounts of normal lung exposed to potentially damaging radiotherapy (20-Gy isodose in *green*). *(Courtesy K. Anslow, Nepean Cancer Care Centre, Penrith, Australia.)* (C) Dose–volume histograms comparing VMAT *(solid lines)* and 3-D conformal radiotherapy *(dotted lines)* plans for locally advanced lung cancer. The volume of normal lung exposed to potentially damaging radiotherapy is reduced with VMAT, but the low-dose wash of 5 Gy covers a larger volume. Radiotherapy planning target volume coverage is equivalent with lower exposure to normal lung. *CRT,* conformal radiotherapy. *(Courtesy K. Anslow, Nepean Cancer Care Centre, Penrith, Australia.)*

In 3-D conformal radiotherapy, beams are placed and adjusted by the dosimetrist or physicist. The beam weighting and angles can be adjusted, but there is no modulation of the beam during treatment. IMRT uses multiple small beams for which fluence may be modulated during treatment delivery. In addition, the process of planning is inverse rather than forward planned, that is, the objectives of the plan that the planner wishes to achieve are specified at the beginning of the planning process, and the planning software optimizes the plan to meet these prespecified criteria. In comparison with 3-D conformal radiotherapy plans, IMRT plans may have a large number of highly modulated beams. This permits great conformity as the high-dose region can be precisely sculpted to match the shape of the planning target volume. However, the large number of beams increases the low-dose wash in IMRT plans, and IMRT plans can be much more heterogeneous than 3-D conformal radiotherapy plans with steep dose gradients. In lung cancer, the heterogeneity of IMRT plans may be exacerbated by the low electron density of pulmonary tissue. In addition, though evidence is contradictory, it is possible that the risk of pneumonitis is related to the low-dose wash in normal lung,[43] which is increased with IMRT because beams are delivered from a large number of angles. The implementation of IMRT requires

care to minimize the risk of geographic miss associated with increased conformity of the high-dose regions, particularly with mobile lung tumors. Incorporating an evaluation of low-dose wash is also important to minimize the risk of toxicity. Despite these risks, the use of IMRT confers great benefits for patients receiving lung radiotherapy, permitting greater sparing of normal tissue and the ability to deliver a higher dose to the tumor; IMRT has also been safely demonstrated in several large series.[44,45]

VMAT is a later development that differs from IMRT as the modulated beam rotates continuously in one or more arcs around the patient. VMAT has been shown in a number of studies to be able to deliver highly conformal dose distributions.[46,47] However, the major advantage of VMAT is the rapid delivery time in comparison with conventional multiple-beam IMRT. VMAT treatment techniques have varying degrees of dose conformity for early stage and locally advanced lung cancer (Fig. 34.2).

The search for methods to reduce toxicity led to the recognition that there was a limited understanding of tumor and normal tissue organ motion during radiotherapy treatment. Evidence from other sites demonstrated the dangers of geographic miss of the tumor with a tightly conformal radiotherapy field. 4-D CT images the tumor over at least a full respiratory cycle and then

binds images from each part of the respiratory cycle together to create a composite image of the movement of the tumor over time. The use of 4-D CT has allowed clinicians to restrict treatment of the tumor to a specific part of the respiratory cycle (gating) and to create radiotherapy target volumes that are more likely to reflect the true position range of the tumor during radiotherapy treatment.

Hadron Therapy

Charged-particle (hadron) radiotherapy can deliver superior dose distributions compared with photon radiotherapy techniques. Unlike photons, the energy loss of a charged particle is relatively small until the end of the range of the particle. The remaining energy is lost over a small distance, forming the Bragg peak. Radiotherapy planning with charged particles exploits these physical characteristics, concentrating the Bragg peaks of multiple charged-particle beams within the radiotherapy target. A number of different charged particles have been used in radiotherapy for lung cancer, but most patients have been treated with protons. Studies in patients with lung cancer treated with proton therapy have demonstrated the safety and efficacy of this technique.[47–49] As the dose to normal tissue can be reduced when compared with standard photon-based techniques, the use of charged-particle therapy may also permit safer dose escalation in patients receiving lung radiotherapy.[50]

Delivery of Conformal Radiotherapy: Image-Guided Radiotherapy

The development of radiotherapy planning technology has facilitated new treatment approaches, such as SABR in which high doses are delivered to small moving targets using highly conformal radiotherapy plans. The increasing conformity of radiotherapy plans potentially reduces the risk of toxicity to surrounding organs at risk, but demands increasingly sophisticated image guidance technology to ensure accurate delivery to the target volume.

- *Electronic portal imaging:* Electronic portal imaging panes are standard on modern linacs and may be used to take orthogonal images prior to treatment. The electronic portal imaging panels may be used for set up based on bone landmarks but are unable to provide sufficient resolution of soft-tissue anatomy to allow soft-tissue matching in general.[51]
- *Cone-beam CT:* An increasing number of linacs are equipped with either kV or MV cone-beam CT. The image quality obtained from cone-beam CT is inferior to diagnostic CT but is still sufficient to permit matching on the basis of soft-tissue anatomy.[52] Some vendors have also made 4-D cone-beam CT available,[53] permitting the assessment of tumor motion on the linac.
- *ExacTrac (Brainlab AG, Feldkirchen, Germany):* The ExacTrac system uses two kV imaging panels that take orthogonal kV images of the bony anatomy and radiotherapy target. This system may be coupled with external optical sensors that can be used to track patient motion during radiotherapy beam delivery or for respiratory motion management.[54]
- *Intrafraction imaging approaches:* A number of approaches have been developed to assess patient and tumor motion while the radiotherapy beam is being delivered.
- *CyberKnife:* During a CyberKnife treatment, more than 100 small radiotherapy beamlets deliver the dose to the target. kV images may be acquired prior to every beam or every few beams, allowing compensation for patient motion or tumor motion.[34] The motion of targets that move with respiration can be predicted by combining external optical sensor tracking of respiratory motion with direct visualization of fiducial markers or the tumor.

- *Implanted markers with radiofrequency guidance:* The Calypso System (Varia Medical Systems, Palo Alto, CA, USA) and other similar systems use markers that emit radiofrequency signals. The position of the marker can be determined by triangulation of the signals, and the radiotherapy beam delivery can be adapted to match the position of a moving tumor target.[55]

MOTION MANAGEMENT

As modern radiation therapy has enabled the delivery of increasingly conformal dose distributions, the importance of understanding and addressing uncertainties in target localization relative to the treatment plan correspondingly increases. One substantial source of uncertainty arises from the fact that targets in the thorax generally move from a number of causes, especially breathing. The magnitude of respiratory motion depends on several factors, such as anatomic location within the thorax, and conditions, such as chronic obstructive pulmonary disease, but also exhibits wide individual patient variability.[56,57] While most tumors move only a small amount, motions of up to several centimeters is possible. The primary objectives of respiratory motion management are to ensure adequate dose coverage of the tumor and to reduce incidental irradiation of normal organs. The process involves characterizing tumor and organ motion, selecting a motion management strategy, and verifying accurate implementation of that strategy by image guidance at the time of treatment. Recommendations for implementation of respiratory motion management strategies are summarized in the report of AAPM Task Group 76.[29]

The most basic approach to managing respiratory motion is to individualize the target design to cover the range of motion during free breathing for each given patient. This is appropriate for most patients as respiratory motion is limited in most. The magnitude of motion can be assessed as part of CT-based simulation by a number of techniques, including slow scanning CT, two-phase inhale/exhale CT, and respiratory-correlated (4-D) CT. Fluoroscopy may also be used as an adjunct to CT to estimate the degree of respiratory excursion. Targeting based on individual patient motion assessment avoids the over-targeting and under-targeting inherent when using a single population-derived respiratory motion target expansion for all patients.

Many more sophisticated options are available for respiratory motion management, requiring different levels of technology, procedural invasiveness, and cooperation from the patient. Some of these approaches depend on the implantation of fiducial markers in or near the tumor or other anatomic structures as surrogates for localizing the corresponding structures. A procedure must be performed to implant internal markers, generally by bronchoscopy or endoscopy or percutaneously under CT or other image guidance. These markers are most commonly used with planar x-ray images or fluoroscopy, in which case they are metallic radio-opaque markers. They may also be radiofrequency transponders whose positions can be read nearly continuously by an external electromagnetic array.

Motion management techniques may also be categorized as those that reduce respiratory motion and those that compensate for free-breathing motion. Methods for reducing respiratory motion include mechanical restriction of motion, such as by external compression of the abdomen to restrict diaphragmatic excursion or by modifications of breathing, such as breath hold or shallow breathing. By contrast, methods for free-breathing motion management include respiratory gating, in which the radiation beam is turned on only during a portion of the breathing cycle in which the target is at a prespecified location, and dynamic tumor tracking, in which the radiation beam follows the target as it moves with breathing. Fig. 34.3 shows an example of respiratory-gated radiation therapy.
Fig. 34.3. A conceptual example of respiratory gating for a tumor with a large excursion during breathing. The beam is on only during a portion of the respiratory cycle (during exhale in this example). This permits use of smaller treatment margins and less irradiation of normal lung tissue. It is important to use image-guidance techniques to verify that this complex treatment is delivered accurately.

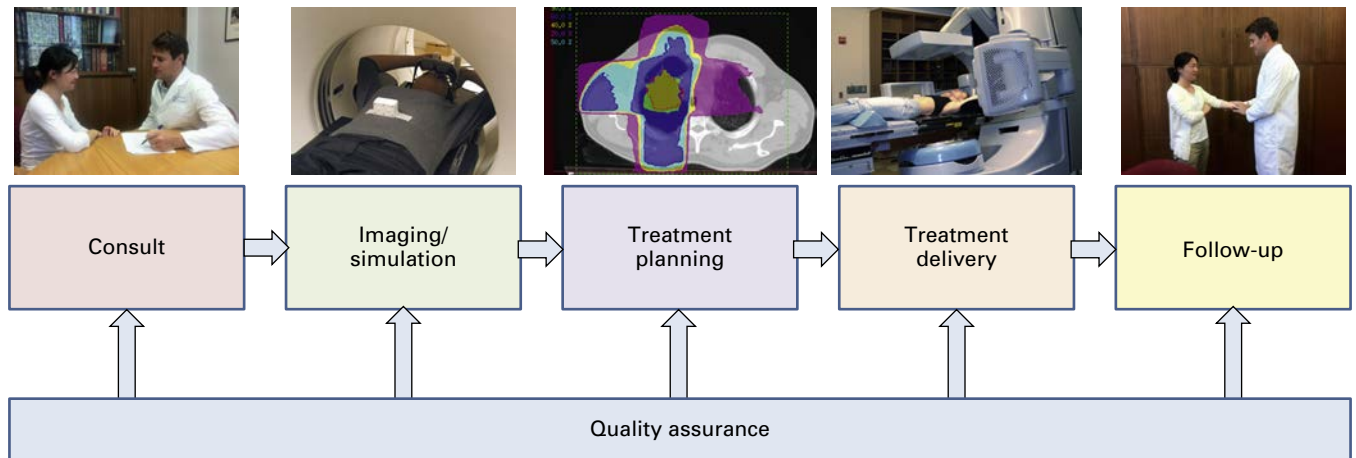
The lung cancer radiotherapy process


Fig. 34.4. Quality assurance underpins each step of the lung cancer radiotherapy process.

With all of these strategies, particularly the more complex ones used with the intent of reducing treatment margins, it is important to ensure that the strategies are achieving the intended result by confirming that the tumor location is as planned when the beam is being delivered. This confirmation is primarily accomplished through image guidance (previously discussed), with each motion management method having specific image guidance strategies that are most appropriate. Particularly, when external surrogates of internal anatomy (such as surface markers) are used to control the radiation beam, imaging should be used to confirm that they correspond accurately to the internal anatomy locations at all times during treatment delivery. Each motion management approach has its strengths and weaknesses, and it is most important that practitioners fully understand the uncertainties in the method of choice and how to mitigate them.

QUALITY ASSURANCE FOR LUNG CANCER RADIOTHERAPY

Cancer radiotherapy uses large doses of radiation that when misused can, and has, caused harm to patients and operators alike. Quality assurance in all aspects of the radiotherapy process is

critical to achieve the highest likelihood of treatment success and to reduce the likelihood and impact of errors (Fig. 34.4). The traditional approach to radiation therapy is being transformed into a more industrial approach using analyses to determine potential errors, or failure modes characterized as most likely, most severe, and hardest to detect, and allocate a proportionate amount of the quality-assurance budget to these failure modes.[58] The forthcoming AAPM Task Group 100 Report will detail this new approach.

In lung cancer, similar to other cancer sites, radiotherapy development and adherence to written guidelines for patient selection, patient immobilization devices, 3-D/4-D CT and/or PET imaging, target and normal tissue delineation, margin determination, planning approach, and dose–volume constraints, and treatment delivery are important.[59]

Lung cancer radiotherapy requires additional quality-assurance procedures over many other radiotherapy procedures due to the dose-calculation challenges from the low-density lung and the motion management methods previously discussed.[29] For example, if respiratory monitors are being used for breath-hold, gated, or tumor-tracking treatments, then the accuracy of these monitoring systems, in isolation and as part of an internal/external correlation model, needs to be verified. Breath-hold

methods require patient training, and therefore staff training is necessary to coach and advise the patients. Due to the respiratory motion occurring during imaging and treatment, special procedures and care should be taken when implementing image-guided radiotherapy procedures. Another challenge of respiratory motion is the interplay effect,[60] a phenomenon introducing dose uncertainty when the motion of the beam and tumor are uncorrelated, which is exacerbated with IMRT procedures.

As with all radiotherapy procedures, constant vigilance by the treatment staff is important. Training and education for all staff involved with lung cancer radiotherapy, as well as periodic retraining, is recommended. A physicist should be available to solve any hardware-related problems. Staffing levels appropriate to the technology, workflow, and patient load are essential.

FUTURE DIRECTIONS IN LUNG CANCER RADIOTHERAPY

Early Stage Lung Cancer and Pulmonary Metastases

SABR is a newer technology in which high doses per fraction are given over a short period of time. The delivery of SABR demands high levels of confidence in the entire quality assurance and planning process from the acquisition of simulation images through the use of complex planning techniques, right through to beam delivery.[61]

A large and increasing body of evidence indicates that SABR is highly effective and that it may be delivered with minimal toxicity. In comparison with conventionally fractionated radiotherapy, SABR has high local control rates and has been associated in population-based analysis with an increase in the survival of elderly patients, who are more likely to be inoperable.[62,63] A large number of studies have shown that SABR may be safely delivered to small, peripheral lung tumors. However, centrally located and larger tumors require dose modification for safe treatment,[64] and ongoing investigations at the time of publication are exploring optimization of SABR for these tumors.

SABR may also be used to treat pulmonary metastases, and there is an increasing body of evidence for the role of ablative radiotherapy to increase both local control and potentially affect survival in patients with oligometastatic disease.[65]

Locally Advanced Lung Cancer

Locally advanced lung cancer remains challenging to treat, with poor local control and high rates of systemic relapse. While the results of the Radiation Therapy Oncology Group (RTOG) 0617 trial have demonstrated that radiation dose escalation to 74 Gy compared with 60 Gy with or without the addition of cetuximab to carboplatin/paclitaxel-based chemoradiation does not increase the survival in locally advanced lung cancer and may increase the patient-assessed toxicity of treatment,[66–68] the results of standard-dose chemoradiation with the high level of quality assurance maintained on that study were nevertheless favorable compared with historical outcomes in this patient population. Future directions related to dose optimization include isotoxic and individualized adaptive dose intensification, an approach that is being tested in the RTOG 1106 trial using metabolic imaging (FDG-PET) as the basis for defining the target volume for higher doses.

Considering the high rates of systemic progression in locally advanced lung cancer, the integration of systemic therapies with radiotherapy continues to be an active area of research. The optimal approach to integrating molecular diagnostics and molecularly targeted therapies and immunotherapies into the curative treatment of locally advanced lung cancer is the subject of numerous active and developing clinical trials.

Individualizing Treatment

Increasingly, thoracic oncologists are focusing on personalizing the approach to patients with lung cancer. Genetic profiling of tumors is already being used to select systemic therapies for patients with lung cancer. Recent work is examining tumor cell burden during and after treatment and may be able to provide prognostic information for patients receiving radiotherapy for lung cancer, eventually identifying patients who could benefit from dose escalation or de-escalation.

A number of investigators are also examining the role of adaptive radiotherapy based on planning using the individual patient's lung biology.[69,70] Assessments of regional lung function may facilitate avoidance of normal lung, reducing the risk of radiotherapy-induced lung toxicity, and imaging assessments during treatment may permit adaptive radiotherapy to mirror the changes seen in tumor size and shape during radiotherapy.[71]

Technical Advances in Radiotherapy Planning and Imaging

The introduction of complex planning techniques has allowed the delivery of highly conformal radiotherapy plans to increasingly large tumor volumes.[72] The potential impact of larger volumes of low-dose wash on lung toxicity from such conformal plans will need to be understood better, and clinical data are continually emerging. Meanwhile, developments in proton and heavy-ion therapy will ultimately reduce both high-dose and low-dose incidental irradiation of normal organs.

Finally, ongoing developments in image guidance will likely lead to the widespread introduction of imaging technologies, such as intrafraction motion monitoring and 4-D cone-beam CT.[53,73] These technologies will in turn facilitate increasing precision in radiotherapy planning and delivery, as the delivery of highly conformal radiotherapy plans and tracking and gating of lung tumors become possible for a larger number of radiotherapy departments.

CONCLUSION

Radiotherapy plays a crucial role in the treatment of lung cancer. The technologies of radiotherapy, bolstered by advances in imaging technologies, have advanced dramatically in recent years, creating new opportunities for improved clinical outcomes in lung cancer. The current technical baseline in developed countries is CT-planned 3-D conformal radiotherapy. Much more sophisticated and promising technologies are being adopted rapidly and being evaluated in clinical trials. By contrast, access to basic radiotherapy is sorely lacking for large populations worldwide. The future of radiotherapy for lung cancer will include both optimizing the use of advanced technologies and increasing its access globally for the treatment of this leading cause of cancer death worldwide.

35 Radiobiology of Lung Cancer

Jose G. Bazan, Quynh-Thu Le, and Daniel Zips

SUMMARY OF KEY POINTS

- The hallmarks of radiobiology are the "4 Rs": *r*epair, *r*eassortment, *r*eoxygenation, *r*epopulation.
- Radiation exerts its biologic effects by causing damage to DNA.
- The linear–quadratic model provides a convenient method to compare different radiation dose and fractionation schedules.
- Radiobiologic principles have underpinned the rationale for many early clinical trials in lung cancer testing including the use of alternative fractionation schedules.
- Ultra-high doses of radiation may have other mechanisms of cell killing in addition to causing DNA damage.
- Chemotherapy is most often used to sensitize the effects of radiation and improve local control in patients with locally advanced lung cancer.
- Tumor hypoxia is a major problem in treating lung tumors; clinical trials that have tried to reverse hypoxia have shown mixed results.
- Predictive biomarkers of radiation response are the subject of continued research.

Radiobiology is central to an understanding of the principles of radiotherapy today. In the early 20th century, the use of large, single doses of radiation declined as scientists and clinicians recognized that these doses caused considerable damage to normal tissues. Radiation oncologists then began applying smaller daily doses over a period of several weeks as a way to reduce this damage yet still achieve tumor control. In the 21st century, radiation oncologists have again been using large doses of radiation, over one to several days, as advances in technology now enable them to more precisely target the tumor while minimizing the amount of normal tissue exposed. In this chapter, we explore the basic tenets of radiation biology in order to understand the rationale behind these vastly different approaches as they apply specifically to the treatment of lung cancer. We also examine ways to exploit the radiobiology of lung cancer by using various strategies, including alternative fractionation schedules, concurrent chemotherapy with radiation, and modifiers of tumor hypoxia. We conclude with a look toward the future of personalized care, by examining potential biomarkers that may be used to predict response to radiotherapy.

RADIOBIOLOGIC BASIS OF CONVENTIONALLY FRACTIONATED RADIOTHERAPY

This section provides a review of the basic principles of radiobiology, including the mechanism of action of x-rays, the linear–quadratic (LQ) model of cell survival, and the four Rs of radiobiology. Taken together, these fundamentals help explain why radiation is most commonly delivered as a fractionated course over 5 weeks to 6 weeks.

DNA: The Critical Target for the Biologic Effects of Radiation Damage

The biologic effects of radiation result principally from damage to a cell's DNA. The damage induced by radiation can be direct or indirect. Direct DNA damage occurs when the absorption of a photon by an atom releases an electron (a secondary electron) that then directly interacts with the DNA molecule. Indirect damage occurs when the secondary electron reacts with a water molecule to produce a free radical. It is the production of this free radical that leads to the DNA damage. Most of the DNA damage produced by the high-energy photons used in most medical linear accelerators is indirect damage.[1]

The types of DNA damage produced by radiation include base damage (>1000 lesions per cell per Gy), single-strand breaks (approximately 1000 per Gy), and double-strand breaks (approximately 20–40 per Gy).[1] Among these lesions, DNA double-strand breaks correlate best with cell killing, because they can lead to certain chromosomal aberrations (dicentrics, rings, anaphase bridges) that are lethal to the cell. Lethality, from the perspective of radiation biology, means the loss of reproductive integrity of tumor clonogens; that is, the tumor cells may still be physically present or intact and may still be able to undergo a few cell divisions, but they are no longer able to form a colony of cells.[1]

The Linear–Quadratic Model

Cell survival curves have a characteristic shape when plotted on a log-linear scale with radiation dose on the x-axis and the log of cell survival on the y-axis. At low doses, the curve tends to be straight (linear). As the dose increases, the curve bends over a region of several Gy; this region is often referred to as the shoulder of the survival curve. At very high doses, the curve tends to straighten out again.[1]

Many biophysical models have been proposed to mathematically capture this relationship between radiation dose and cell survival. A comprehensive review of all of these models is beyond the scope of this chapter but can be found in Hall and Giaccia[1] and Brenner et al.[2] The most commonly used model is the LQ model, which assumes that there are two components to cell killing: one that is proportional to the radiation dose and another that is proportional to the square of the dose.[1] Cell survival in this model is represented by the following exponential function:

$$S(D) = e^{-(\alpha D + \beta D^2)} \qquad \text{[Eq. 35.1]}$$

where S is the fraction of cells surviving a dose, D; e is the mathematical constant approximately equal to 2.71828; and α and β are constants that represent the linear and quadratic components of cell killing, respectively. At dose $D = \alpha/\beta$, the contributions from the linear and quadratic components of cell killing are equal.

The LQ model is convenient in that it depends on only two parameters (α and β) and it is relatively easy to manipulate mathematically. However, there is also a biologic rationale for using this model. As mentioned earlier, DNA double-strand breaks are believed to be the primary mechanism leading to cell death.

A single hit of radiation (one electron) can cause lethal injury by inducing breaks on two adjacent chromosomes (αD component). However, when two separate electrons cause the two chromosome breaks, cumulative injury can occur, and the probability of this occurrence is proportional to the square of the dose (βD^2).[1]

The Four Rs of Radiobiology

The principles underlying fractionated radiotherapy can best be understood in terms of the classical four Rs of radiobiology: *r*epair, *r*eassortment, *r*eoxygenation, and *r*epopulation.[1]

Repair

Repair refers primarily to the ability of normal tissues to recover from sublethal DNA damage. Sublethal damage repair is the operational term for the increase in cell survival that is seen when a given radiation dose is split into two fractions separated by a time interval. Sublethal damage repair is simply the repair of DNA double-strand breaks.[1] In terms of the LQ model, tissues that have a greater capacity for DNA double-strand break repair have larger values for β and, therefore, a low α/β ratio. By contrast, most tumors and acutely responding tissues have a low capacity for repair and, therefore, a high α/β ratio.

Reassortment

Experiments have demonstrated that the most radiosensitive phases of the cell cycle are the M and G_2 phases and the most radioresistant phase is the late S phase.[1] Reassortment is the principle that cells progress through the cell cycle during the interval between two doses of radiation. Cells that were not killed by the first dose of radiation were likely in a radioresistant phase of the cell cycle at that time. Between the first and second doses of radiation, these cells would have time to progress to the M or G_2 phase, and thus they would be more sensitive to the second dose of radiation.

Reoxygenation

The presence of oxygen within microseconds of radiation exposure is crucial for radiation-induced cell killing. Oxygen acts at the level of free radicals to effectively fix the radiation damage by inducing a permanent conformational change in the DNA molecule.

In the absence of oxygen (hypoxic conditions), as much as triple the amount of radiation may be needed to induce as much cell killing as would occur in the presence of oxygen.[1] Most tumors have areas of hypoxia. Hypoxia can be acute or chronic: acute hypoxia results from the temporary closing or blockage of a blood vessel, whereas chronic hypoxia results from the limited diffusion distance (70 μ) of oxygen.[1]

In the late 1960s, Van Putten and Kallman[3] performed a set of experiments to determine the proportion of hypoxic cells in a transplantable sarcoma in a mouse model. They measured the proportion of hypoxic cells in the untreated tumor at 14%. They then administered five fractions of daily radiotherapy (1.9 Gy per fraction) to the tumor on Monday through Friday. The subsequent Monday, the hypoxic fraction was nearly the same, at 18%. They repeated the experiment except that they administered four fractions of 1.9 Gy each to the tumor on Monday through Thursday, and the hypoxic fraction measured on Friday was again constant at 14%.

These experiments provided some of the first evidence that reoxygenation occurs between deliveries of fractions of radiation. If reoxygenation did not occur, the proportion of hypoxic tumor cells would be expected to increase by the end of a fractionated course of treatment. Therefore if enough time is allowed for reoxygenation to occur, the negative effects of hypoxia can be overcome.

Repopulation

Fractionation of radiation can lead to an increase in the surviving fraction of cancer cells if the interval between the two doses of radiation exceeds the length of the cell cycle time needed for the tumor cells to divide. Therefore repopulation of tumor cells as a result of fractionation can be detrimental. In addition, treatment with any cytotoxic agent (e.g., chemotherapy drug or radiation) can trigger surviving tumor cells to divide faster than their normal cell cycle time or can reduce the number of cells lost; this phenomenon is known as accelerated repopulation.[4] A high level of evidence supports this phenomenon in human tumors, including tumors of the lung and squamous cell carcinomas of the head and neck and the cervix. Because of this phenomenon, it is recommended that radiotherapy courses be completed without interruption.

Summary

The use of conventionally fractionated radiotherapy can now be understood in terms of the four Rs of radiobiology. Advantages of fractionation include reoxygenation of tumor cells to overcome hypoxia, reassortment of tumor cells into more sensitive phases of the cell cycle, and repair of sublethal damage in normal tissues to help reduce radiation toxicity. The main disadvantage of a fractionated course of radiation is that repopulation of tumor cells may occur, especially if the treatment course is prolonged beyond the expected time frame for completion.

Biologically Effective Dose (BED)

The biologically effective dose is a single dose value that can be used to compare the effectiveness of different fractionation schemes. This quantity is derived from the LQ model.[1] For a treatment schedule of *n* fractions each of size *D*, Eq. 35.1 can be rewritten as

$$S = e^{-\left(\alpha D + \beta D^2\right)} \text{ or, alternatively,}$$

$$\text{as } \frac{1ns}{\alpha} = nD \left(1 + \dfrac{D}{\dfrac{\alpha}{\beta}} \right) \qquad \text{[Eq. 35.2]}$$

The quantity $1nS$ is referred to as the biologically effective dose. When calculating the biologically effective dose for most tumors and tissues that respond acutely to radiation injury, the α/β ratio is usually set at 10 Gy; these tumors and tissues have a low capacity for repair, so the α term dominates the ratio. Late-responding tissues (e.g., the spinal cord) have a greater capacity for repair between fractions of radiation, so the β term dominates the ratio α/β; when calculating the biologically effective dose for these tissues, $\alpha/\beta = 3$ Gy is the most common convention.

As an example, a common fractionation schedule used to treat nonsmall cell lung cancer (NSCLC) is 60 Gy in 30 fractions of 2 Gy each. Assuming $\alpha/\beta = 10$ for the tumor and $\alpha/\beta = 3$ for late-responding tissue, the biologically effective dose for this schedule would be given as follows:

$$\text{BED}_{\text{tumor}} = (30 \text{ fractions}) \, (2 \text{Gy/fraction})$$
$$1 + \frac{2 \text{Gy}}{10 \text{ Gy}} = 72 \text{ Gy} \qquad \text{[Eq. 35.3]}$$

$$\text{BED}_{\text{late-responding tissue}} = (30 \text{ fractions}) \, (2 \text{ Gy/fractions})$$
$$1 + \frac{2 \text{ Gy}}{3 \text{ Gy}} = 100 \text{ Gy} \qquad \text{[Eq. 35.4]}$$

Alternatively, a fractionation schedule now used to treat patients who have a poor performance status or who are not candidates for concurrent chemotherapy is 60 Gy in 15 fractions of 4 Gy each. Again assuming $\alpha/\beta = 10$ for the tumor and $\alpha/\beta = 3$ for late-responding tissue, the biologically effective dose for this approach is

$$BED_{tumor} = (15 \text{ fractions}) (4 \text{ Gy/fractions})$$
$$1 + \frac{4 \text{ Gy}}{10 \text{ Gy}} = 72 \text{ Gy} \qquad \text{[Eq. 35.5]}$$

$$BED_{late-responding\ tissue} = (15 \text{ fractions}) (4 \text{ Gy fraction})$$
$$1 + \frac{4 \text{ Gy}}{3 \text{ Gy}} = 100 \text{ Gy} \qquad \text{[Eq. 35.6]}$$

Although the total dose was the same in both cases (60 Gy), the treatment schedule of 15 fractions of 4 Gy each has a higher tumor effective dose than the schedule of 30 fractions of 2 Gy each, but the 15-fraction schedule confers a higher risk to the late-responding tissue, such as the spinal cord if it is kept in the high-dose areas. The biologically effective dose is therefore a very useful tool that radiation oncologists often use when varying the fraction size from the standard 2 Gy/d. However, this simple concept does not take into account other factors that affect the biologically effective dose, such as repopulation, reassortment, and reoxygenation. In addition, the applicability of the LQ model for estimating the biologically effective dose at larger doses per fraction is under debate, as will be discussed.[5]

ALTERNATIVE FRACTIONATION SCHEDULES AND DOSE ESCALATION

In 1980, the Radiation Therapy Oncology Group (RTOG) conducted a prospective randomized study of various radiation dose and fractionation schedules among patients with unresectable stage III lung cancer.[6] Most of these patients were treated with conventional fractionation (CF) of 2 Gy/d to a dose of 40 Gy, 50 Gy, or 60 Gy. One group of patients received 40 Gy in a split-course fashion (20 Gy in 4 Gy/d over 5 days, 2-week rest period, 20 Gy in 4 Gy/d over 5 days). This trial showed a small benefit in local control for patients who received 50 Gy or 60 Gy compared with patients who received 40 Gy, although this benefit was no longer present after 2 years of follow-up. Nonetheless, this trial established 60 Gy given over 6 weeks as the optimal dose for stage III NSCLC.

Since that time, numerous approaches have been studied in an effort to improve the survival of individuals with locally advanced or early stage unresectable lung cancer. Alternative fractionation schedules can be used as a means of improving outcomes without worsening toxicity.

Hyperfractionated Radiation Therapy in Lung Cancer

Hyperfractionation refers to giving an increased number of fractions but smaller fraction sizes (e.g., <1.8 Gy to 2.0 Gy) to deliver a higher total dose over the same overall treatment time as with CF.[1] Hyperfractionation is most commonly performed by delivering the radiation treatments two or three times per day, as opposed to once daily with conventional fractionation. The final total dose delivered is often higher than the total dose administered on a conventional schedule. The overall goal of a hyperfractionated schedule is to achieve dose escalation and intensification while minimizing the likelihood of the late effects of radiotherapy.

Clinical Applications of Hyperfractionation

The role of hyperfractionation in treating NSCLC has been studied extensively. One of the first cooperative group trials examining this question was RTOG 81-08.[7] In this dose-finding and toxicity trial, all patients received 1.2 Gy twice daily (with 4 hours to 6 hours between fractions) to a dose of 50.4 Gy, 60 Gy, 69.6 Gy, or 74.4 Gy. No treatment-related deaths occurred, and severe toxicity (pneumonitis, esophagitis, or pulmonary fibrosis) developed in only six patients (<9%). In the long-term update, the 5-year overall survival rate was 8.3% for patients who received 69.6 Gy, which compared favorably with the rate of 5.6% seen among patients who received 60 Gy with CF in RTOG 78-11/79-17.[8]

In RTOG 83-11, 848 patients were randomly assigned to one of five arms: 60.0 Gy, 64.8 Gy, 69.6 Gy, 74.4 Gy, or 79.2 Gy.[9] The fractionation schedule for all arms was 1.2 Gy twice daily separated by 4 hours to 8 hours. No significant differences were found in early or late effects of radiotherapy across all the treatment arms. In addition, no significant differences were found in overall survival (60 Gy, 9.2 months; 64.8 Gy, 6.3 months; 69.6 Gy, 10.0 months; 74.4 Gy, 8.7 months; and 79.2 Gy, 10.5 months). In a subgroup analysis of patients with favorable characteristics as defined by Cancer and Leukemia Group B criteria (Karnofsky Performance Status 70–100 and <6% weight loss), a significant dose–response was found for median overall survival among the three arms with lowest total dose, favoring the 69.6 Gy arm: 60 Gy, 10 months; 64.8 Gy, 7.8 months; and 69.6 Gy, 13.0 months ($p = 0.02$). No significant improvements in median overall survival occurred with dose escalation beyond 69.6 Gy in this trial.

The RTOG and Eastern Cooperative Oncology Group (ECOG) conducted an intergroup trial in which they performed a direct comparison of hyperfractionation and CF in NSCLC. In RTOG 88-08/ECOG 4588,[10] patients were randomly assigned to one of three arms: CF to 60 Gy (2 Gy daily), hyperfractionation to 69.6 Gy (1.2 Gy twice daily), or induction chemotherapy followed by conventional fraction to 60 Gy. In this trial, induction chemotherapy was found to be superior to the treatments in the other two arms. In a direct comparison of patients who received hyperfractionation and patients who received CF (without chemotherapy), no significant difference in median overall survival was found (12.3 months vs. 11.4 months, respectively).

Fu et al.[11] also conducted a phase III trial comparing CF and hyperfractionation in NSCLC. In this trial, patients were randomly assigned to receive 63.9 ± 1.1 Gy CF (1.8 Gy to 2.0 Gy daily) or 69.6 ± 2.1 Gy hyperfractionation (1.2 Gy twice daily). Toxicity and overall survival did not differ significantly between the two arms. In a subset analysis of patients with stages I–IIIA disease only, 2-year overall survival and local control were significantly superior in the hyperfractionation arm (32% vs. 6% and 28% vs. 13%, respectively; $p < 0.05$ for both).

Summary

In conclusion, although there is a strong radiobiologic rationale for a hyperfractionation approach, modest dose escalation (above 60 Gy) has not led to a convincing survival advantage in the randomized setting. Nonetheless, these trials were conducted at a time when computed tomography and three-dimensional planning were not widely available, thereby leading to large radiation-treatment fields often including elective node radiation. In addition, the accuracy of staging was limited, especially because of the lack of positron emission tomography. With the technology available today and the unexpected initial

results of RTOG 06-17 (to be discussed), radiation oncologists may now be able to fully exploit the expected radiobiologic advantages of hyperfractionation and other alternative fractionation regimens.

Accelerated Fractionation Schedules in Lung Cancer

Accelerated fractionation is defined as delivering the same total dose of radiation as in CF in a shorter overall treatment time by giving two or more fractions of radiation daily.[1] The rationale for using accelerated fractionation is to overcome repopulation of clonogenic tumor cells during fractionated radiotherapy, which should result in an increase in local control for a given total radiation dose. Practically speaking, pure accelerated fractionation (e.g., delivering 60 Gy in 2-Gy fractions over 3 weeks) is not possible because acute effects of radiation become limiting. As a result, accelerated fractionation schedules in the clinic must reduce the daily fraction size, introduce a predetermined rest period (split course), or reduce the final total dose. Most accelerated fractionation schedules incorporate smaller fraction sizes given multiple times daily and are therefore hybrids of accelerated fractionation and hyperfractionation.

Clinical Applications of Accelerated Fractionation

The Medical Research Council of United Kingdom compared CF with an accelerated fractionation regimen for patients with stage I–III or unresectable lung cancer.[12] Of these patients, 37% had stage I or II disease and 82% had tumors with squamous cell histology. In this trial, the accelerated fractionation regimen consisted of continuous hyperfractionated accelerated radiotherapy (CHART). CHART was delivered to a total dose of 54 Gy given in 1.5-Gy fractions three times per day (with a 6-hour interfraction interval) over 12 consecutive days (including weekends). Patients in the CF arm received 60 Gy in 30 fractions over 6 weeks. Despite the lower total dose, patients in the CHART arm had a significant reduction in the risk of death, with a hazard ratio of 0.76, which corresponded to an increase in 2-year overall survival of 9% (29% vs. 20%; $p = 0.004$).[12] Patients in this arm had a similar relative risk reduction with respect to local disease progression, with a hazard ratio of 0.77. As indicated in a subsequent report on the trial, the results for overall survival and disease progression were maintained with longer follow-up.[13] As expected, short-term toxicity was worse in the CHART arm, with severe dysphagia occurring at a rate of 19% compared with 3% in the CF arm. The rates of late toxicity were not different between the two arms.

More recently, ECOG 2597 compared CF with accelerated fractionation radiation after induction chemotherapy (two cycles of carboplatin and paclitaxel) for patients with stage III lung cancer.[14] Patients in the CF arm received a total dose of 64 Gy (2 Gy daily). Patients in the accelerated fractionation arm received hyperfractionated accelerated radiotherapy (HART) to a total dose of 57.6 Gy in three daily fractions of 1.5 Gy (fraction 1), 1.8 Gy (fraction 2), and 1.5 Gy (fraction 3) given over 12 days. This trial was terminated early because of poor accrual. The median overall survival in the HART arm was numerically superior to that in the CF arm (20.3 vs. 14.9 months), but this difference did not reach significance. Overall, acute grade 3 or higher toxicity did not differ between the two arms, although rates of esophagitis tended to be higher in the HART arm (25% vs. 18%). The results of this study are provocative, but induction chemotherapy followed by radiotherapy is no longer the standard of care for this group of patients.

In a similar study, termed CHARTWEL (CHART weekend less), investigators compared CF given as 66 Gy in 33 fractions over 6.5 weeks with the CHARTWEL regimen of 60 Gy in 1.5 Gy fractions three times per day over 2.5 weeks.[15] No difference in overall survival or local control was found for patients in either arm, but increased acute toxicity was found among patients in the CHARTWEL arm. However, in the subset of patients with more advanced cancer and among patients who received neoadjuvant chemotherapy, patients who received the CHARTWEL regimen had a significant local control advantage.[15]

Modestly Hypofractionated Radiation Schedules

Problems with the CHART and CHARTWEL regimens include inconvenience to the patient and the radiation therapy department due to the multiple visits per day. Another way to shorten the treatment duration while maintaining once-daily treatments is to increase the daily fraction size (e.g., >3 Gy/d). This still results in dose intensification. This strategy is attractive for situations in which concurrent chemotherapy and radiation would be recommended, but the patient is unfit for combined modality therapy. Although the structures in the mediastinum (heart, esophagus) may be more sensitive to larger fraction sizes of radiation, advances in radiation treatment planning and delivery now enable more accurate targeting of the tumor volume while minimizing dose to normal tissues.

In 2013, Osti et al.[16] performed a prospective, phase II study of patients with unresectable stage III or oligometastatic stage IV NSCLC who were unfit for chemotherapy. The prescription dose was 60 Gy in 20 fractions (3 Gy/fraction). The target volumes included gross disease (tumor and involved lymph nodes) with small margins (4 mm to 5 mm for clinical target volume expansion; 5 mm for planning target volume expansion) and daily image guidance with cone-beam computed tomography scans. A total of 30 patients were enrolled. This regimen resulted in low rates of grade 3 toxicity and a 2-year overall survival of 38%.

The University of Texas-Southwestern and Stanford led a phase I dose escalation study in patients with stage II–IV (oligometastatic) or recurrent NSCLC in which the patients were not amenable to surgery, concurrent chemotherapy, or stereotactic body radiation therapy.[17] The maximum tolerated dose was defined as the dose at which over one-third of patients experienced a grade 3 toxicity up to 90 days postradiation. All patients received 15 fractions of radiation therapy at one of three different dose levels: 50 Gy (3.33 Gy/fraction); 55 Gy (3.67 Gy/fraction); or 60 Gy (4 Gy/fraction). This study also required small margins with daily image guidance. A total of 55 patients were enrolled: 50 Gy ($n = 15$); 55 Gy ($n = 21$); and 60 Gy ($n = 19$). While there were three deaths (1 in the 55-Gy arm and 2 in the 60-Gy arm), the maximum tolerated dose was not reached. The regimen of 60 Gy in 15 fractions is now being compared in a randomized trial with 60 Gy in 30 fractions in this group of patients with poor performance status (NCT01459497).

Summary

Overall, the results of accelerated fractionation regimens for treating lung cancer appear promising. Although the CHART data in particular appear to correspond well with the expected radiobiologic results of an accelerated fractionation schedule, the inclusion of a large percentage of patients with early stage (stages I–II) cancer and the high percentage of patients with squamous cell histology make it hard to extrapolate the findings to current patients with locally advanced NSCLC among whom the proportion of squamous cell histology is declining. In addition, as a result of trials such as RTOG 9410,[18] the current standard of care for patients with locally advanced lung cancer is concurrent chemoradiation therapy. Modestly hypofractionated regimens may be reasonable for patients who are not candidates for chemotherapy.

A meta-analysis of individual data from 2000 patients treated in 10 trials showed a significantly improved overall survival with modified fractionation (i.e., hyperfractionation or accelerated fractionation) for patients with nonmetastatic NSCLC (p = 0.009). For patients with small cell lung cancer (SCLC), a positive trend toward improved overall survival was found. As expected, dose intensification resulted in higher rates of acute esophageal toxicity.[19]

STEREOTACTIC ABLATIVE RADIOTHERAPY

Stereotactic ablative radiotherapy (SABR), also known as stereotactic body radiotherapy, employs extreme acceleration by delivering a large radiation dose per fraction over one to five treatments. This type of therapy has long been used to treat malignant (and benign) conditions in the brain (stereotactic radiosurgery). In the 1990s, investigators began applying the principles of stereotactic radiosurgery to tumor sites outside the brain, such as the lung, the liver, and the spine. SABR has become the treatment of choice for patients with medically inoperable stage I lung cancer.

Radiobiology of Stereotactic Ablative Radiotherapy

The Linear–Quadratic Model

If we apply the LQ formalism to the fractionation schemes used in lung SABR, we can see that SABR delivers a large biologically effective dose (biologically effective dose in the equation) to the tumors. For example, one of the most commonly used schedules is 60 Gy given in three fractions of 20 Gy each. Using the assumption that α/β = 10, the BED_{10} of this regimen is BED_{10} = 60 Gy (1 + 20/10) = 180 Gy. In order to achieve this same BED_{10} using CF with 2 Gy per fraction, one would have to deliver a total dose of 150 Gy in 75 fractions. If these treatments were given once a day, it would take more than 15 weeks to complete the treatment course and efficacy would be lost because of repopulation. Simply put, one could argue that the success of SABR is due mostly to the delivery of very high doses of radiation to the tumor in a short time. By contrast, loss of treatment efficacy may result from hypoxia-related radioresistance when large doses per fraction are used.[20]

Universal Survival Curve

Whether the LQ model appropriately applies to the high doses per fraction used in SABR is a subject of debate. Some investigators have argued that because the LQ model is continuously curving downward as the dose increases, this model actually overestimates clonogenic cell killing in the SABR dose ranges. This has led to the proposal for a piecemeal function for cell survival, termed the universal survival curve.[21] This function combines the LQ model for low doses per fraction and another model, known as the multitarget model,[22] for larger doses per fraction. These authors found that the fit for the survival curve of an NSCLC cell line (H460) up to more than 15 Gy per fraction was vastly improved using the universal survival curve rather than the LQ model, especially as the dose per fraction increased above 10 Gy.[21]

Effects of SABR: New Mechanisms of Cell Killing?

As discussed earlier, the principles of classic radiobiology can be understood in terms of DNA double-strand break damage and the four Rs of radiobiology. However, this understanding has been driven in large part by experiments that used CF (1.8 Gy to 2 Gy per fraction). Despite the finding that the LQ model may overestimate cell killing in vitro (because the βD^2 component

predicts a continuously bending curve as the dose increases but experimental models are more consistent with a linear curve at these high doses), clinical studies have shown that the LQ model may actually underestimate tumor control by stereotactic radiosurgery and SABR.[23] Thus several groups have hypothesized that mechanisms other than DNA double-strand breaks may be responsible for the enhanced effects of SABR.

One hypothesis is that the vascular endothelium is a unique target of the high-dose radiation used in SABR. More specifically, the hypothesis is that large, single fractions of radiation (>8 Gy to 10 Gy) activate the acid sphingomyelinase pathway, ultimately resulting in the generation of ceramide, which stimulates endothelial cell apoptosis.[24,25] Another hypothesis is that SABR doses of at least 10 Gy induce substantial vascular damage, disrupting the intratumoral microenvironment and thereby indirectly leading to tumor cell death.[26] Another potential mechanism for the increased efficacy of SABR is that radiation creates a large amount of tumor antigens, which may augment the immune response, leading to further tumor cell death.[27]

Although these proposed mechanisms are intriguing and may well help to explain the excellent clinical results seen with SABR, some experts believe that SABR is successful because of the large biologically effective dose delivered to the tumor. A group of investigators pooled the data from nearly 2700 patients with medically inoperable stage I NSCLC who were treated with three-dimensional conformal radiotherapy or single-fraction or multifraction SABR.[5] Using both the LQ model and the universal survival curve, they calculated the biologically effective dose for each patient. They then plotted the tumor control probability as a function of the BED, and the results were consistent in that the tumor control probability increased as the biologically effective dose increased, regardless of which treatment patients received. At least for patients with stage I NSCLC, the results of this analysis indicated that different biologic mechanisms are not necessarily responsible for the success of SABR. The analysis does not, however, rule out the existence of these alternative or supplementary mechanisms.

MODIFICATION OF RADIATION RESPONSE

Chemotherapy

Conceptually, chemotherapy combined with radiotherapy has been explored to improve the therapeutic ratio. Chemotherapy may be integrated with radiotherapy in a variety of ways.[28] In induction therapy, chemotherapy is given before local therapy (radiotherapy or surgery). This approach, which reduces the local tumor burden and addresses micrometastatic disease up front, may be advantageous in that a reduced tumor size would result in smaller radiation treatment volumes, which could reduce acute and long-term toxicity. However, using induction chemotherapy followed by a course of radiotherapy extends the patient's overall treatment time. From a radiobiologic perspective, the extended treatment time could allow for accelerated repopulation in the primary tumor and thereby result in inferior outcomes.

Another approach is to give concurrent chemotherapy, that is, to deliver chemotherapy during the course of radiotherapy. With this approach, the overall treatment time is not extended because the definitive local and systemic therapies are given together. A disadvantage of this approach is that it often results in more acute toxicity, both local and systemic (myelosuppression).

Clinical Application: Radiation-Dose Escalation in the Setting of Concurrent Chemotherapy

Dose–response curves for local tumor control with radiotherapy have a sigmoidal shape:[1] as the radiation dose increases, the

probability of tumor control also increases. Likewise, the risk of toxicity also increases as the radiation dose increases. The hyper-fractionation studies mentioned earlier included modest dose escalations, mostly without concurrent chemotherapy. Since the mid-1990s, it has become clear that concurrent chemoradiation therapy is superior to other strategies of combining the two modalities. Of note is that the better survival achieved with concurrent chemoradiation therapy is due mainly to better local–regional tumor control and not to a lower rate of distant metastases.[29] Nonetheless, long-term survival, even with chemoradiation therapy to doses of 60 Gy to 66 Gy, remained low. Efforts have since been made to safely combine escalated radiation doses with concurrent chemotherapy as a way to improve patient outcomes.

In the early 2000s, several groups conducted prospective trials of radiation-dose escalation for patients with lung cancer; in these trials, doses in the range of 74 Gy to 78 Gy were consistently found to be safe.[30–32] Therefore the RTOG conducted a phase III randomized trial in protocol 06-17.[53a] This study had a 2 × 2 factorial design in which patients were randomly assigned to either 60 Gy or 74 Gy of radiotherapy, with or without cetuximab. All patients received concurrent chemotherapy with carboplatin and paclitaxel.

The preliminary results for the 60-Gy or 74-Gy assignment were initially presented at the 2011 meeting of the American Society for Radiation Oncology shortly after an interim analysis led to closure of the randomization to 60 Gy versus 74 Gy, and the results were published in 2015.[33] The median overall survival was higher for the 60 Gy versus 74 Gy arms: 28.7 months versus 20.3 months ($p = 0.0007$). When examining cases only in which there were no protocol violations of doses administered to normal tissues and when selecting cases in which at least 90% of the planning target volume received over 95% of the prescription dose (another measure of quality), the differences in survival remained significantly in favor of the 60-Gy arm. There were significantly higher rates of grade 3 or greater esophagitis in the 74-Gy arm. Radiation dose to the heart (V5Gy) was associated with increased mortality, and further analysis regarding this finding is yet to be completed. Local failure rates were numerically higher in the 74-Gy arm, although this result was not statistically significant (2-year local failure 39% vs. 30%, $p = 0.19$).

The clinical results of RTOG 06-17 are in conflict with our current understanding of basic radiobiology. As a result of this trial, dose escalation to 74 Gy is not recommended and the standard radiation dose in the setting of concurrent chemotherapy remains 60 Gy to 66 Gy.[53a]

Addressing Tumor Hypoxia

As mentioned earlier, tumor hypoxia may reduce the efficacy of radiotherapy. Intraoperative measurement of tumor partial pressure of oxygen (pO_2) among patients undergoing resection of early stage NSCLC demonstrated that tumor hypoxia existed to a certain degree in these tumors and correlated with higher expression of hypoxia-induced genes such as carbonic anhydrase IX (*CAIX*).[34] In addition, tumor hypoxia and elevated expression of osteopontin correlated with worse prognosis in these patients. Therefore investigators are interested in targeting hypoxia with radiotherapy in NSCLC. Two classes of drugs have been investigated to help overcome the detrimental effects of tumor hypoxia: hypoxic cell radiosensitizers and hypoxic cytotoxins.

Hypoxic Cell Radiosensitizers

In the 1960s, investigators began searching for compounds that mimic oxygen and that could therefore overcome chronic hypoxia by diffusing deep into the poorly vascularized portions of a tumor. These efforts led to the development of a class of drugs known as azoles, which have been extensively studied in the clinical setting. The results of earlier meta-analyses indicated that the

benefit of using these agents (and other modifiers of hypoxia) is most pronounced for patients with head and neck cancers and less pronounced for patients with lung cancer.[35,36]

Investigators are showing a renewed interest in the azoles, for their use in combination with single-fraction SABR.[37] A potential shortcoming of single-fraction SABR from the perspective of classic radiobiology is that this treatment does not take advantage of tumor reoxygenation. Multifraction SABR regimens could potentially be converted to single-fraction regimens in combination with a hypoxic radiosensitizer. Clinical trials with patients with NSCLC are needed to fully address this question.

Hypoxic Cytotoxins

An alternative to radiosensitizing hypoxic tumor cells is to develop a compound that selectively targets hypoxic cells. One common hypoxic cytotoxin is mitomycin C, which is a component of chemotherapy regimens used to treat squamous cell carcinomas of the anal canal. This drug has also been used as part of chemotherapy regimens for NSCLC, but it is no longer in widespread use for this indication.

Another hypoxic cytotoxin, tirapazamine, has been prospectively studied in patients with locally advanced NSCLC and limited-stage SCLC in several trials.[38–40] The results have been mixed. Two prospective nonrandomized trials examining tirapazamine added to concurrent chemoradiation therapy for patients with SCLC have showed promising results.[38,39] However, among patients with NSCLC, adding tirapazamine to standard chemoradiation therapy did not improve survival but did result in increased toxicity.[40] At this time, modifying hypoxia by adding tirapazamine or other hypoxic cytotoxins is not routinely performed for patients with lung cancer.

Future Directions

The U.S. National Cancer Institute has recognized that in order to continue improving the therapeutic index of radiotherapy, the technologic innovations that have occurred in radiation oncology must be supplemented with biologic innovations such as new radiosensitizing agents.[41] The National Cancer Institute recommends a series of steps to promote the rapid development of combined radiotherapy with targeted agents. However, appropriate preclinical models are needed to test the benefit of radiation combined with targeted therapy, especially agents targeting the tumor microenvironment or tumor hypoxia. One study has shown that the level of tumor oxygenation, as reflected by hypoxia imaging and the uptake of a hypoxic cell marker (pimonidazole), is highly dependent on the location of the xenograft tumor; the same tumor growing in the lungs showed considerably less hypoxia than it did growing subcutaneously. Moreover, the level of imaging hypoxia correlated well with tumor response to hypoxic cell cytotoxin.[42] The results of studies like this one indicate that judicious selection of a preclinical model may improve the link between preclinical research and clinical practice.

BIOMARKERS PREDICTIVE OF RADIATION RESPONSE

At a time when we are moving toward personalized health care, oncologists are highly interested in finding biomarkers to help tailor treatment strategies for a given patient. With the increasing number of gene mutations being discovered in NSCLC, medical oncologists are now able to select patients who may have a higher probability of having a response to the available targeted therapies specific to those mutations. For example, patients with NSCLC tumors that contain activating mutations in the epidermal growth factor receptor (EGFR) are known to have a better response to tyrosine kinase inhibitors, such as gefitinib and erlotinib.[43] Although it is widely recognized that SCLC is more radiosensitive than NSCLC, the underlying molecular

mechanisms for this difference remain unknown. Among patients with NSCLC, response to radiation varies widely, both in vitro and in the clinical setting.[44] Traditional predictive biomarkers of radiation response have included tumor hypoxia, tumor repopulation, and intrinsic radiosensitivity.[45] However, measuring these parameters is difficult and cumbersome in the clinical setting.

The expression of ERCC1, a protein involved with DNA excision repair, has emerged as a potential biomarker of interest for predicting radiation response. In a study of two separate lung cancer cell lines, increased expression of ERCC1 was found in the more radioresistant cell line.[46] In a retrospective analysis of NSCLC patients with mediastinal lymph node involvement who all received neoadjuvant concurrent chemoradiation therapy, increased expression of ERCC1 in the tumor (as demonstrated by immunohistochemistry) was prognostic of worse overall survival; however, ERCC1 expression was not predictive of clinical or pathologic response.[47] Emerging data suggest that no reliable immunohistochemical means exists to specifically detect the unique functional ERCC1 isoform. The epitopes recognized by 16 commercially available ERCC1 antibodies were mapped and investigated for their capacity to identify the different ERCC1 isoforms.[48] Unfortunately, none of these antibodies could distinguish among the four ERCC1 protein isoforms and detect the one isoform that is critical for nucleotide excision repair. Until a better tool is developed, the role of ERCC1 as a biomarker for predicting radiation response among patients is unclear.

Similarly, expression of mutations in the tyrosine kinase domain of the EGFR has been found to correlate with increased radiation sensitivity in vitro.[49] In a retrospective analysis, patients with *EGFR*-mutant NSCLC had a better response to chemoradiation therapy than did patients with *EGFR*-wild-type tumors.[50] In addition, preclinical work demonstrated that radiation sensitivity was enhanced when tumors with wild-type *EGFR* were treated with erlotinib and radiation.[51] Although the preclinical data are promising, results from phase III trials examining the combination of thoracic radiotherapy and an *EGFR* inhibitor are lacking.

Several preclinical studies have been undertaken to address the need to find gene expression signatures that correlate with radiation response in NSCLC and other human cancer cell lines.[52–54] One such signature has been validated in cancers of the rectum, esophagus, head and neck, and breast.[54–56] However, this signature has not yet been evaluated in lung cancers. A robust and simple gene expression signature panel for the response of lung cancer to radiotherapy is still lacking.

The introduction of next-generation sequencing has added to what we know about the mutation patterns in lung cancers.[57] Circulating tumor DNA carrying tumor-specific sequence alterations can be found in the plasma or serum and may represent a new way of tracking tumor response during therapy. Advances in sequencing technologies have enabled the rapid identification of somatic genomic alterations in individual tumors, and these alterations can be used to design personalized assays to monitor circulating tumor DNA. In a study of patients with metastatic breast cancer, circulating tumor DNA levels showed a greater correlation with changes in tumor burden than did cancer antigen 15-3 or circulating tumor cells. This study also provided the earliest measure of treatment response in more than half the patients tested.[58] We envision a future biomarker for predicting response to radiation that involves a panel of specific single-nucleotide variations, deletions, and insertions derived directly from the patient's own tumor DNA and identified in his or her circulating DNA. This panel will be quantified and monitored during the course of radiotherapy, and this information will help the radiation oncologist determine the dose needed to eradicate such a tumor. Instead of a one-size-fits-all 60-Gy dose for all patients with NSCLC, some patients will need a lower dose for a tumor highly sensitive to radiation and some will need a higher dose for a less sensitive tumor.

CONCLUSION

Radiotherapy remains a critical treatment modality for patients with lung cancer. Use of the fundamental principles of radiation biology has led to the development of novel radiation treatment approaches, including alternative fractionation schedules, combined chemoradiation therapy, and SABR, and these approaches have had a substantial effect in the clinical setting. Nonetheless, unanswered questions remain that can be resolved by coordination between radiation biologists and clinicians, eventually translating these into meaningful applications for patient care: Are there truly new mechanisms of cell death at play in SABR? Is the LQ model valid at the doses used in SABR? What is the optimal radiation dose for treating locally advanced lung cancer? How can we best combine existing and emerging targeted agents and immunotherapy agents with radiation? The ultimate goal of answering these types of questions is to improve the outcomes for patients with lung cancer.

36 Patient Selection for Radiotherapy

Dirk De Ruysscher, Michael Mac Manus, and Feng-Ming (Spring) Kong

SUMMARY OF KEY POINTS

- Patient selection is crucial to ensure treatment selection and optimal outcome.
- The performance status, described by, for example, the Karnofsky or the Eastern Cooperative Oncology Group (ECOG) score, is the most important prognostic parameter.
- The benefit of concurrent chemotherapy and radiotherapy has only been demonstrated in patients with an ECOG score of 0–1.
- Patients with a bad performance status (ECOG 3 or even 4) with important local symptoms, for example, pain, obstruction, or superior venous cava syndrome, may still benefit from palliative radiotherapy.
- A poor pulmonary function either because of the presence of tumor or due to chronic lung disease is not a contraindication to high-dose radiotherapy.
- Comorbidities significantly impair the long-term survival of lung cancer patients, but are not necessarily a contraindication for high-dose radiotherapy; for example, patients with extensive emphysema show less pulmonary damage after stereotactic ablative radiotherapy.
- Interstitial lung disease and autoimmune disorders such as systemic lupus erythematosus and scleroderma have been associated with enhanced intrinsic radiosensitivity of normal tissues and, therefore, a higher risk of serious toxicity resulting from radiotherapy.
- Older and/or frail patients have a higher risk for important side effects, but should not necessarily be treated with palliative intent.
- Even in elderly patients with thoroughly staged stage III nonsmall cell lung cancer, 5-year survival rates of 15% to 20% are consistently reported with radiotherapy alone.
- Continued smoking during curative-intent radiotherapy reduces local tumor control and survival; smoking cessation is therefore essential.
- Adequate calorie and protein intake should be ensured.
- Physical activity should be encouraged; it also reduces fatigue.

Patient selection is of central importance in the management of lung cancer as it ensures that each patient receives the optimal treatment. However, in order to achieve this objective, clinically relevant parameters that are reproducible and quantifiable should be identified. A highly accurate prognostic model (or, even better, a predictive model) that has been validated on the basis of external data sets or, ideally, randomized studies should be the ultimate goal.[1] However, no such model is currently available. An international task force failed to identify high-quality data for selecting patients for radical radiotherapy.[2] Nevertheless, knowledge regarding these criteria is increasing and is needed in daily practice. In this review, we will discuss the most relevant patient and tumor-related factors that may influence the selection of patients for potentially curative radiotherapy.

PATIENT-RELATED FACTORS

Patient-related factors are often associated with overall survival, quality of life, and response to radiation. These factors (including, but not limited to, age, gender, race, performance status, weight loss, baseline pulmonary function, comorbidities, and smoking status) should be taken into consideration when the decision regarding high-dose radiotherapy is made.

Performance Status

Performance status, a measure of general well-being and activities of daily life, is one of the most important factors associated with outcome for patients with cancer. Various systems are used to evaluate performance status. The most generally used measures are the Karnofsky score and the Zubrod score (also known as the World Health Organization or ECOG score).[3] The Karnofsky score, named after David A. Karnofsky, ranges from 100 to 0, with 100 indicating "perfect" health and 0 indicating death. The Zubrod score, named after C. Gordon Zubrod, ranges from 0 to 5, with 0 denoting "perfect" health and 5 denoting death. Translation between the Zubrod and Karnofsky scales was validated in a large sample of patients with lung cancer.[4] A Zubrod score of 0 or 1 corresponds with a Karnofsky score of 80–100, a Zubrod score of 2 corresponds with a Karnofsky score of 60–70, and a Zubrod score of 3 or 4 corresponds with a Karnofsky score of 10–50.

In general, a poor performance status is not a contraindication to radiotherapy. However, the value of definitive radiotherapy for a patient with a poor performance status may be limited, as survival times are often shorter for these patients.[5] The benefit of radiotherapy in terms of survival time should be weighed against the risk of treatment toxicity and the time needed to complete the definitive course of treatment. Similar to chemotherapy, radiotherapy may offer notable benefit to selected patients with a poor performance status.[6,7] Radiotherapy is therefore recommended for this population.[8] The regimen of radiotherapy and its combination with other therapy should be individualized for each patient to achieve a maximum therapeutic effect.[8] Meanwhile, palliative radiotherapy often can be used to improve the quality of life for patients with poor performance status and, therefore, should be recommended for those with advanced disease in whom the tumor is causing clinical symptoms or syndromes. For example, a patient with an ECOG score of 3 or 4 as a result of superior venous cava syndrome, obstructive lung disease, or chest pain may have substantial improvement in quality of life after a short course of palliative radiotherapy. Patient selection for radiotherapy should thus be individualized on the basis of a balanced consideration of both the potential benefits and the potential side effects of such treatment.

Lung Function

Patients with lung cancer often present with poor baseline lung function because of the presence of a tumor or a chronic lung

condition. Although it is clear that a patient who has poor lung function caused by a local tumor would benefit from radiotherapy, the impaired baseline lung condition from noncancer reasons can often make high-dose radiotherapy challenging. Traditionally, definitive radiotherapy has been considered to be contraindicated for patients with poor lung function. For example, some Radiation Therapy Oncology Group (RTOG) studies, such as RTOG 9311, have excluded patients with a forced expiratory volume in 1 second (FEV_1) of less than 0.85 L or 0.75 L from treatment with high-dose radiation. Other studies, such as RTOG 0617 and RTOG 1106, allow such treatment only for patients with an FEV_1 of 1.3 L or more. However, baseline lung function has not consistently been shown to be a risk factor for radiation-induced lung toxicity after conventionally fractionated three-dimensional conformal radiotherapy or hypofractionated stereotactic ablative radiotherapy (SABR). Moreover, the results of pulmonary function tests often are not changed remarkably after modern conformal radiotherapy.[9,10] Modern dose-escalation studies such as that from the University of Michigan did not limit lung function for very high-dose radiation.[11] In a study of 47 patients, the incidence of lung toxicity had no significant correlation with the results of pulmonary function tests after concurrent chemotherapy and radiotherapy.[12] In a study of 438 patients, FEV_1 along with other patient-related factors seemed to be more important than dosimetric factors for predicting radiation pneumonitis.[13] In a study of 260 patients, the addition of FEV_1 and age to the mean lung dose (MLD) slightly improved the predictability of clinically important radiation-induced lung toxicity.[14] Similar to the SABR series,[10] the study showed that patients with higher baseline lung function tests had significantly more clinical lung toxicity.[14]

In summary, pulmonary function should be considered on an individual basis by balancing the improvement in lung function related to tumor shrinkage with the reduction in lung function related to radiotherapy. In the modern era, poor pulmonary function should not be considered a contraindication to definitive radiotherapy.

Comorbidities

Serious comorbidities are very common in patients with lung cancer and can severely affect outcomes. Long-term tobacco consumption is associated with chronic obstructive pulmonary disease (COPD), ischemic heart disease, cerebrovascular disease, and peripheral vascular disease. Furthermore, other tobacco-related cancers, including head and neck cancers, may be diagnosed before, after, or synchronously with lung cancer, thereby complicating the management of the lung cancer, the other cancer, or both. Luchtenborg et al.[15] studied 3152 patients with nonsmall cell lung cancer (NSCLC) who had surgical resection and reported that serious comorbidity caused a decrement in survival equivalent to a single increment in stage grouping. Comorbidities also reduce the tolerability of chemotherapy to patients with NSCLC.[16] High-dose radiotherapy is poorly tolerated by patients with limited cardiorespiratory reserve due to heart or interstitial lung disease,[17] who are at risk of severe dyspnea or even death if they have insufficient reserve to tolerate impaired organ function after treatment. Smith et al.[18] reported that for patients with NSCLC who were managed with curative-intent radiotherapy, a worse score on the Charlson Comorbidity Index correlated with inferior overall survival but not cause-specific survival. Paradoxically, the scarred lungs of patients with severe COPD may be less likely to be affected by severe radiation pneumonitis after SABR.[19] SABR should not be withheld from patients solely because of COPD.[20]

Although the risks of curative radiotherapy can be difficult to estimate for individual patients, it is usually possible to make a reasonable estimate of the consequences related to loss of a substantial proportion of residual lung or heart function. Apart from general comorbidities such as heart disease, several specific conditions may exacerbate the toxicity of radiotherapy.

Autoimmune disorders such as systemic lupus erythematosus and scleroderma have been associated with enhanced intrinsic radiosensitivity of normal tissues and, therefore, a higher risk of serious toxicity resulting from radiotherapy.[21]

Age and Frailty

Age and frailty are obviously two separate entities: the former is expressed as an objective, trivial number, and the latter is derived from the Latin word *fragilis*, which means "fragile" (i.e., weak). Frailty clearly increases with age, but a young individual can be frail as well. In most geriatric literature, frailty has been defined as either a threshold beyond which the functional reserve of a person is critically reduced and the tolerance of stress is negligible or as a progressive reduction of functional reserve due to a progressive accumulation of deficits.[22] Thus functional reserve should be measured objectively and used as a prognostic indicator of the survival of the patient and/or the tolerance of the treatment.

Many authors have shown that the older population is a very heterogeneous group in terms of physical, biologic, emotional, and cognitive functions. Nevertheless, increased age is associated with comorbidities as well as higher rates of hospitalization and chemotherapy-related toxicity,[23–25] shifting the overall risk-to-benefit ratio.[26] Older patients and patients with important comorbidities are underrepresented in clinical trials.[26,27] Because of the lack of data as well as the fear of iatrogenic complications, older patients generally receive less aggressive treatment,[28–30] which may result in suboptimal survival rates.[31] In selected patients, it has been shown that intensive, state-of-the art therapy benefits older patients.[32–37] Remarkably, the 5-year survival rate is 15% to 20% with radiotherapy alone for patients with stage III disease who are older than 75 years, have good performance status, and have thorough staging.[37] Defeatism thus is definitively not appropriate. Moreover, oncologic assessment methods specifically designed for older patients have been developed.[38–40] The clinical implementation of these methods will lead to more rational and appropriate care of older patients with cancer. These methods probably are also useful for younger, frail patients. These developments should move the field forward.

Concurrent Medication (Other Than Chemotherapy)

Many patients take medications because of comorbidities. The influence of common medications on the side effects associated with radiotherapy in patients with lung cancer is unknown. Angiotensin-converting enzyme inhibitors and statins are the groups of medications that have received the most interest as being potential protectors against radiation pneumonitis. However, at the present time, their influence on side effects has not been clarified.[41,42]

Molecular Factors

Molecular and genetic markers that could be used to select patients for a specific radiation schedule are of great interest. However, although some single-nucleotide polymorphisms have been associated with radiation pneumonitis and although C4b-binding protein alpha chain and vitronectin have been associated with toxicity,[43,44] these and other findings need to be validated in other data sets and their therapeutic role needs to be investigated in prospective trials.

A worse survival rate has been reported for patients with a high pretreatment level of C-reactive protein or interleukin-6 in addition to classic prognostic factors.[45] Again, the practical utility of these findings needs to be determined.

Smoking Status

Tobacco consumption is the primary cause of most lung cancers, and smoking during treatment can have a substantial negative effect on outcomes. In a study of 237 patients with complete smoking histories who were treated with definitive radiotherapy or chemoradiotherapy between 1991 and 2001, Fox et al.[46] reported worse survival for smokers with early-stage disease. Similarly, Rades et al.,[47] in a study of 181 patients who received radiotherapy for the treatment of NSCLC, reported that improved local–regional control was associated with a lower T stage ($p = 0.007$) and with no smoking during radiotherapy ($p = 0.029$) but not with hemoglobin levels or respiratory insufficiency. Jin et al.,[48] in a study of 576 patients, found that smoking status, when corrected for dose–volume effects, was the only factor that appeared to reduce the risk of treatment-related pneumonitis. Nguyen et al.[49] reported that smoking at the time of the initial consultation was associated with reduced local and local–regional control in patients who were treated with radiotherapy after surgery for the management of NSCLC.[49] It is therefore important to ensure that patients with lung cancer have access to smoking-cessation programs and that concerted efforts are made to help them to stop smoking before, during, and after treatment.[50,51]

Nutrition

The nutritional status of patients with lung cancer can be compromised as a direct result of cancer-induced alterations in metabolism and the side effects of radiotherapy. Koom et al.[52] reported malnutrition in more than one-third of patients with cancer in a multi-institutional study. Malnutrition can lead to weight loss and, in the most serious cases, cachexia. Nutritional status may be associated with survival and ideally should be assessed before the initiation of any treatment, including radiotherapy.[53,54] Weight loss is associated with poor survival among patients who are treated with radiation, and cachexia is characterized by involuntary weight loss, muscle wasting, decreased quality of life, and poor survival. In general, these conditions are not contraindications to radiotherapy. Nutritional assessment and weight monitoring are vital during radiotherapy for the treatment of lung cancer. Patients who maintain good nutrition are more likely to tolerate the side effects of treatment. Adequate calories and protein can help to maintain strength and prevent further catabolism. Individuals who do not consume adequate calories and protein use stored nutrients as an energy source, which leads to protein wasting and further weight loss. Patients with lung cancer need to be educated about radiation esophagitis, a common side effect that decreases oral intake and compromises nutritional status.

Fatigue and Physical Activity

Fatigue is one of the most common and distressing patient-reported symptoms associated with cancer. Rather than being a selection measure for radiotherapy, fatigue is a condition that needs to be managed in order for treatment to be successful. Physical training has been shown to be beneficial for patients with breast and colorectal cancer.[55,56] Patients with lung cancer often have a higher incidence and longer duration of cancer-related fatigue, leading to decreased lung function and increased functional impairment in daily living and dramatically reducing the tolerability of treatment, the quality of life, and the chance for

prolonged survival.[57] Physical activity has been shown to reduce fatigue in patients with lung cancer and COPD,[58] and studies have indicated that exercise therapy may be an important consideration in the management of both early- and advanced-stage lung cancer.[59,60] For patients receiving concurrent radiotherapy, the value of physical training or pulmonary rehabilitation is limited, although the level of physical activity appears to be an additional prognostic factor to the level of performance. Preliminary evidence from a small pilot study suggested that physical training was associated with an improvement in 6-minute walking distance.[61] Until more evidence is available, we believe that patients who receive radiation-based therapy would behave similarly to those who have surgery or chemotherapy alone and would equally benefit from physical training. These patients should be advised to remain as active as possible and to continue to engage in regular physical activity and pulmonary training to the level of their tolerance.

Repeat Radiation

As the prognosis of patients with cancer improves, more individuals are at risk for the development of a local recurrence or a new primary tumor in organs that were previously treated with radiation. New radiation techniques, better imaging, and more knowledge of dose–volume relationships have led to the use of repeat radiation at high doses.

We are aware of only one prospective study of repeat radiotherapy for recurrent lung cancer,[62] with the rest being retrospective.[63–72] In the prospective trial, which included 23 patients with a local recurrence after external radiotherapy, the median interval between primary and repeat radiotherapy was 13 months.[62] The median first dose was 66 Gy, and the median second course was 51 Gy (range, 46 Gy to 60 Gy), delivered in 1.8 Gy to 2 Gy per fraction. No clinically severe toxicity was noted, but the 1-year and 2-year survival rates were only 59% and 21%, respectively. The results of the prospective study were in line with those of the retrospective series, which included 29–48 patients.[63–72] However, in one study, severe toxicity, including lethal bleeding, was reported in 3 of 11 patients with centrally located tumors that were treated with SABR.[70] Cumulative doses in excess of a cumulative biologically effective dose of 120 Gy to the aorta clearly should be avoided.[72]

Repeat radiotherapy can be considered for selected patients. In the future, individual radiosensitivity measurements, possibly with genetic profiles, may contribute to appropriate patient selection.

TUMOR-RELATED FACTORS

The management of lung cancer is determined largely by the extent of the disease. Patients who are selected for treatment with definitive radiotherapy must have disease that can be encompassed within a tolerable radiotherapy target volume, and they should have no distant metastasis. The great majority of patients who are treated with curative-intent radiotherapy have stage III disease, but there has been an increasing trend toward the use of SABR for the management of stage I disease in patients who are unable to tolerate surgical resection.[73] Accurate determination of stage involves a synthesis of all available sources of information, which may include the results of bronchoscopy, the operative findings at the time of thoracoscopy or thoracotomy, the results of pathologic evaluation of lymph node samples obtained by transbronchial biopsy,[74] and the findings on imaging studies, both structural and functional. Only a small proportion of patients who are treated with definitive radiotherapy or chemoradiation therapy would have had full mediastinal staging at the time of thoracotomy, and therefore imaging plays the central role both in selecting patients for curative therapy and in defining the

target for treatment. Ultrasound-guided transbronchial biopsy has been assuming an increasing role in confirming the status of suspicious nodes that are detected on imaging studies,[75] ensuring both that patients with false-negative nodes are not inappropriately excluded from surgery and that equivocal nodes can be included within the radiotherapy target volume if they are true positive.

Accurate staging of patients with NSCLC involves correct allocation of T, N, and M stages according to the international staging system, the current edition of which resulted from the International Association for the Study of Lung Cancer Lung Cancer Staging Project.[76] The most accurate imaging staging modality currently available is ^{18}F-2-deoxy-D-glucose-positron emission tomography–computed tomography ([18]FDG-PET–CT), which has rapidly supplanted CT and [18]FDG-PET alone when the newer modality has become available.[77] There is a large and growing body of evidence that shows that PET and PET–CT are superior to CT for the determination of mediastinal node status and for the detection of distant metastasis.[78,79] However, [18]FDG-PET does not provide accurate staging of the brain,[80] and therefore candidates for curative radiotherapy who are at high risk for occult brain metastasis (e.g., patients with involvement of mediastinal nodes) should have separate imaging of the brain, ideally with magnetic resonance imaging.

Three prospective studies have evaluated the use of PET and PET–CT to select patients for definitive radiotherapy. In the first study, 153 candidates for radical radiotherapy had staging with PET after being found suitable for radiotherapy on the basis of conventional imaging.[81] PET and conventional staging evaluations were discordant approximately 40% of the time, and only two-thirds of the patients actually received definitive radiotherapy because, in the remaining patients, PET showed either distant metastasis (18%) or intrathoracic disease that was too extensive for high-dose radiotherapy (12%). The predominant impact of PET was upstaging, and this effect was greatest for patients with the most advanced tumors. In the second study, a group of Polish investigators reported that only 75 of 100 patients with NSCLC remained eligible for curative radiotherapy after PET–CT.[82] In the third study, 25 of 75 candidates were found to be unsuitable for definitive radiotherapy after PET–CT was performed with the patient in the radiotherapy planning position.[83] The survival rate for patients who actually received definitive radiotherapy after PET–CT was remarkably good, with 32% of patients with stage IIIA disease being alive at 4 years. Only 4% of patients who received palliative treatment in the study survived for 4 years, suggesting that that PET-based patient selection had been appropriate.

Radiated Volume and Toxicity

The relationship between the volume of normal tissue that is radiated and the risk of serious pulmonary toxicity, including radiation pneumonitis and later radiation-induced fibrosis, is complex. It is made even more complex by the interaction of radiation-induced lung damage and serious preexisting cardiopulmonary comorbidities that may influence the capacity of the patient to endure high-dose radiation without becoming disabled or even dying as a result of toxicity. Consequently, the volume of lung and other normal tissue, such as heart tissue, that will be included in the target volume is an important factor that determines the suitability of a patient for definitive radiotherapy. If the volume of normal tissue, especially lung tissue, is too great, curative radiotherapy is simply not possible and other therapeutic approaches, such as palliation, must be preferred.

This consideration raises the question "What volume of normal tissue is too large?" This decision often was subjective in the past, but the advent of advanced radiotherapy planning systems has made it possible to precisely estimate the volume of lung

tissue that will be radiated to any particular dose level. With the increase in computing power, it has become straightforward to display radiation lung volumes as dose–volume histograms, and these dosimetric parameters have been compared with clinical outcomes in large numbers of patients. The risk of pneumonitis can be estimated from a number of different but related dosimetric parameters. These parameters include the percentage of total lung volume radiated to 5 Gy (V5), 20 Gy (V20), and 30 Gy (V30) and the MLD. As these values increase, the risk of complications increases. The risk tends to increase with concurrent chemotherapy and may be decreased by smoking. The use of intensity-modulated radiotherapy may lead to an increase in the volume of lung tissue that is exposed to lower doses of radiation, and this increase should be accounted for to avoid potentially fatal complications.[84] The Quantitative Analysis of Normal Tissue Effects in the Clinic report recommended that V20 (the volume of both lungs minus the planning target volume receiving 20 Gy) should be limited to no more than 30% to 35% and that the total MLD should be limited to no more than 20 Gy to 23 Gy (with conventional fractionation) to limit the risk of radiation pneumonitis to 20% or less in patients with NSCLC who are treated with definitive radiotherapy.[85]

These dose limits cannot be relied on in all cases. For example, patients who have had previous pneumonectomy or other major lung resections will be less capable of surviving pneumonitis, and it has been suggested that a V5 of less than 60%, a V20 of less than 4% to 10%, and an MLD of less than 8 Gy are reasonable dose limits for intensity-modulated radiotherapy in the setting of mesothelioma after pneumonectomy.[86] Although these parameters are useful for conventional daily fractionation, limited data on their utility for multiple daily fractionation or accelerated schedules are available.[87] Similarly, dose constraints for SABR applied to the lung are in the process of being established.[88] Severe pneumonitis is relatively rare after SABR, but it is clear that increasing values of V20 and MLD are associated with an increased risk of pneumonitis.[89]

F-2-Deoxy-D-Glucose Uptake

In lung lesions, the association between increased glucose metabolism and malignancy is powerful. Intensely metabolically active lesions are much more likely to be malignant than lesions with little or no FDG uptake on PET. Lesions with low FDG avidity are commonly benign or are of low-grade malignancy. The results of a systematic review showed that primary malignant tumors with greater FDG uptake are generally aggressive and are associated with a worse prognosis.[90] However, it is less clear whether FDG uptake is an independent prognostic factor because FDG avidity is strongly correlated with the extent of disease and the size of the tumor. In surgically treated patients with stage I or II NSCLC, a higher standard uptake value (SUV) is associated with lower rates of disease-free survival and overall survival.[91,92] It also has been reported that a higher SUV and metabolic tumor volume are associated with worse prognosis in patients with stage I NSCLC who are treated with SABR.[93] A number of retrospective studies have indicated that a higher SUV is associated with a worse prognosis for patients who have definitive chemoradiation therapy for the management of locally advanced disease. However, a large prospective multicenter trial involving patients with locally advanced NSCLC who were managed with definitive chemoradiation therapy (ACRIN 6668/RTOG 0235) did not confirm a significant effect of the pretreatment SUV but did suggest that the posttreatment SUV was important.[94] In that study, pretreatment SUV was evaluable for 226 patients and posttreatment SUV was evaluable for 173 patients. The mean pretreatment SUV_{peak} and SUV_{max} values (10.3 and 13.1, respectively) were not associated with survival. However, the posttreatment SUV_{peak} value was associated with survival in a continuous variable model (hazard ratio, 1.087;

95% confidence interval, 1.014–1.166; *p* = 0.020). The authors concluded that a higher posttreatment SUV (SUV$_{peak}$ or SUV$_{max}$) was associated with worse survival in cases of stage III NSCLC, although a clear cutoff value for routine clinical use could not be recommended.

Computed Tomography and Positron Emission Tomography Metrics

Although small tumor volume may be associated with a better prognosis, this benefit is no longer evident at 5 years, and tumor size per se should not be a factor influencing radical chemoradiation therapy.[95,96] Increasingly, researchers are aware that, in addition to the volume of tumors, which is partly reflected in the T stage, images show many other features that could be both prognostic and predictive. In addition to the primary tumor, all regional and distant metastatic deposits could be evaluated and classified on the basis of imaging studies.

PET has been used for this purpose. Beyond FDG, PET-labeled drugs such as ^{11}C-docetaxel and ^{11}C-erlotinib and other molecules that could be used together with radiotherapy are of great interest for the future.[97,98]

As CT is widely available and highly standardized, features of CT images increasingly have been investigated. For example, texture on CT images is quantified as mean gray-level intensity, entropy, and uniformity.[99] Goh et al.[100] found a relationship between the texture features of NSCLC on noncontrast-enhanced CT and tumor metabolism and stage. In the study by Win et al.,[101] univariate analysis demonstrated CT-derived heterogeneity, [18]FDG-PET–derived heterogeneity, diffusion-enhanced (dynamic contrast-enhanced)-CT–measured permeability, and stage were prognostic for survival of patients with NSCLC.[101] In the same study, multivariate analysis showed that permeability was the most important survival predictor, followed by stage and CT-derived textural heterogeneity. The same technology also could be used to characterize organs at risk in order to improve the individual therapeutic ratio.[102]

Mutation Status

Although most NSCLC tumors do not express a molecular target that can be blocked with currently available drugs, it is conceivable that this proportion will grow dramatically in the coming years. The question arises whether these molecular characteristics influence the sensitivity for radiotherapy.

Unfortunately, we are not aware of any prospective studies on this subject. Overexpression of epidermal growth factor receptor (EGFR) is associated with resistance to chemotherapy and radiotherapy.[103] EGFR modulates DNA repair via an association with the catalytic subunit of DNA protein kinase. However, although in vitro EGFR expression correlates with both cellular and tumor response to radiation, in vivo EGFR expression does not.[104] In addition, the type of EGFR inhibition turned out to be important: only the monoclonal antibody cetuximab improved local tumor control in some, but not all, tumors, whereas EGFR tyrosine kinase inhibitors were not synergistic.[105] Although several

retrospective reports have indicated that patients who have a tumor with *EGFR* mutation have a better response to radiotherapy and a longer progression-free survival than patients who have a tumor with wild-type *EGFR*, it remains to be shown if the long-term survival will be increased.

The relationship between radiosensitivity and the echinoderm microtubule-associated protein-like 4-anaplastic lymphoma kinase (*EML4-ALK*) fusion gene has not been investigated in depth. Contrasting results have been reported on the radiosensitivity of tumor cells bearing an ALK fusion protein with or without crizotinib treatment.[106,107] To our knowledge, at the time of writing, no clinical data are available.

At the present time, mutational status does not affect the treatment strategy with regard to the use of radiotherapy.

CONCLUSION

Many known and unknown factors influence the decision with regard to which patients will receive high-dose radiotherapy. Among the patient-related factors, performance status remains the most important. Comorbidities are mostly important for overall survival but have not consistently been associated with cause-specific survival and toxicity. Tumor-related parameters such as size and volume, and, probably, genetic characteristics, are of prognostic value.

The knowledge regarding the selection of patients for the most appropriate therapy will surely evolve markedly in the coming years with the combination of all types of information into a clinical algorithm.

Stage I Nonsmall Cell Lung Cancer and Oligometastatic Disease

Suresh Senan, Umberto Ricardi, Matthias Guckenberger, Kenneth E. Rosenzweig, and Nisha Ohri

SUMMARY OF KEY POINTS

- Stereotactic ablative radiotherapy (SABR) is recommended in treatment guidelines as the nonoperative therapy of choice for early-stage nonsmall cell lung cancer (NSCLC).
- SABR can be adequately performed using either traditional linear accelerators equipped with suitable image-guidance technology or linear accelerators specifically adapted for SABR and using dedicated delivery systems.
- Clinical assessment, staging of disease, and multidisciplinary discussion should be based on published guidelines for early-stage NSCLC.
- Guideline-specified nodal staging should be performed before SABR, as nodal regions are not radiated.
- SABR dose constraints, which are based on the constraints used in the RTOG 0618, 0813, and 0915 SABR trials, are summarized in the current National Comprehensive Cancer Network guidelines.
- Results of SABR have been consistent, with both the high local control rates and low toxicity found in prospective clinical trials also being reported in large single-institution series and pooled multi-institutional analyses.
- A widely used working definition for so-called central lung tumors is tumors located either adjacent to the proximal bronchial tree or located 1 cm or less from the heart or mediastinum.
- Three distinct cohorts of patients with oligometastases can be identified: patients with oligometastatic disease at the time of diagnosis, patients with oligoprogressive disease after cytoreductive therapy, and patients with oligorecurrent disease after curative local–regional therapy.
- Results appear generalizable across centers when current SABR guidelines are followed.

Changes in the epidemiology of lung cancer are particularly relevant for the field of radiation oncology. Globally, lung cancer represents the leading cause of cancer death in men and is the second leading cause in women.[1] A key challenge is that older patients are the fastest growing population—nearly 25% of patients are 75 years of age or older.[2] Approximately 20% of all patients diagnosed with nonsmall cell lung cancer (NSCLC) have stage I disease, and surgery is currently the guideline-specified treatment for fit patients who are willing to accept the procedure-related risks.[3] However, a population study from the Netherlands showed that, among patients with stage I disease, resection was done in 49% of patients 75 years of age or older compared with 91% of patients who were 60 years of age or younger.[4] Similarly, in an analysis of data in the Surveillance, Epidemiology and End Results (SEER)-Medicare database for the period 1998 to

2007, the percentage of patients who had a surgical procedure decreased over time (75.2% in 1998 vs. 67.3% in 2007) and the percentage of patients who did not receive any local treatment increased (14.6% in 1998 vs. 18.3% in 2007).[5] These findings were explained by the increase in the proportion of patients 85 years of age or older (from 4.5% to 9%), as well as an increase in patients with three or more comorbidities (from 15% to 30%) during the study period. The reluctance to operate on older patients is mainly due to their frailty, as comorbidities are more common in the older population.[6] Although severe comorbidity has the greatest impact on outcomes during the first month following surgery, the increased death rate associated with impaired performance status persists with longer follow-up.[7]

The apparent reluctance of clinicians to refer older patients for conventional radiotherapy was partly due to the 30 or more once-daily treatments that were typically required, which is cumbersome for frail older patients. In the era before stereotactic ablative radiotherapy (SABR), outcomes of radiotherapy in early-stage NSCLC were poor despite treatment with doses ranging from 60 to 66 Gy. Local tumor recurrences occurred in approximately 40% of patients, with an overall survival rate at 3 years of approximately 30%.[8] Furthermore, a modest 6-month increase in median survival was reported in an analysis of 2010 SEER data when older radiotherapy techniques were applied.[9]

SABR: BACKGROUND AND DEFINITIONS

In the mid-1990s, the principles of cranial stereotactic radiotherapy (or radiosurgery) were transferred to extracranial sites by work pioneered at the Karolinska Hospital in Sweden.[10] Stereotactic body radiation therapy (SBRT) and SABR are equivalent terms for this technique in the body. This stereotactic approach was further developed by centers in Japan and Germany.[11–13] In subsequent years, encouraging results from both prospective and retrospective studies resulted in rapid adoption of SABR for early-stage NSCLC. A national survey in the United States found that 57% of all responding physicians used SABR for the treatment of lung cancer in 2010,[14] whereas a similar survey in Italy found that 41% of responding radiotherapy centers used SABR in 2009.[15] At present, SABR is recommended in treatment guidelines as the nonoperative therapy of choice for early-stage NSCLC.[3]

Guidelines for SABR have been released by several professional groups: the American Association of Physics in Medicine Task Group 101,[16] the American Society for Therapeutic Radiology and Oncology and the American College of Radiology,[17] the Canadian Association of Radiation Oncology-Stereotactic Body Radiotherapy,[18] the National Radiotherapy Implementation Group of the UK,[19] and the working group Stereotactic Radiotherapy of the Germany Society of Radiation Oncology.[20] Current definitions of SABR adhere to the following criteria: a high degree of accuracy, use of high doses of radiation, and delivery of radiation in one or a few treatment fractions to an extracranial target.

The rationale of SABR for early-stage NSCLC is that higher radiation doses are more effective for local control of the tumor, which translates into longer overall survival.[21,22] SABR differs

from conventional radiotherapy in that SABR involves delivery of very high radiation doses only to the visible tumor, with planning and delivery of treatment optimized to ensure safety margins of a few millimeters. In addition, radiation doses to surrounding normal organs are often lower than with conventional techniques.[23] As a result, local tumor control rates of 90% and higher can be achieved and rates of severe toxicity are typically below 10%.

SABR for lung cancer is a multidisciplinary endeavor, involving all disciplines related to the diagnosis and treatment of the disease, but particularly specialists working on a radiotherapy team. Accuracy of delivery is achieved using an optimized workflow and appropriate quality assurance procedures, including development of written protocols, which is an essential component of the process.

SABR can be adequately performed using either traditional linear accelerators equipped with suitable image-guidance technology or linear accelerators specifically adapted for SABR and using dedicated delivery systems. The SABR procedure was initially defined by the use of frame-based patient set-up, the goal of which was stable and reproducible patient positioning. However, frame-based stereotactic patient set-up has been replaced by image guidance, which makes the term stereotactic somewhat misleading. With non–frame-based patient set-up, external stereotactic coordinates are replaced by visualization of a patient's anatomy using images acquired on-table and subsequently compared with pretreatment planning images. Soft-tissue images of the tumor itself, or of an implanted fiducial marker, can be used for setting up the target (Fig. 37.1).
Fig. 37.1. Some techniques used for image guidance in stereotactic ablative radiotherapy for lung cancer, showing tumor visualization using a cone-beam computed tomography and implanted fiducial markers.

SABR Protocol Development, Implementation, and Quality Assurance

A dedicated SABR team should consist of radiation oncologists, medical physicists, and technicians (e.g., radiographers, radiation therapists), all of whom should have attended appropriate training courses organized by professional bodies and/or industry in accordance with the above-mentioned guidelines. Written treatment protocols that are consistent with national regulations, institution-specific equipment, and training and education of the individual radiotherapy team members should be available. SABR requires additional and more frequent physical quality assurance: verification and quality assurance of the entire SABR treatment chain is mandatory, and end-to-end tests for overall uncertainty estimation are recommended. It is paramount to verify that the radiation isocenter coincides with the mechanical isocenter, including couch rotation, room lasers, and, especially, the imaging isocenter.

CLINICAL ASSESSMENT

Clinical assessment, staging of disease, and multidisciplinary discussion should be based on published guidelines for early-stage NSCLC.[24] Unlike the toxicity found following surgery in older individuals,[25] no increased toxicity or treatment-related mortality has been noted when SABR has been extensively applied to patients between 75 and 80 years old.[26,27] The poorer overall survival rates reported in this older population after SABR are related to comorbidities, and the number of comorbidities predicts overall survival after both SABR and surgery.[7,28] SABR-related toxicity is also not increased in patients with very poor pretreatment pulmonary function,[29,30] and the available data suggest that SABR should be offered to all patients regardless of age and preexisting pulmonary comorbidities, unless their predicted survival time is short.

Diagnosis and Staging Before SABR

Diagnosis and confirmation of NSCLC based on tissue biopsy is recommended before starting any local treatment for early-stage NSCLC.[24] However, obtaining a histologic diagnosis may not be possible for peripheral lung lesions or may pose a high risk of toxicity in a patient group with considerable medical and/or pulmonary comorbidities. In the latter case, radiographic criteria of malignancy are used to establish a diagnosis. Models that predict the probability of malignancy in solitary pulmonary nodules based on both clinical and radiographic characteristics have been described and validated.[31,32] It is important to note that these criteria may not hold true in geographic regions with a high incidence of infectious and/or granulomatous lung diseases. Therefore, current guidelines state that any treatment for a possible early-stage NSCLC without a pathologic diagnosis should proceed only after assessment by an experienced multidisciplinary tumor board.[24] If the clinical and radiographic findings are inconclusive, repeated imaging to evaluate the growth pattern is an option for some patients, but careful follow-up is required because patients with malignancy are at risk for early disease progression.[33]

Guideline-specified nodal staging should be performed before SABR, as nodal regions are not radiated. Staging with ^{18}F-2-deoxy-D-glucose-positron emission tomography (FDG-PET) is essential because of its higher diagnostic accuracy for the detection of node metastases (negative predictive value, 90%)[34,35] and also because unsuspected distant metastases and second primary tumors can be excluded.[36] In the event of pathologic FDG uptake in regional lymph nodes, further evaluation by endobronchial ultrasound or endoscopic ultrasound is recommended and, if the findings are inconclusive, a mediastinoscopy may be necessary. Staging with PET–computed tomography (CT) should ideally be performed within 6 to 8 weeks before SABR is given because of the risk of disease progression in the interim.[37]

TECHNICAL OVERVIEW FOR RADIATION ONCOLOGISTS

Target Volume Definition and Treatment Planning

All imaging should be acquired in the treatment position, with standard practice dictating that planning CT images encompass the entire lung volume, and a slice thickness of 2 mm to 3 mm is used.[23] Using intravenous contrast medium may improve the delineation of centrally located primary tumors. As conventional three-dimensional (3-D) CT risk introduces artifacts and systematic errors, four-dimensional (4-D) CT, also known as respiration-correlated CT, is the recommended technique for SABR planning.[38] Although a single 4-D CT planning image provides only a snapshot of a patient's breathing pattern, several studies have demonstrated that the motion pattern and amplitude are stable over time,[39–41] making routine repeated 4-D CT imaging unnecessary. The use of FDG-PET alone is not appropriate for a reliable assessment of target motion in SABR planning.[42]

Target Volume Concept and Motion Management Strategy

Gross tumor volume is determined on the basis of CT findings in the lung and soft-tissue window. Current guidelines do not recommend the use of clinical target volume margins when SABR is delivered,[17,23] as the high radiation doses combined with rather flat dose profiles in pulmonary tissue of low electron density result in sufficient coverage of potential microscopic disease extension.[43] Integration of breathing-induced target motion into the target volume concept will ensure patient-tailored tumor targeting, with clinical implementation dependent on the chosen motion management strategy. Several different approaches are used in routine clinical practice.[44,45] Continuous radiation in free breathing is performed using the internal target volume concept, the mean target position concept, or real-time tumor tracking. Tumor tracking is possible using dedicated robotic delivery machines,[46] by dynamic multileaf tracking,[47] a gimbaled multileaf collimator,[48] or a dynamic treatment couch.[49] Noncontinuous radiation of the tumor in a reproducible position is performed using gated beam delivery in predefined phases of the breathing cycle,[50] in voluntary breath-hold,[51] or in breath-hold using the active breathing coordinator.[52]

It is important to emphasize that active motion management strategies, such as gating and tracking, require continuous intrafractional monitoring; however, continuous intrafractional monitoring is less critical for passive strategies, such as the internal target volume or mean tumor position concept. Although patient-specific motion management is strongly recommended, data from the available prospective trials did not involve the use of advanced motion management strategies. Of the individualized 4-D motion management strategies used, resulting field sizes are largest for the internal target volume concept; however, this motion management strategy is straightforward to implement and ensures adequate target coverage. Even if all uncertainties in treatment planning and delivery are minimized by currently available technologies, residual errors still remain and require minimum planning target volume (PTV) margins of about 5 mm.[53]

Dose Fractionation and Prescription

Dose prescription and reporting should comply with the International Committee on Radiation Units and Measurements Report on Prescribing, Recording, and Reporting Intensity-Modulated Photon-Beam Therapy as closely as possible, but historical practice and experiences need to be considered as well. Most prospective and retrospective studies used inhomogeneous dose distributions within the PTV, with maximum doses ranging between 105% and 150% of the prescribed dose. Inhomogeneous dose distributions offer the opportunity to deliver an extra dose to the center of the PTV, where the (potentially hypoxic) macroscopic tumor is located, without increased doses to the peripheral normal tissue.[54]

As a result of large differences in single-fraction and total doses between SABR studies, a comparison of physical doses is less meaningful. The linear quadratic model has been widely used for modeling of SABR outcomes data, but it has not been validated for very high single doses.[55] Despite uncertainty surrounding the linear quadratic model, several groups have independently demonstrated a clear dose-effect relationship for local tumor control using biologic effective doses (BEDs), with a minimum PTV dose of more than 100 Gy BED (α/β ratio, 10 Gy) required for local tumor control rates of higher than 90%.[56–58] The current recommended tumor dose for SABR of lung tumors is a minimum of 100 Gy BED, prescribed to the target volume encompassing isodose.[24] A meta-analysis demonstrated a potential detrimental effect of SABR doses exceeding more than 146 Gy BED.[59]

Total doses are typically delivered in one to eight fractions, but insurance reimbursement rules have resulted in a widespread use of five or fewer fractions in the United States. However, use of very high single-fraction doses and total doses (e.g., delivery of three fractions of 20 Gy) can damage normal tissues in or adjacent to the target volume.[60] Consequently, treatment of tumors in proximity to critical normal organs has led to the use of so-called risk-adapted fractionation schemes that deliver the required dose of 100 Gy BED in a larger number of treatment fractions with lower single-fraction doses. Fractionation appears to spare some critical normal organs while ensuring sufficiently high doses to achieve local tumor control.[61]

Fractionation appears to be especially valuable in SABR for centrally located tumors, as it allows for radiobiologic sparing of critical organs such as large bronchi, vessels, heart, and esophagus. High-quality prospective data on the safety and efficacy of SABR for centrally located lesions are limited, but a systematic review of the literature demonstrated local control rates of 85% or greater when the prescribed BED to the tumor was 100 Gy or higher. The overall treatment-related mortality was 2.7%, and when the BED to normal tissue was 210 Gy or lower (α/β ratio, 3 Gy), the rate was 1.0%.[61] Until mature prospective multicenter data become available, a recommended fractionation scheme for experienced centers is 8 × 7.5 Gy, with D_{max}(PTV) of 125%.

Treatment Planning

The voxel size of the dose calculation grid should be 2 mm or less, and both heterogeneity correction and use of type B algorithms improve accurate dose calculation, especially at the interface of lung tissue and soft tissue.[62] Monte Carlo dose-calculation algorithms achieve the most accurate results, but differences to collapsed cone algorithms appear small. All published prospective trials have used 3-D conformal treatment planning. Intensity-modulated radiation therapy and advanced rotational techniques such as volumetric modulated arc therapy have the potential to increase dose conformity and homogeneity and reduce treatment delivery times.[63] More data are needed on the biologic consequences of potential interplay effects between multileaf collimator motion and tumor motion. The effects of using flattening filter-free radiation, in particular, for faster delivery remain unclear.[64] Single-institution data suggest that the flattening filter-free technique is both safe and effective.[65-66] Published tolerance doses for SABR have largely not been validated, although adherence to published protocols appears reasonable at this time, as rates of severe toxicity were low as a result (Table 37.1). These dose constraints, which are based on the constraints used in the RTOG 0618, 0813, and 0915 SABR trials, are summarized in the current National Comprehensive Cancer Network guidelines.[67]

Patient Immobilization and Set-Up

Customized patient immobilization devices such as the stereotactic body frame or vacuum cushions have been used, but are not considered essential; although they may improve intrafractional patient stability, they do not negate the need for image guidance. A number of studies demonstrated that image-based verification of the target position has the single largest effect on improving the accuracy of lung SABR. Average internal shifts of 5 mm to 7 mm of the pulmonary target relative to the osseous structure are regularly found, and this shift may exceed 2 cm in individual patients.[68,69] Therefore, daily pretreatment imaging is performed with online correction of set-up errors and baseline shifts—imaging needs to demonstrate the lung tumor directly, or implanted markers as a surrogate, for the tumor position (see Fig. 37.1). Imaging during or after completion of SABR serves as a quality assurance purpose, especially in single-fraction SABR. Several technologies for image guidance are commercially available, and superiority of one method over the other has not been demonstrated. Use of volumetric imaging, as opposed to only implanted fiducial markers, has the advantage of allowing for assessment of changes in target shape and position relative to the position of organs at risk.

CLINICAL RESULTS OF SABR

The strongest evidence in support of SABR for treating early-stage NSCLC comes from population-based data.[70] In one population-based study from the Netherlands, survival rates for patients 75 years of age and older were improved after widespread access to SABR.[69] This finding was attributed to both a reduction in the proportion of untreated patients after short-course SABR became available, as well as to local control rates of up to 90% found with this modality. Of the nearly 30% of older Dutch patients who remained untreated despite the availability of SABR, the 30- and 90-day mortality rates measured from the date of diagnosis for untreated patients were 17.9% and 33.3%, respectively.[71] The 90-day mortality rate may be a result of extensive comorbidity with competing causes of death in this patient population. Therefore, overtreatment in very frail patients, even with SABR, may be avoided by carefully reassessing some less-fit patients a few weeks after diagnosis. Another population-based analysis of the National Cancer Data Base (NCDB) demonstrated improved survival in elderly (aged ≥70 years) patients with early-stage medically inoperable NSCLC receiving SABR compared with observation alone.[3,72] In an analysis of SEER data, survival rates following SABR were similar to those after lobectomy, with poorer outcomes following conventional radiotherapy or observation only.[73]

The results of SABR have been very consistent, with both the high local control rates and low toxicity found in prospective clinical trials also being reported in large single-institution series and pooled multi-institutional analyses (Table 37.2).[74–82] Data from these sources demonstrate an average 90% rate of freedom from local progression at 2 years to 3 years. disease recurrence following SABR was reported in a series of 676 patients, all of whom were treated with a BED of more than 100 Gy (Table 37.3).[61] At a median follow-up of 33 months, median overall survival was 40.7 months; actuarial 2-year rates of local, regional, and distant recurrence were 4.9%, 7.8% and 14.7%; and actuarial 5-year rates were 10.5%, 12.7%, and 19.9%, respectively.

Three randomized trials were initiated to evaluate SABR versus surgery for early-stage NSCLC. All three closed early due to poor accrual. A pooled analysis of two of the trials was reported. The rate of 3-year overall survival was 79% in the surgery group and 95% in the SABR group ($p = 0.037$). The rate of recurrence-free survival at 3 years was similar in the SABR and surgery groups (86% vs. 80%, respectively; $p = 0.54$).[83] Since there were only 58 patients in the pooled analysis, it is difficult to make conclusions on the superiority of either treatment. However, it does confirm the efficacy of SABR in the absence of patient selection bias that is inherent in phase I and II trials and the use of SABR as an alternative to surgery.

Patterns of early disease recurrence after curative SABR in early-stage NSCLC are similar to recurrences after primary surgery, where the predominant pattern of disease recurrence is also one of distant recurrence, despite staging FDG-PET.[84] This pattern suggests that occult distant metastases at the time of initial diagnosis remain a major challenge. In an analysis of nearly 1300 patients who had resection, the risk of subsequent disease recurrence ranged from 6% to 10% per person-year during the first 4 years after surgery, but decreased thereafter to 2%.[84] Conversely, the risk of second primary lung cancer ranged from 3% to 6% per person-year after surgery and did not diminish over time, a finding similar to the 6% incidence of second primary lung tumors after SABR.[61]

Toxicity

After a median follow-up of 1.6 years following SABR, the most common toxicity reported for 505 patients was pneumonitis; the rate of grade 2 or higher pneumonitis was 7%, the rate of grade 3 or higher pneumonitis was 2%, and the rate of grade 5 pneumonitis was 0.2%.[80] The median time to onset of pneumonitis was 0.4 years. The other most common toxicities included rib fracture (3%), dermatitis (2%), and myositis (1%). Serial measurements of pulmonary function parameters showed an average decrease of 3.6% in the forced expiratory volume in 1 second and of 6.8% in the diffusing capacity for carbon monoxide within 6 months and 7 to 24 months after SABR.[30] Changes in lung function correlated strongly with pretreatment pulmonary functions, with the largest decreases in function occurring in patients with the best pretreatment values, whereas pulmonary function was stable or even improved in patients with the worst pretreatment values. In addition, symptomatic radiation pneumonitis is uncommon following the treatment of peripheral lung tumors measuring 5 cm or smaller.[75,79,85]

Doses to the contralateral lung predicted for the risk of pneumonitis when larger tumors are treated using a volumetric modulated arc therapy delivery technique. Limiting volumes of the contralateral lung receiving 5 Gy to less than 26% reduces risk of acute pneumonitis,[86] and an analysis in a larger patient group indicated that both the mean dose to the contralateral lung and tumor size were strong predictors of grade 3 or higher radiation pneumonitis after treatment.[87] The findings of this study suggested that limiting the mean dose to the contralateral lung to below 3.6 Gy was optimal.

A higher incidence of severe radiation pneumonitis has been reported for patients with preexisting pulmonary fibrosis.[88] Patients with idiopathic pulmonary fibrosis have an increased risk for grade 3 or higher pneumonitis after both conventionally fractionated radiotherapy[89] and chemoradiation therapy,[90] as well as after surgical resection.[91] Although accurate estimates of the risk of high-grade radiation pneumonitis in idiopathic pulmonary fibrosis are unknown, clinicians should be aware that interstitial lung abnormalities are found on nearly 9% of CT images among individuals over 50 years of age, with definite fibrosis in 2% in a study population of patients over 50 years old.[92] A genetic polymorphism, the *MUC5B* promoter, has been found to be associated with interstitial lung disease.

The chest wall and ribs are at risk for toxicity when tumors are located in the proximity. Current guidelines recommend limiting doses to the chest wall to 30 Gy or less,[23] with approximately 3% of patients reporting severe chest wall pain and rib fractures (Fig. 37.2) after SABR using similar constraints.[93]

Less common toxicities after SABR include myositis, skin toxicity, and neuropathy.[94] Brachial plexus injury can occur following SABR for apical lung tumors, with neuropathic pain developing in the shoulder or arm, motor weakness, or sensory alteration.[95] Limiting the total dose delivered to the plexus in three or four fractions to less than 26 Gy can lower the risk of

this complication. Both tracheoesophageal fistulae and esophageal perforations have been reported following SABR to vertebral or lung SABR target in the proximity of the esophagus.[96] Careful treatment planning is necessary when performing SABR in this situation; guidelines for contouring normal organs in the thorax, as well as a summary of normal organ dose recommendations, have been published.[97]

SABR FOR CENTRAL LESIONS

A widely used working definition for so-called central lung tumors is tumors located either adjacent to the proximal bronchial tree or located 1 cm or less from the heart or mediastinum (Fig. 37.3).[66] A higher incidence of complications has been reported after SABR for central tumors;[98,99] however, in a systematic review of the literature, SABR was found to be a relatively safe and effective curative treatment, provided that appropriate fractionation schedules are used for central tumors.[61] Preliminary analysis of the RTOG 0813 trial, which is a phase I/II study designed specifically to determine the maximum tolerated dose and efficacy of SABR for centrally located tumors, showed a 7.2% rate of grade 3 or worse toxicity using a 12 Gy × 5 fraction SABR regimen. A phase II analysis will examine efficacy rates.[100] A similar single institution study was performed at Washington University in St. Louis, USA, which revealed that 11 Gy × 5 fractions was a safe effective dose. There was a single episode of fatal hemoptysis among the 42 patients treated.[101] Further progress in the use of SABR for central tumors requires ongoing prospective multi-institution trials in order to establish reliable normal organ tolerance dose constraints. However, even the use of so-called risk-adapted fractionation schemes cannot completely preclude a risk of bronchial stenosis when central lung tumors are treated,[96,102,103] but the continued use of this technique in less-fit patients is justified in light of the reported toxicity associated with surgery.[104]

FOLLOW-UP AFTER SABR

Approximately 6% of patients are diagnosed with second primary lung cancers during follow-up after SABR.[61,105] This finding supports the recommendation that patients treated with radical intent should be followed up for detection of treatable relapse, or the occurrence of a second primary lung cancer.[24] While disease progression or recurrence typically occurs within the first 2 years after treatment, current and former smokers remain at elevated risk for developing second primary lung cancers beyond 2 years.[105] A follow-up visit every 3 months to 6 months is recommended during the second and third year after SABR, with annual thoracic CT thereafter. In addition, patients with NSCLC should be offered a smoking-cessation program, as smoking cessation leads to superior treatment outcomes.

Persistent radiographic changes are common after lung SABR (Fig. 37.4), with some degree of late change being nearly universal.[106] Radiation induced lung injury surrounding the treated tumor has been found to correlate with radiation

treatment isodose.[107] A standardized classification system for benign changes has been proposed, with changes classified as acute (within 6 months after treatment) or late (more than 6 months after treatment) (Fig. 37.5). Acute changes include diffuse consolidation, patchy consolidation, diffuse ground-glass opacities, and patchy ground-glass opacities; late changes include a modified conventional pattern, defined as volume loss, traction bronchiectasis, consolidation similar to changes after conventional radiotherapy (but less extensive), mass-like fibrosis, and scar-like fibrosis. Such changes often continue to evolve more than 2 years after SABR, with late changes occasionally showing mass-like effects.[106] Multidisciplinary teams should recognize this finding in order to avoid unnecessary diagnostic procedures.

In a systematic review of the literature, so-called high-risk radiographic features associated with tumor recurrences on CT were identified.[108] These features were (1) an enlarging opacity at the primary site, (2) sequential enlarging opacity, (3) enlarging opacity after 12 months, (4) bulging margins of the opacity, (5) loss of a linear margin, and (6) loss of air on bronchograms. The review also suggested that a maximum standard uptake value of more than 5 on FDG-PET carried a high predictive value of recurrence.

Subsequently, a blinded assessment of serial CT images of 12 patients with pathology-proven local recurrence, which were matched 1:2 to images of 24 patients without recurrence, demonstrated that all previously identified high-risk features were significantly associated with local recurrence ($p < 0.01$). One additional high-risk feature—craniocaudal growth—was identified.[109] The best individual predictor of local recurrence was opacity enlargement after 12 months (100% sensitivity, 83% specificity, $p < 0.001$). The odds of recurrence increased fourfold for each additional
Fig. 37.6. Serial computed tomography images of patients (A) without or (B) with pathology-proven recurrence. High-risk CT features for detection of local recurrence after stereotactic ablative radiotherapy for lung cancer. Radiother Oncol. 2013;109(1):51–57.)*

high-risk feature detected (Fig. 37.6). The presence of three or more high-risk features was highly sensitive and specific (greater than 90%) for recurrence. These findings suggest that assessment of CT images after SABR for the presence of high-risk features may enable an accurate prediction of local recurrence. This information has been incorporated into an imaging follow-up algorithm for patients who are candidates for salvage therapy (Fig. 37.7) in order to allow for the timely administration of curative salvage therapy.[109]

SALVAGE THERAPIES

The use of salvage surgery for suspected recurrence after SABR has been reported by some investigators.[110–112] The limited experience thus far suggests that this procedure is safe in experienced hands, even for some patients who were initially considered to be inoperable. The limited literature on the use of SABR for repeat radiation of local failure following initial SABR suggests that toxicity may be increased, particularly for centrally located lesions.[113]

REPRODUCIBILITY OF SABR RESULTS

A favorable therapeutic ratio of high local control and simultaneous low toxicity has been maintained even after a more widespread adoption of SABR outside of clinical trials and specialized radiotherapy centers.[82] Despite relevant variability and time trends in SABR practice, this reproducible therapeutic ratio suggests that clinical outcomes after SABR are fairly robust. Implementation of modern imaging, treatment planning, and image-guidance technology in recent years may not have increased local tumor control directly but may have improved outcomes on a population-based level by contributing to the rapid adoption of SABR in the radiotherapy community as a result of a streamlined SABR workflow and improved confidence of the treatment team.

ALTERNATIVES TO SABR FOR EARLY-STAGE NSCLC

The three prospective clinical trials comparing surgery and SABR in stage I NSCLC have been prematurely closed because of poor accrual.[114] In the absence of data from randomized trials, propensity score-matched pair analysis can be used to obtain two comparison groups with similar known prognostic factor characteristics. A propensity score-matched pair analysis comparing local–regional control after video-assisted thoracoscopic surgery lobectomy and SABR demonstrated superior local–regional control after SABR, but no differences in overall survival.[115]

In contrast, a propensity matched analysis of the SEER and Medicare databases comparing SABR to thoracoscopic sublobar resection or lobectomy in elderly patients showed that surgical resection may be associated with improved cancer-specific survival, particularly for larger tumors.[116] These conflicting results highlight the limitations of retrospective analyses and the need for strong randomized data.

It has been suggested that in patients who are borderline surgical candidates, a segmentectomy or extended wedge resection with adequate margins and evaluation of hilar and mediastinal nodes is a safe and effective alternative to lobectomy.[91] However, a recent propensity-matched analysis of the NCDB showed worse overall survival with segmentectomy and wedge resection compared with lobectomy for clinical stage IA NSCLC.[117] Additionally, considerably higher rates of morbidity and mortality are associated with surgical procedures in such patients in unselected populations, and mortality from competing risks is considerable.[118] Furthermore, compliance with guideline-specified mediastinal node staging is often poor in surgical populations, with SEER data demonstrating that the mediastinal lymph nodes were not examined in 62% of patients with a diagnosis of pathologic N0 or N1 NSCLC.[119] Another analysis of SEER data showed that no lymph nodes were examined in 51% of sublobar resections performed between 1998 and 2009.[120] The results of European studies also suggest poor compliance with node staging in fit patients who had surgery,[121] thereby minimizing any potential benefits of surgery. A Markov model analysis comparing the cost-effectiveness of SABR with wedge resection and lobectomy for patients with stage I NSCLC who are borderline surgical candidates concluded that SABR was almost always the most cost-effective treatment strategy.[122] In contrast, the same analysis for patients who were deemed to be fit for surgery for early-stage disease suggested that lobectomy may be the more cost-effective option.

Radiofrequency ablation (RFA) involves the image-guided percutaneous placement of one or more probes in the tumor, to which thermal energy is applied. In a 2012 literature review, the rates of local progression in early-stage NSCLC were lower after SABR than after RFA (3.5% to 14.5% vs. 23.7% to 43%).[123] Similarly, the 5-year survival rates were higher with SABR (47%) than with RFA (20.1% to 27%). The most common complication following RFA was pneumothorax, which occurred in 19.1% to 63% of patients. Guidelines from the American College of Chest Physicians and Society of Thoracic Surgeons recommend that, among high-risk patients with stage I NSCLC, use of RFA should be limited to patients who are not candidates for SABR or a sublobar resection.[91]

OLIGOMETASTASES FROM LUNG CANCER

The current clinical staging of lung cancer separates patients rather dichotomously into two groups: patients with and without distant metastases. Patients with overt metastases at the time of diagnosis are primarily treated with palliative systemic treatments. In the spectrum of patients who have no metastases and patients with overt diffuse disseminated systemic disease, an intermediate state exists when metastases are limited in number. This state is referred to as oligometastatic,[124] and patients in this subgroup may have longer overall survival, provided that all detectable tumor deposits are treated radically with surgery and/or radiotherapy. In a systematic review of 49 studies (2176 patients) of oligometastatic NSCLC, survival outcomes varied, with half of the patients having disease progression within approximately 12 months.[125] However, there are long-term survivors, and favorable subgroups have been identified in some—but not all—studies. The interest in oligometastases has grown because of the availability of molecular targeted therapies that have resulted in considerably longer treatment responses and median survival in subgroups of patients with metastatic NSCLC.

The oligometastatic subgroup lacks a precise definition, but a common clinical cut-off point between oligometastases and polymetastases is the number of distant metastases, currently defined as one to five, in two or fewer organs. Eradication of all tumors with less invasive surgical and nonsurgical ablative techniques is becoming increasingly more feasible, thus leading to a growing interest in the incorporation of these techniques into the management of metastatic NSCLC.[126] Nevertheless, the only level I

evidence that supports the existence of the oligometastic state, and the value of aggressively managing the metastases, pertains only to patients presenting with a single brain metastasis.[127,128] Despite the common surgical management of isolated liver and lung metastases in colorectal cancer, this approach has never been prospectively evaluated and proven superior to systemic treatment only for lung cancer.

IMMUNE EFFECTS OF SABR FOR OLIGOMETASTASES

The biologic mechanisms of radiation-induced tumor cell death at fractions greater than 8 Gy to 10 Gy appear to be different from the classical radiobiology paradigms applied to conventionally fractionated radiotherapy.[129] Hypofractionated high-dose radiotherapy is associated with the activation of the innate and adaptive immune responses, enhancing the surface expression of major histocompatibility complex class I molecules and promoting the priming of antigen-specific dendritic cells.[130] High-dose radiotherapy can also increase the number of antigen-presenting cells.[131] The CD8 T-cell response appears to be essential for the antitumor effects of radiotherapy and contributes to the effect of radiotherapy on distant macroscopic disease, also termed an abscopal effect. The so-called abscopal effect is illustrated by preclinical data demonstrating T-cell–dependent antitumor effects in tumors that develop outside of treatment fields.[132]

CLINICAL RESULTS OF SABR FOR OLIGOMETASTASES

In an emerging body of nonrandomized data, SABR has been found to be a relatively nontoxic approach to controlling disease at multiple metastatic sites.[133] In general, patient selection criteria for SABR are broadly similar to those applied to surgical management of oligometastases, but without the requirement of fitness for surgical candidates.

Three distinct cohorts of patients with oligometastases can be identified: patients with oligometastatic disease at the time of diagnosis, patients with oligoprogressive disease after cytoreductive therapy, and patients with oligorecurrent disease after curative local–regional therapy.[134] However, varying criteria used for selecting patients with oligometastases hampers effective comparison, as does the wide range of dose–fractionation schedules used.[135] Clinical data on SABR outcomes in the three oligometastatic categories are mainly derived from retrospective or prospective phase I and II studies, which were not limited to patients with NSCLC. A common approach identifies oligometastatic as being fewer than five lesions, and occurring in no more than two or three different organs, as more extensive disease is associated with a poorer prognosis.[136,137]

The majority of patients with brain metastases from NSCLC have a poor prognosis if unfavorable factors such as extensive extracranial disease and/or poor performance status (Karnofsky score of less than 70) are present. In these patients with a poor prognosis, palliative treatments, including a short course of whole-brain radiotherapy (WBRT), are most appropriate. Several classification systems using prognostic factors such as performance status, control of primary tumor, activity of extracranial disease, and age have been developed in order to identify subsets of patients who may have long-term survival. These classification systems identify patients who are suitable for aggressive treatment of brain metastases; the recursive partitioning analysis classification and disease-specific graded prognostic assessment score are the most widely used for patient prognosis.[138,139]

As demonstrated in smaller studies, prolonged survival is possible for patients with a primary lung cancer with a limited number of synchronous brain metastases if both the brain and the primary tumor are treated aggressively.[136,140] Survival may be further improved in patients with oligometastases limited to the brain only.[141]

Radiosurgery refers to single-fraction stereotactic radiotherapy, and high-precision delivery of a single fraction of 18 Gy to 20 Gy to brain metastases results in local control rates of 60% to 90%. The introduction of so-called frameless radiosurgery, where dedicated mask systems replace use of invasive frames, has improved procedural logistics and lowered the threshold for performing radiosurgery. The role of adjuvant WBRT in addition to local ablative therapies for patients who have one to three brain metastases was addressed in a European Organisation for Research and Treatment of Cancer study. In this study, planned WBRT following either surgery or radiosurgery was reported to reduce intracranial events and neurologic death but failed to improve the duration of functional independence and overall survival.[142] These findings were corroborated in another randomized trial comparing stereotactic radiosurgery (SRS) alone with SRS and WBRT in patients with one to three brain metastases that showed less cognitive deterioration at 3 months with SRS alone and no difference in overall survival.[143] In select patients with as many as five brain metastases, a good performance score, and absence of progressive extracranial disease, advanced techniques integrating simultaneous treatment of WBRT and stereotactic radiosurgery may prolong local control.[144]

There is a considerable amount of literature on the use of SABR for treatment of lung metastases, with results of high rates of tumor control and limited toxicity.[145] A literature review showed that the number of synchronous lung metastases in most trials was between one and three, with limited experience in up to five lesions.[146] Regardless of the use of either single- or multiple-fraction SABR, the 2-year weighted rate of local control was approximately 78%, with a corresponding overall survival rate of 50% to 53%. Grade 3 or higher toxicities were seen in fewer than 4% of all patients. For patients with a single lung metastasis, surgical data from the International Registry of Lung Metastases showed an overall survival rate of 70% at 2 years and 36% at 5 years.[147] Comparable results for surgery and SABR in terms of local control and progression-free survival were found in a retrospective study, despite the fact that fitter patients, in general, were operated on.[148] Overall toxicity after SABR was scored as grade 3 to 5 for 0% to 15% of patients. A pooled analysis of 700 patients in Germany receiving SABR demonstrated 2-year local control and overall survival of 81% and 54%, respectively. There was grade 2 or worse pulmonary toxicity in 6.5% of patients.[149]

Adrenal Gland

Isolated adrenal metastases are not uncommon in NSCLC. Better median and overall survival rates were reported in a systematic review of outcomes after adrenalectomy.[150] Data on the use of SABR suggest that 1-year local control rates range from 55% to 66% with little toxicity, even though most studies have a limited sample size and short follow-up. The risk of adrenal insufficiency should be considered, especially if both glands need to be treated.[151–153]

Liver

A variety of ablative techniques, including RFA, transarterial chemoembolization, percutaneous ethanol injection, and SABR have been used to treat liver metastases from all primary tumors. Reported experience with isolated liver metastases from NSCLC is limited; several prospective studies of SABR have shown that local control rates of approximately 90% are possible, but follow-up in these studies is generally limited.[154–161]

Lymph Nodes

Safety and efficacy data on the use of SABR for hilar and mediastinal nodes are limited, and patients with lymph node metastases should preferably be treated in clinical trials. The available data suggest that SABR may achieve tumor control in cases of isolated

and well-defined nodal recurrences, mainly from abdominal tumors, with out-of-field relapse developing in most patients.[133]

Vertebrae

The vertebrae are commonly involved in metastatic lung cancer, and this can result in spinal cord compression or cauda equina involvement. Although the use of SABR is growing for the management of vertebral oligometastasis, radioresistant spinal metastasis, and previously radiated but progressive spinal metastasis (Fig. 37.8), American College of Radiology appropriateness criteria state that more research is needed to validate the findings of the available phase I and II studies.[162] Phase II studies have been performed with either pain control or radiographic response as
Fig. 37.8. Stereotactic ablative radiotherapy delivery for vertebral metastases, showing patient immobilization (A), highly conformal dose distribution with noticeable reduction in spinal cord (B), and delivery based on daily image guidance through cone-beam computed tomography (C).

study end points, but no randomized comparisons between conventionally fractionated radiotherapy and SABR have yet been published. The fractionation schedules used have varied widely, but local control and/or pain control rates of nearly 80% have been suggested by clinical evidence.[163]

Multiple Organs

Few studies have evaluated outcomes of local ablative strategies in selected patient cohorts with oligometastatic disease at the time of diagnosis, when only one of many metastases progresses during systemic treatment (oligoprogression), or when recurrence manifests in only one of multiple sites that had responded to initial therapy (oligorecurrence).

Two prospective pilot trials of SABR in limited oligometastatic disease enrolled 121 patients with five or fewer metastases.[164] Prior chemotherapy and radiotherapy were allowed, and most sites treated with SABR were in the lung, thoracic lymph nodes, and liver, with few brain metastases. For patients with cancer other than that of the breast, the 2-year overall survival and local control rates were 39% and 74%, respectively. Factors strongly associated with prolonged survival included the presence of one metastasis (compared with more than one) and smaller tumor volume.[164] Similarly, results from a prospective dose-escalation trial of SABR for patients with one to five lesions from various primary tumors have been reported.[165] Patients were included only if they had no brain metastases or had controlled brain disease, if they had no prior radiotherapy, or of if they had tumors smaller than 10 cm or more than 500 mL in volume. Toxicity was uncommon, and the maximum-tolerated dose was not reached in any cohort until a dose level of 48 Gy in three fractions. Patients with lung tumors comprised 26% of the 61 included patients, who had a total of 113 metastases. At a median follow-up of 20.9 months, the 2-year progression-free survival was 22%, with an overall survival of 56.7%. The authors did not find differences in outcomes between patients who had oligometastatic disease after induction therapy and patients who had de novo oligometastases. Patients with one to three metastases tended to have better outcomes than patients with four to five lesions, and disease progression after SABR mainly consisted of a limited number of new metastases.

In a prospective phase II study, which included 39 evaluable patients who had NSCLC with five or fewer metastases,[136] 87% had a single metastasis, and brain metastasis represented 44% of disease localizations. Thoracic disease was classified as stage IIIA in 23.1% of patients and as stage IIIB in 51.3%, and 95% received chemoradiotherapy for local–regional disease. Surgery or radiotherapy was permitted as local ablative treatment. The median overall survival was 13.5 months, and the median progression-free survival was 12.1 months.

Strategies for integrating systemic therapies with SABR have been reported for NSCLC and are based on the hypothesis that acquired resistance to tyrosine kinase inhibitors (TKIs) occurs in only a limited number of sites, the treatment of which may result in prolonged disease control.[166] A study was designed to investigate the effect of local therapies plus continuation of a TKI on the time to second progression. The study included 51 patients who had NSCLC with either anaplastic lymphoma kinase (*ALK*) gene rearrangement or epidermal growth factor receptor (*EGFR*) mutation, and who had oligoprogressive disease after first-line therapy with a TKI.[166] Among 25 patients treated with either crizotinib (15 patients) or erlotinib (10 patients) plus local surgery and/or radiotherapy to sites of progression, the median time to second progression was 6.2 months.

Another single-arm phase II analysis that showed promising results with the use of systemic therapy and SABR for oligometastatic disease included patients with stage IV NSCLC who failed early systemic therapy and had no more than six sites of extracranial disease. Patients were treated with erlotinib and concurrent SABR. Median progression-free survival was 14.7 months, and median overall survival was 20.4 months, both substantially higher than historical values for patients receiving systemic therapy alone.[167] These preliminary findings suggest that local ablative therapies may allow select patients to continue with the same systemic therapy. Comparable results were seen in another group of 18 patients with *EGFR* mutations and extracentral nervous system oligoprogression, treated either with surgery, RFA, or stereotactic radiosurgery plus continuation of a TKI.[168]

Given that the only randomized data to guide radiographic ablative management pertain to patients with brain metastases, more prospective controlled studies are needed to gain an understanding of the real effect of this strategy on clinical outcomes. Some clinical trials were ongoing at the time of publication (ClinicalTrials.gov identifiers: NCT01446744, NCT01345552, NCT01345539, NCT01565837, and NCT01185639). Advances in tumor biology and improved clinical knowledge on the oligometastatic state through improvements in imaging and molecular diagnostics are likely to be needed before progress can be made in treating patients with this disease presentation.

CONCLUSION

The recent advances in SABR have led to new treatment options for both early-stage NSCLC and oligometastatic disease. High-level population data are now available to support the role of SABR as the preferred treatment modality in early-stage NSCLC when patients are unfit for surgery or refuse to undergo the procedure. New randomized trials are underway to evaluate SABR versus surgery. When current SABR guidelines are adhered to, the results appear to be generalizable across centers. For oligometastatic NSCLC, more prospective data are required in order to establish the role of SABR in this setting.

38 Ablation Options for Localized Nonsmall Cell Lung Cancer

Carole A. Ridge and Stephen B. Solomon

SUMMARY OF KEY POINTS

- Since the initial identification of radiofrequency ablation (RFA) as the prototypical thermal ablation technique, it has been joined by microwave ablation, cryoablation, and, more recently, irreversible electroporation as potential options for tumor ablation.

- Factors that influence size of the ablation zone can be divided into probe and tissue characteristics. Probe characteristics can vary by the number of probes used, the use of internal cooling, and their configuration (linear or curved array). Tissue characteristics greatly influence the ablation zone size; lung tissue is prone to tissue dehydration when heat is applied. RFA in the lung can be impeded by tissue dehydration with resultant decreased electrical conductivity. Microwave energy, by contrast, can penetrate charred tissues, thus allowing continuous power application for the duration of the treatment and generation of very high temperatures in the lung.

- Thermal ablation can be offered to patients with medically inoperable stage I nonsmall cell lung cancer (NSCLC). Patients should be selected by an interdisciplinary team, and the maximum tumor diameter should probably not exceed 3 cm to 3.5 cm.

- Aside from its use in stage I lung cancer, RFA is useful for the treatment for patients with a solitary pulmonary nodule remaining after standard therapy of a stage IIIa or IV NSCLC; for salvage therapy of residual or recurrent disease after resection, chemotherapy, and/or radiation; and for pulmonary metastases where the primary disease is controlled in a patient who is a poor surgical candidate.

- Major complications from RFA are rare. The reported rate of major complications is 9.8% and comprises pleuritis, pneumonia, lung abscess, hemorrhage, and pneumothorax requiring pleurodesis.

- Reported 3-year and 5-year survival rates after RFA range from 36% to 88% and from 19% to 27%, respectively. Estimated 3-year cancer-specific survival ranges from 59% to 88%.

- The expected postablation findings on computed tomography include a residual nodule, fibrosis, atelectasis, and cavitation.

Radiofrequency ablation (RFA) was first described with use of a modified Bovie knife in the liver in animal studies published in 1990.[1,2] Subsequent descriptions of successful ablation of liver tumors in the mid-1990s elicited interest in using the technique in other organs.[3,4] RFA in the lung was first found to be safe and efficacious in animal studies in both healthy lung and VX2 sarcomas in the lungs of rabbits.[5,6] Successful use of RFA for lung tumors in humans was described in 2000 in a study of patients with inoperable NSCLC.[7] RFA has since been adopted as a treatment alternative for patients with early stage NSCLC who are unable to undergo surgical resection. Since the initial identification of RFA as the prototypical thermal ablation technique, it has been joined by microwave ablation, cryoablation, and, more recently, irreversible electroporation as potential options for tumor ablation.

MECHANISM OF ACTION OF ABLATION TECHNIQUES

Radiofrequency Ablation

Radiofrequency refers to the portion of the electromagnetic spectrum from 3 Hz to 300 GHz.[8] Thermal ablation using RFA occurs as a result of delivery of an electrical current to tumor cells surrounding the RFA probe tip. Molecules adjacent to the tip are forced to vibrate rapidly, thus creating frictional energy loss between adjacent molecules (Fig. 38.1). These energy losses are manifested as a rise in tissue temperature, known as the Joule effect. Tissues nearest to the electrode are heated most effectively, whereas more peripheral areas are heated by thermal conduction.

Thermal ablation with RFA results in coagulative necrosis. Once cytotoxic temperatures are achieved in the ablation zone, denaturation of intracellular proteins and destruction of the cell-membrane lipid bilayer result in irreversible cell death.[9,10] Heat is transferred from cells immediately adjacent to the electrode tip away from the electrode by thermal conduction. A temperature at the electrode tip above 60°C is needed to achieve cell death.[11,12] Tissue conductivity can, however, be impaired at temperatures above 95°C. Such overheating leads to boiling of the water-predominant tissues, causing steam formation, tissue charring, and a sharp rise in tissue impedance, thereby limiting the effectiveness of RFA.[13,14] Therefore the aim of thermal tumor ablation is to achieve a temperature range of 50°C to 100°C throughout the entire target volume for 4 minutes to 6 minutes without charring or vaporizing tissues.[15] Multiapplicator ablation is possible by rapidly switching from one electrode to another during electrode activation. The radiofrequency circuit requires a return path from the ablation probe tip. This return path consists of two to four grounding pads applied to the patient's skin. The grounding pads disperse current over a much wider surface area than the probe tip, which is therefore the only site of tissue damage.

Microwave Ablation

When an electromagnetic frequency of either 915 MHz or 2.45 GHz is applied to tissue, some of the energy forces molecules with an intrinsic dipole moment, such as water molecules, to continuously realign with the applied field. This rotation of molecules increases kinetic energy and local tissue temperatures in a process

known as dielectric hysteresis (Fig. 38.2).[16] Tissue destruction occurs when tissues are heated to lethal temperatures, which can reach up to 150°C. Microwave power does not rely on electrical conductivity and can therefore penetrate tissues of low electric conductivity, such as lung and desiccated or charred tissue. The high temperatures achievable at the probe tip improve ablation efficacy by increasing thermal conduction into the surrounding tissues. Because it is not part of an electrical circuit, microwave ablation does not require grounding pads. Multiapplicator ablation is possible with microwave energy, and, unlike with RFA, this can be powered continuously without switching from one electrode to another during electrode activation. Also unique to microwave ablation is the ability to use multiple antennas, which are positioned and phased to exploit overlap of the electromagnetic field.[17]

Molecules adjacent to the tip are forced to vibrate rapidly, thus creating frictional energy loss between adjacent molecules that is manifested as a rise in tissue temperature. *(Reprinted with permission from Hong K, Georgiades C. Radiofrequency ablation: mechanism of action and devices.* J Vasc Interv Radiol. *2010;21(8 Suppl):S179–S186.)*
Cryoablation

Cryoablation involves rapid cooling of the tissues by means of the Joule–Thompson effect, whereby rapid expansion of a high-pressure gas results in a change in the temperature of the gas.[18,19] When the gas, typically argon, reaches the distal tip of the cryoablation probe, it is forced through a narrow opening and rapidly expands at atmospheric pressure, leading to rapid cooling. This process occurs inside the needle so that the patient is not directly exposed to the emitted gas. The probe is then sequentially warmed and cooled again, to augment cellular damage. Warming is performed by the release of high-pressure helium through the probe tip, which increases in temperature when released into the atmosphere.[19,20]

During rapid tissue cooling, water is trapped within the cellular membrane, resulting in intracellular ice formation. When the temperature is maintained below the freezing point of water, intracellular ice formation can cause recrystallization and extension of the ice within the intracellular matrix. Alternatively, if gradual cooling occurs, extracellular ice crystals form, which sequester extracellular water. During the thawing cycle, water returns to the intracellular space and causes cellular lysis and enzymatic and membrane dysfunction (Fig. 38.3). As a secondary effect in the adjacent tissues, intracellular ice crystal formation in blood vessels causes damage to the vascular endothelial cells. Reperfusion in the post-thaw period recruits platelets, which contact the damaged endothelium, resulting in thrombosis and ischemia.[21,22] With each successive freeze–thaw cycle, tissue cooling is faster, and the volume of frozen tissue and extent of tissue destruction are enlarged.[15] The optimal temperature to ensure tumor death is around –50°C. Cryoablation has an advantage over other thermal ablation modalities in that the ice ball created during cryoablation is visible on computed tomography (CT) images, allowing the operator to monitor the extent of ablation.[23]

Irreversible Electroporation

Irreversible electroporation is a nonthermal technique for tumor ablation that causes irreversible damage to the cell membrane by applying pulsed electric fields of up to 3 kV/cm to the ablation target, thereby inducing cell death.[24,25] The cellular lipid bilayer is disrupted by these high-voltage electrical currents because of the formation of permanent nanopores, which in

Fig. 38.2. Mechanism of action of microwave ablation. Electromagnetic frequency is applied to the target tissue, forcing water molecules to continuously realign with the applied field. This rotation of molecules increases kinetic energy and local tissue temperatures in a process known as dielectric hysteresis. *(Reprinted with permission from Brace CL. Radiofrequency and microwave ablation of the liver, lung, kidney, and bone: what are the differences?* Curr Probl Diagn Radiol. *2009;38(3):135–143.)*

turn disrupt cellular homeostasis (Fig. 38.4).[26] Irreversible electroporation has two theoretical advantages over thermal ablation: (1) because it is nonthermal, the heat-sink phenomenon is not observed; and (2) irreversible electroporation theoretically preserves tissue interfaces and therefore is thought to spare sensitive structures such as the airways and nerve sheaths.[16] Its use in the lung has not been fully studied in humans, but its potential for preserving airways and mediastinal vessels makes it an attractive future option for the treatment of unresectable lung tumors in anatomically sensitive locations. Irreversible electroporation must be performed using general anesthesia with complete neuromuscular blockade, to avoid generalized muscle contractions. High-voltage pulses are delivered with electrocardiographic gating to minimize the risk of cardiac arrhythmias.[26] Further research is needed before the clinical application of this interesting technology can be optimized.

TECHNICAL FACTORS INFLUENCING SIZE OF THE ABLATION ZONE

Factors that influence size of the ablation zone can be divided into probe and tissue characteristics.

Probe Characteristics

Probe characteristics include electrode exposure length, number of probes, treatment duration, maximum temperature reached, type of energy used, and energy pulsing and cooling (in the case of RFA). Length of the RFA zone has been shown to increase proportionally using exposure lengths of up to 3 cm in the liver. Above this tip size, however, a cylindric ablation zone is not achieved and heterogeneity is more often observed, leading to a dumbbell-shaped ablation zone.[27] To offset this limitation, more than one probe can be used to produce overlapping ablation zones in larger or nonspherical lesions.[28] Umbrella-configuration RFA probes with multiple hooked arrays have also allowed the creation of larger ablation zones.[29] In addition, the size of the ablation zone increases linearly in proportion to the probe gauge size from 24G to 18G. Treatment duration is proportional to ablation zone volume up to a maximum of 6 minutes using RFA in the liver, but no additional benefit is achieved by using ablation times beyond 6 minutes.[27,30]

To avoid the deleterious effects of tissue vaporization and charring and to increase the size of the ablation zone, internally cooled probe tips have been devised, whereby chilled saline is pumped through the shaft of the needle.[31] Saline infusion of microwave ablation probes has also been shown to produce larger ablation zones in the lung and liver.[32] However, the viscosity of water can limit flow and cooling capacity in small-diameter microwave antennas,[33] and therefore compressed gas may be used to cool the microwave probe.[34] Similar advantages have been described using a pulsed RFA system, whereby cyclic periods of low-current deposition are alternated with higher peak currents; this strategy allows the tissues to rehydrate during the ablation, thus reducing tissue impedance and charring.[35] High levels of impedance at the ablation probe tip (e.g., >1000 ohm) can also be fed back to the radiofrequency generator and inhibit RFA impulse generation. As mentioned earlier, radiofrequency technology allows the combination of multiple probes to achieve a larger, more confluent ablation zone over a shorter treatment duration than with sequential ablation.[36]

The type of energy applied influences the size of the ablation zone and the time required to reach an ablative temperature. Radiofrequency relies on both electrical and thermal conductivity. Heating a tissue to temperatures near or above 100°C causes water to boil and evaporate, leading to tissue dehydration and altered electrical conductivity (e.g., charred tissue), which inhibits the flow of electrical current. Microwave energy, by contrast, can penetrate charred or desiccated tissues, thus allowing continuous power application for the duration of the treatment, generation of very high temperatures, and less susceptibility to heat-sink effects than radiofrequency energy. These high temperatures can be reflected along the probe shaft, raising concerns about fistula formation and skin burns at the needle entry site; these complications can be avoided by using shorter ablation sessions and cooled antenna devices.[33,37,38]

Tissue Characteristics

The electrical, thermal, and mechanical properties of the ablated tissue are largely dependent on water content and cellular makeup. Normal lung tissue, when compared with the liver, has lower electrical and thermal conductivity, relative permittivity, and effective conductivity. A low level of electrical and thermal
Fig. 38.3. Mechanism of action of cryoablation. Rapid expansion of a high-pressure gas within the cryotherapy probe tip results in rapid cooling within the ablation target; water is trapped within the cellular membranes, resulting in intracellular ice formation. If gradual cooling occurs, extracellular ice crystal formation sequesters extracellular water. During the thawing cycle, water returning to the intracellular space causes cellular lysis and cellular enzymatic and membrane dysfunction. Intracellular ice crystal formation in adjacent blood vessels causes damage to endothelial cells. *(Reprinted with permission from Erinjeri JP, Clark TW. Cryoablation: mechanism of action and devices.* J Vasc Interv Radiol. *2010;21(8 Suppl):S187–S191.)*
Fig. 38.4. Mechanism of action of irreversible electroporation (IRE). Pulsed electric fields are applied to the ablation target, thereby creating permanent nanopores in the cellular lipid bilayer, which in turn disrupt cellular homeostasis.

conductivity limits the flow of radiofrequency energy.[39] Lung tumors have relatively densely packed cells and therefore behave similar to solid organs, with higher conductivity than adjacent lung tissue. Enhanced heating has been observed in experimental models at the interface between these tissues (e.g., tumor and aerated lung), but the clinical application of this feature has not been elucidated.[40] Microwave ablation takes advantage of the low relative permittivity and effective conductivity of the lung and as a result leads to deeper penetration than in solid organs. Cryoablation relies on thermal conductivity and ice-ball formation, and because most tissues have a high water content, thermal conductivity is usually good. However, cryoablation in the lung is limited by its inherently low thermal conductivity. Nevertheless, this drawback is progressively overcome as ice-ball formation progresses, which increases the thermal conductivity of the ablation target.[41] Cryoablation in the lung produces an ablation zone slightly smaller than that produced in the kidney but larger than that produced in the liver.[42]

Heat Sink

Blood vessels within the target tissue provide a source of convective tissue cooling (or heating in the case of cryoablation) known as heat sink. Heat sink theoretically applies to all methods of thermal ablation, but is clinically observed in varying degrees. Vessel size within the target tissue is a major determinant of this effect. The presence of vessels larger than 3 mm in diameter in direct contact with the ablation target was reported to be associated

with decreased coagulation necrosis in RFA and an increased rate of local recurrence in the liver and lung, respectively.[43,44] Microwave ablation appears to be less sensitive to the heat-sink effect because of a greater magnitude of heating and better tissue penetration than with RFA.[45] Cryoablation, which relies on thermal conductivity, has not shown a measurable heat-sink effect in the lung or liver.[22,46]

INDICATIONS FOR THERMAL ABLATION

The standard of care for stage I NSCLC is surgical resection. However, only one-third of patients are eligible for surgical intervention.[47] Thermal ablation can be offered to patients with medically inoperable stage I NSCLC using standards described by the Society of Interventional Radiology.[48] Patients should be selected by an interdisciplinary team, and the maximum tumor diameter should probably not exceed 3 cm to 3.5 cm.[49]

Because the duration of clinical experience and the volume of published data are greater for RFA than for other ablation modalities, RFA has received endorsement by means of clinical guidelines.[50] However, microwave ablation is likely to be increasingly used for NSCLC because of its theoretical advantages over RFA, including a less severe heat-sink effect and faster, greater heating. Cryoablation and irreversible electroporation have not yet been formally recommended for use in lung tumor ablation outside of a research setting.[23,51]

Aside from its use in stage I lung cancer, RFA has been identified as useful for the following: treatment for patients with a

solitary pulmonary nodule remaining after standard therapy of a stage IIIa or IV NSCLC; salvage therapy of residual or recurrent disease after resection, chemotherapy, and/or radiation;[52] and pulmonary metastases where the primary disease is controlled in a patient who is a poor surgical candidate.[53] Combined RFA therapy and inhibition of the epidermal growth factor receptor (EGFR) receptor may also confer a benefit in the treatment of patients who have NSCLC with an EGFR mutation and acquired resistance to EGFR tyrosine kinase inhibitors in one or more metastases.[54]

COMPLICATIONS OF THERMAL ABLATION

Pneumothorax is the most commonly reported complication for all thermal modalities.[55] Self-limited pneumothorax had a reported incidence of 22.4% after RFA, and pneumothorax requiring chest tube insertion (but not pleurodesis) had a similar incidence (22.1%) in a retrospective study of 1000 patients.[55] Major complications from RFA are rare. The reported rate of major complications is 9.8% and comprises aseptic pleuritis, pneumonia, lung abscess, hemorrhage, and pneumothorax requiring pleurodesis.[55] Rarer major complications include bronchopleural fistula, tumor seeding, and nerve or diaphragmatic injury (<0.5% incidence). The reported mortality rate after RFA for lung tumors is 0.4%. Nerve injury has an incidence of 0.2% to 0.3%, affecting the phrenic, brachial, left recurrent laryngeal, and intercostal nerves and the stellate ganglion.[56]

The literature on microwave ablation includes reports of similar complication rates, including self-limited pneumothorax (27%), pneumothorax requiring chest tube insertion (12%), and skin burns (3%).[32] Although not commonly reported in the literature on RFA, skin burns have been described in two patients who had microwave ablation, one of whom required debridement and chest wall reconstruction, presumably due to shaft heating.[32] Intraprocedural or periprocedural death has not been described after microwave ablation. One death was reported from a delayed infectious complication at 6 months after microwave ablation.[57] Bronchopleural fistula has also been reported as a rare complication of microwave ablation, although endobronchial valve insertion is reported to be a potential therapy for fistulas.[58,59]

Complications from cryotherapy of lung tumors are similar to those of previously described ablation modalities. The risk of hemorrhage with cryotherapy is theoretically greater because this procedure lacks the cautery effect of heat-based ablation. Two studies of cryoablation-related complications reported hemoptysis in 36.8% to 55.4% and massive hemoptysis in 0% to 0.6%.[60,61] Pneumothorax and pleural effusion are the most common complications, with incidence rates of 61.7% and 70.5%, respectively. Less common complications include phrenic nerve palsy, frostbite, and empyema (0.5% each), and tumor seeding (0.2%).

Pulmonary function testing after RFA has been described in the literature. One study reported impairment of vital capacity and forced expiratory volume at 1 second at both 1 month and 3 months after ablation. In this study, severe pleuritis and ablation of a large volume of adjacent parenchyma were shown to be independently associated with a decline in pulmonary function. However, two other studies reported no deterioration in pulmonary function at 3 months, 6 months, or 24 months, which suggests that the functional impact of RFA may be transient.[62–64]

Careful patient selection may minimize the risk of complications. For example, in the largest case series that included a report of complications after RFA, previous systemic chemotherapy was a significant risk factor for aseptic pleuritis, and prior external-beam radiotherapy and advanced age were significant risk factors for pneumonia. Patients with emphysema had a greater predilection for lung abscess and pneumothorax requiring pleurodesis. Finally, serum platelet count (≤180,000 cells/μL) and tumor size (>3 cm) are significant predictors of hemorrhage ($p < 0.002$ and 0.02, respectively).[65]

REPORTED OUTCOMES OF THERMAL ABLATION

Survival and Recurrence

The literature analyzing outcomes after RFA as a therapy for stage I primary NSCLC is limited by study size and population heterogeneity in terms of concomitant treatments administered (e.g., chemotherapy and in-field radiation) and selection bias.[66,67] The latter relates to the fact that long-term survival data are strongly influenced by medical comorbidity. For example, the all-cause mortality rate for patients with inoperable early stage lung carcinoma (19.1%) is substantially higher than that of operable patients (3.4%).[68] Therefore, lung cancer–specific survival and disease-free intervals may be better measures of treatment outcome. With allowance for these limitations, recurrence rates after RFA of stage I NSCLC were reported in 11 studies; the aggregate rate of local progression was 24% (95 of 403 patients)[63,64,67,69–74] and the rate of metastasis at any site was 31% (42 of 137; Table 38.1).[63,67,69,71,72] Reported 3-year and 5-year survival rates ranged from 36% to 88%[67,70,72–74] and from 19% to 27%, respectively.[63,67,75] Estimated 3-year cancer-specific survival ranged from 59% to 88%.[63,67,70,73] Patients with synchronous and metachronous primary NSCLCs were also reported to have similar local control rates and survival outcomes.[76] The cellular subtype previously called bronchioloalveolar carcinoma (now referred to as adenocarcinoma in situ or minimally invasive adenocarcinoma) may have a better prognosis after RFA. Lanuti et al.[72] described a 90% local control rate of bronchioloalveolar carcinoma after RFA, compared with 68.5% for all cell types.

Most of the literature on microwave ablation and cryoablation includes patients with both primary lung and metastatic lesions who were treated for varied indications (for both local control and palliation). The outcomes of patients with early stage lung cancer are not uniformly reported separately from those of patients with metastases; therefore firm data on long-term survival for stage I NSCLC treated with microwave ablation and cryoablation are currently lacking. Three retrospective studies report an aggregate local recurrence rate of 30% (27/90). Reported 3-year and 5-year survival rates were 43% to 48% and 28%, respectively. Estimated 3-year cancer-specific survival is reported in one study to be 65%.[77,78] Two small studies included reports of outcomes for patients with stage I lung cancer treated with cryoablation and described local recurrence rates of 3% and 11%, respectively, overall 3-year survival rates of 77% and 88%, respectively,[66,79] and a 3-year cancer-specific survival of 90.2%.[67]

Surveillance

CT is the most common modality used for surveillance after ablation of lung cancer. After an initial increase in size due to inflammation during the first 2 months, the ablation zone is expected to decrease in size. The expected findings on CT include the following: (1) a residual nodule; (2) fibrosis, which usually has an elongated linear appearance; (3) atelectasis; and (4) cavitation (Fig. 38.5). Cavitation occurs more frequently in patients with NSCLC near the chest wall or with emphysema.[81] Complete disappearance of the opacity at the ablation site is rarely observed.[82] Positron emission tomography (PET)–CT at 24 hours and at 1 month after ablation can demonstrate tracer activity at the ablation site, despite adequate treatment,

[a]Mean value.

CSS, cancer-specific survival; *MWA,* microwave ablation; *NR,* not reported; *RFA,* radiofrequency ablation.
Fig. 38.5. Expected appearance on computed tomography after thermal ablation. At 1 month after radiofrequency ablation of a stage I adenocarcinoma in the left upper lobe (A), the ablation zone exhibits perilesional ground-glass opacity; cavitation can then develop within 6 months (B), followed by fibrosis, which has an elongated linear appearance (C).

as a result of inflammation. This is expected to resolve by 3 months after ablation.[83] The absence of tracer activity at the site of ablation on PET–CT at 6 months after ablation has been shown to correlate better with clinical outcome at 1 year than does PET–CT performed 4 days after ablation.[84] The expected appearance on early PET–CT is that of a ring or halo of low peripheral activity in the ablation zone with central photopenia, which may persist until 6 months but should resolve by 12 months (Fig. 38.6).[85]

Residual disease or recurrence of disease should be considered if imaging shows increasing uptake of contrast material in the ablation zone, growth of peripheral nodules, a change within the ablation zone from ground-glass opacity to solid opacity, enlargement of regional or distant lymph nodes, new sites of intrathoracic disease, or new extrathoracic disease. Other signs include increased metabolic activity on PET–CT more than 3 months after ablation (Fig. 38.7) or residual metabolic activity centrally or in a nodular pattern.[10]

TREATMENT CONSIDERATIONS

Identifying the Ideal Candidate for Ablation

Characteristics of the patient and lung lesion are important factors in selecting the ideal candidate for ablation. Ablation of stage I primary NSCLC can be considered for patients who are not candidates for curative surgical resection as a result of cardiorespiratory comorbidity or insufficient vital lung function. Patients being considered for ablation should have an Eastern Cooperative Oncology Group performance status of less than
Fig. 38.6. Expected appearance on positron emission tomography–computed tomography after thermal ablation. (A–D) Nonfused PET images and (E–H) CT images of a left lower lobe adenocarcinoma before (A and E) and after radiofrequency ablation at surveillance periods of 4 months, 9 months, and 42 months exhibit a halo of low peripheral activity in the ablation zone with central photopenia at 4 months, which resolves by 9 months and remains photopenic at 42 months, indicating successful ablation.

3 and a life expectancy of more than 1 year.[86,87] Lesions larger than 3 cm have a higher incidence of tumor recurrence.[88] Lesions within 1 cm of sensitive structures such as the trachea, main bronchi, esophagus, and central vessels are associated with a higher risk of complications and may often receive incomplete ablation because of the heat-sink effect.[47]

Immunologic Effects

Spontaneous regression of untreated prostate and liver tumors has been reported after thermal ablation.[89–91] Damaged cells are thought to trigger an alarm to the immune system, which protects against self-damage, for example, in the setting of cell death due to necrosis. In particular, heat-shock proteins chaperone antigenic peptides of the cells from which they are derived and stimulate the maturation of dendritic cells, inducing the production of antigen-specific T cells.[92,93] Thermal ablation therefore represents an opportunity to induce antitumor immunity. This immunity is weak, however, and would not eradicate established

tumors if used as a sole therapy. Thermal ablation may be used in the future in combination with chemotherapeutic or immunotherapeutic agents to treat tumors.[94] Serologic evidence of an immune response has been documented after ablation of renal, lung, liver, soft tissue, and bone tumors, and this leads to an elevation of serum cytokine interleukin-6 and interleukin-10 levels, which are attractive potential targets for immunotherapy.[95]

Thermal Ablation in Combination With Adjunctive Therapies

Combined therapy using thermal ablation and radiotherapy may act synergistically to improve survival compared with either modality alone. In one study, thermal ablation followed by external-beam radiotherapy was given to 41 patients with inoperable stage I or II NSCLC. The local recurrence rate was 11.8% for tumors smaller than 3 cm and 33.3% for larger tumors, with an acceptably low complication rate of combined therapy.[96] A smaller series of 24 patients treated with a combination of RFA
Fig. 38.7. Positron emission tomography–computed tomography (PET–CT) appearance of local recurrence after thermal ablation. This patient with left upper lobe squamous cell carcinoma after right pneumonectomy had radiofrequency ablation followed by PET–CT immediately after ablation (A) and 3 months after ablation (B, C). Residual tumor is demonstrated in the medial aspect of the lesion, where increasing metabolic activity and peripheral nodular opacity are shown (C, D).

and adjuvant external-beam radiotherapy resulted in a local recurrence rate of 9%.[96] However, the use of external-beam radiotherapy with RFA increases the potential for toxicity to normal lung tissue by ionizing radiation. A potential solution to this problem may be the use of brachytherapy to optimize local control while also sparing normal lung tissue. RFA followed by high-dose-rate brachytherapy, delivered via a catheter, yielded good local control in 82% of treated patients while lowering the risk of pulmonary toxicity.[98] The synergistic effect is thought to be due to the fact that thermal ablation is most effective in the central portion of the tumor, whereas radiation is better at treating tumor margins; in addition, thermal ablation causes neovascularity, whereby superoxide anions and free radicals form and cause DNA damage; this process is also thought to enhance the effect of radiotherapy.[87]

CONCLUSION

The field of ablation is evolving because of improved devices and greater operator experience. Ablation offers an effective way to treat localized NSCLC while limiting damage to the adjacent normal lung. Ablation options for the treatment of localized NSCLC include RFA, microwave ablation, and cryotherapy. Irreversible electroporation is a novel ablation method with potential application to lung tumors in sensitive locations and merits further research. The mechanism of action of each ablation technique differs based on the ablation modality used and the tissue to which it is applied. Understanding these aspects for each modality is essential for their effective and safe use. Selection of appropriate candidates is based on patient and lesion characteristics and influences clinical outcomes in terms of local recurrence, survival, and complication rates. Thermal ablation can be offered to patients with medically inoperable stage I NSCLC. Suitable lesions are selected based on a size of less than 3 cm to 3.5 cm and a location that avoids sensitive structures and minimizes the heat-sink effect. Clinical outcomes after RFA of stage I NSCLC are good in terms of local recurrence rate and cancer-specific survival. Thermal ablation therefore offers a therapeutic alternative for patients who are ineligible for surgical intervention. Long-term data after treatment

with microwave ablation and cryotherapy are awaited. Imaging surveillance after ablation of lung tumors includes both anatomic and metabolic imaging. The ablated lesion exhibits typical features on CT and PET, which evolve over time. Future directions for lung tumor ablation include combined approaches using thermal ablation and other therapies, which may synergistically improve clinical outcomes compared with either therapy alone.

39 Radiotherapy for Locally Advanced Nonsmall Cell Lung Cancer Including Combined Modality

Paul Van Houtte, Hak Choy, Shinji Nakamichi, Kaoru Kubota, and Francoise Mornex

SUMMARY OF KEY POINTS

- Concerning radiotherapy, higher physical or biologic dose (altered fractionation) is associated with better local control and, in some trials, with better survival. Current evidence favors a schedule of 60 Gy to 66 Gy in 6 weeks to 7 weeks, with no benefit for doses beyond that.
- Concurrent chemoradiation therapy is the optimal treatment strategy with curative intent for fit patients not candidates for surgery.
- Currently, there is no place for adding a molecularly targeted agent to the combined-modality regimens outside a clinical trial, which should select patients based on the relevant biomarker.
- The choice between surgery and chemoradiotherapy should be discussed within a multidisciplinary tumor board based on patient comorbidity and preferences, and prognostic factors.
- Prophylactic cranial radiation is not recommended as a standard therapy.

Stage III disease accounts for one-third of all lung cancers and comprises the most heterogeneous group of tumors in terms of clinical presentation and treatment options.[1,2] Two articles published in 2012 highlight the debate and controversy about managing stage IIIA nonsmall cell lung cancer (NSCLC).[3,4] Among thoracic surgeons surveyed, 84% of thoracic surgeons favored neoadjuvant therapy followed by surgery for microscopic N2 disease.[4] For grossly involved N2, 62% of these surgeons favored neoadjuvant therapy followed by surgery in the context of mediastinal downstaging but only 32% choose this approach for bulky disease.[4] In a survey of oncologists, 92% favored a neoadjuvant approach followed by surgery for minimal N2 and 52% chose chemoradiation therapy for bulky disease.[3] Treatment options for NSCLC range from aggressive use of a single modality through to trimodality treatment that includes surgery, chemotherapy, and radiotherapy.

Significant advances in treatment have improved outcomes for patients with locally advanced NSCLC since the 1980s. Active areas of research include determining the appropriate sequence of systemic treatments, discovering novel agents, and improving delivery of radiotherapy through technologic advances. Current treatment paradigms extend beyond age, performance status, and nonsmall cell histology and incorporate an expanding list of factors in the decision-making process. In the near future, therapeutic strategies will be individualized based on the identifiable molecular characteristics of a tumor,[5] leading to better patient outcomes and more effective clinical trial design. Technologic improvements in radiotherapy enable oncologists to target tumors with more precision and effectiveness, thus making it an option for patients who previously might have not been candidates for this treatment modality.

Definitive radiotherapy had been the standard of care for patients with locally advanced NSCLC until results from clinical trials showed that chemoradiation therapy improved survival. (When considering the trials reviewed in this chapter, it is important to remember that the old tumor, node, metastasis [TNM] classification system—the sixth edition—was usually used.)

Radiation alone is the definitive treatment for patients with locally advanced NSCLC who are not candidates for chemoradiation therapy. Radiotherapy also has a role in the treatment of select patients with isolated thoracic recurrence. Benefits of radiotherapy include palliation of tumor-related symptoms, local control of tumor growth, and a potential survival advantage.

RADIOTHERAPY DOSE AND FRACTIONATION

Dose

When radiotherapy alone is used to treat locally advanced NSCLC, the median survival is approximately 10 months and the 5-year survival rate is 5%.[6–9] In the 1970s, the Radiation Therapy Oncology Group (RTOG) conducted a phase III trial (RTOG 73-01) to evaluate the effect of radiotherapy dosage on local control rates and overall survival.[10] Patients were randomly assigned to treatment with 40 Gy, 50 Gy, or 60 Gy in 2-Gy daily fractions or to a split-course schedule. Local control rates were significantly better with the highest dose (52% vs. 62% vs. 73%, respectively; $p = 0.02$), although median survival rates were similar (10.6 months vs. 9.5 months vs. 10.8 months, respectively). The split-course schedule was associated with inferior local control and survival. This trial established 60 Gy in 30 fractions as the standard radiotherapy dose-fractionation scheme for decades.

Early radiotherapy portals were designed to cover the primary tumor, ipsilateral hilum, ipsilateral and contralateral mediastinum, and ipsilateral supraclavicular nodes, leading to a large irradiated volume. This approach was called elective nodal irradiation. As the toxicity of this approach and the relation between local failure occurring mainly at the level of the gross tumor volume and poor patient outcomes became more apparent, treatment planning shifted toward involved field radiation.[11] Concern about the potential for nodal recurrence has slowed the adoption of involved field radiation; however, a prospective randomized trial from China showed promising results. Patients with locally advanced NSCLC were treated with 68 Gy to 74 Gy involved field radiation or 60 Gy to 64 Gy elective nodal irradiation.[12] At 5 years, patients who received involved field radiation had significantly better overall response rates (90% vs. 79%, $p = 0.032$), local control (51% vs. 36%, $p = 0.032$), and fewer cases of pneumonitis (17% vs. 29%, $p = 0.044$). Treatment with involved field radiation significantly improved overall survival at 2 years (39.4% vs. 25.6%, $p = 0.048$). Despite several limitations of this study, the results are intriguing and suggest that involved field radiation is unlikely to compromise clinical outcomes. Furthermore, several studies have clearly demonstrated that the number of isolated nodal failures outside the involved field radiation remains very low.[13,14]

Technologic advances have enabled researchers to determine the optimal volume and explore the role of dose escalation in improving local control rates. The introduction of positron emission tomography (PET)–computed tomography (CT) imaging has enhanced treatment planning. The addition of cone-beam CT on linear accelerators has led to new radiotherapy such as intensity-modulated radiotherapy (IMRT)—either static or rotational—and image-guided radiotherapy, which improves the accuracy of daily radiotherapy delivery.[15] Because of these improvements, the classical safety margins can be decreased, allowing researchers to increase the total dose either physically or biologically.

In early phase I/II trials, increasing the radiotherapy dose to 74 Gy or more improved the median survival times to 24 months.[16–18] Given the promising results of these trials and a pooled analysis of Cooperative Group studies, a phase III randomized trial (RTOG 06-17 trial) was designed to compare concurrent chemoradiotherapy and dose-escalated radiotherapy with standard radiotherapy dosage. There was a second randomization to evaluate the role of cetuximab. Patients with locally advanced NSCLC were randomized to a standard-dose radiotherapy (60 Gy in 30 daily fractions) or a high-dose radiotherapy (74 Gy in 37 fractions) concurrently with weekly paclitaxel and carboplatin followed by two cycles of consolidation and to cetuximab or not. The 2-year survival rates were 58% for the standard dose and 45% for the high radiation dose.[19] The local failure rate was also higher in the experimental arm: 38.6% versus 30.7%, respectively, at 2 years. Planning target volumes were very similar between the two arms as well as the use of IMRT. However, although 10 patients died in the 74-Gy arms compared with two in the 60-Gy arms, the toxicity rates were not different between the two groups. Several explanations have been put forward to explain these worse outcomes in the higher dose arm, including heart toxicity and the loss of efficacy through longer overall treatment time and accelerated repopulation. It is important to note that the outcomes in the low-dose arm are among the best ever observed in a population with stage III NSCLC. A subsequent analysis examined the role of IMRT as patients were stratified according to the radiation technique: the planning target volume was larger for patients treated by IMRT compared with three-dimensional conformal radiation therapy (486 mL vs. 427 mL), but the outcomes were similar for the two techniques.[20] Less grade 3 pneumonitis, lower heart dose, and less dose reduction for chemotherapy were observed for patients treated by IMRT. There was a concern that IMRT could result in very low doses of radiation to large volumes of normal lung with increased pneumonitis risk, but an increased incidence of radiation pneumonitis was not observed.

Altered Fractionation Schedules

Multiple trials have tested the use of altered dose-fractionation schedules to improve the therapeutic index of radiotherapy. These approaches have included hyperfractionation (two or three fractions per day with a lower dose per fraction over the standard treatment duration), accelerated fractionation (use of a standard fraction size and total radiation dose, given over a shorter overall time), or a combination of these approaches. Compared with standard chemoradiation therapy, hyperfractionated radiotherapy with concurrent chemotherapy, delivered continuously or as a split course, has not been shown to increase survival in randomized studies.[21,22] However, studies have demonstrated improved outcomes with hyperfractionated accelerated radiotherapy (HART). In one randomized trial, the 2-year survival rate was better with continuous HART, delivering 54 Gy in 36 fractions of 1.5 Gy over 12 days, than with conventional radiotherapy alone, 60 Gy in 30 fractions (29% vs. 20%).[23] In Eastern Cooperative Oncology Group (ECOG) 2597, patients were given two cycles of carboplatin and paclitaxel and then randomly assigned to HART (1.5 Gy three times per day for 2.5 weeks) or standard radiotherapy (64 Gy in 2-Gy daily fractions). There was

a nonsignificant improvement in median survival (20.3 months vs. 14.9 months, $p = 0.28$) and 3-year overall survival (23% vs. 14%) for patients in the HART arm.[24]

The most informative results come from a meta-analysis of data from 2000 patients (eight trials) who had been randomly assigned to an altered regimen or conventional fractionation.[25] The analysis was limited to trials in which the chemotherapy was identical in both treatment arms. Modified fractionation resulted in a small, but significant, improvement in 5-year overall survival (10.8% vs. 8.3%; hazard ratio, 0.88; 95% confidence interval [CI], 0.80 to 0.97; $p = 0.009$). Severe esophageal toxicity was more frequent in the modified fraction group (19% vs. 9%).

Widespread adoption of modified radiotherapy schedules instead of conventional once-daily treatments has been limited by the logistical challenges of HART for the patient and treatment centers, as well as the higher rates of toxicity.

Hypofractionation

Hypofractionated radiotherapy is the delivery of fewer, larger (>2 Gy) doses of radiotherapy and is another potential strategy for improving dose intensity. This approach has become more feasible as a result of decreasing radiotherapy volumes, which allow for more conformal radiotherapy delivery and limit the dose delivered to normal tissue. Few studies have evaluated hypofractionation with modern radiotherapy techniques for locally advanced NSCLC. Two prospective phase II studies evaluating concurrent platinum-based chemotherapy with radiotherapy (2.4 Gy/d to 2.75 Gy/d) have reported an encouraging median survival of 20 months.[26,27] In the sequential or concurrent cancer radiation (SOCCAR) trial, 55 Gy was delivered in 20 fractions over 4 weeks with sequential or concurrent chemotherapy (cisplatin [DDP]–vinorelbine). In this limited phase II trial, 2-year survival rates were similar (50% vs. 46%) with 8% experiencing grade 3 esophagitis.[27] Additional studies using modern radiotherapy techniques are currently being conducted within a cooperative group setting as well as in single institutions. One study of interest is a phase III trial comparing a hypofractionated course of 60 Gy in 15 fractions over 3 weeks with conventional radiotherapy (60–66 Gy in 30–33 fractions over 6 weeks to 7 weeks) without concurrent chemotherapy for patients with stage II–III NSCLC and poor performance status (NCT01459497).

Ongoing research is examining isotoxic dose escalation based on normal tissue tolerance or using the stereotactic body irradiation therapy technique to increase the dose to ^{18}F-2-deoxy-D-glucose-avid portions of the tumor based on intratreatment PET–CT. Currently, a randomized trial is comparing a homogeneous dose distribution to the primary tumor or a heterogeneous dose distribution based on the metabolic image provided by a PET–CT (Fig. 39.1).[28] Last but not least, protons are under investigation in stage III NSCLC to take advantage of better dose distribution, especially allowing better sparing of the heart,[29] but the results of a randomized trial were disappointing.

In summary, higher physical or biologic dose (altered fractionation) is associated with better local control and, in some trials, with better survival, but the optimal dose and fractionation are yet to be defined. Currently, 60 Gy to 66 Gy in daily fractions of 2 Gy remains the most common schedule.

CHEMORADIATION THERAPY

Chemoradiation therapy is now the standard treatment for stage III NSCLC classified as N2 or N3. Results from meta-analyses of patients with unresectable stage III locally advanced NSCLC have demonstrated the benefits of platinum-based chemoradiation therapy given concurrently or sequentially in comparison with radiation alone.[30–33] Furthermore, a third meta-analysis has clearly demonstrated the superiority of a concurrent approach to sequential treatment.[34]

Role of Chemotherapy

For patients with medically inoperable or technically unresectable locally advanced NSCLC, thoracic radiotherapy alone, which is potentially curative, was regarded as a standard therapy in the 1980s; however, the treatment results were unsatisfactory due to a high rate of relapse and distant metastases. It was thought that chemotherapy with radiosensitizing anticancer drugs might improve survival by controlling remote metastases and increasing tumor sensitivity to radiotherapy, and several trials tested this hypothesis. Results from meta-analyses showed that survival after sequential or concurrent chemoradiation therapy that included a platinum agent was better than survival after radiotherapy alone.[30–33] The important role of chemotherapy was demonstrated with an absolute benefit of 3% at 2 years and 2% at 5 years. Furthermore, a third meta-analysis has clearly demonstrated the superiority of a concurrent to a sequential approach.[34]

Nevertheless, these findings were still not satisfactory, and subsequent investigations aimed to establish the optimal timing and type of chemotherapy needed to control micrometastases, increase the effects of radiotherapy, and improve local control and survival.

Sequential and Concurrent Therapy

Sequential chemoradiation therapy has been compared with concurrent chemoradiation therapy in several studies[21,35–37] (Table 39.1). The first published trial was from Furuse et al.:[35] radiotherapy (56 Gy using a split-course schedule) was given either concurrently or after an induction with mitomycin, vindesine, and DDP in unresectable locally advanced NSCLC. Median survival was significantly superior in patients receiving concurrent therapy (16.5 months), as compared with those receiving sequential therapy (13.3 months; p = 0.03998). The 5-year survival in the concurrent group (15.8%) was better than that in the sequential group (8.9%). The three other trials showed a trend in favor of the concurrent arm. RTOG 9410 was a randomized three-arm phase III trial comparing sequential with concurrent chemoradiation therapy.[21] The sequential arm consisted of DDP (100 mg/m^2) on days 1 and 29 and vinblastine (5 mg/m^2) per week for 5 weeks with chest radiotherapy (60 Gy) starting on day 50. One of the concurrent arms used the same chemotherapy regimen as the sequential arm with thoracic radiotherapy (60 Gy) starting on day 1. This concurrent arm had a significantly better 5-year survival rate compared with the sequential arm (16% vs. 10%, p = 0.046).

The NSCLC Collaborative Group performed a meta-analysis of six randomized trials and was based on individual patient data.[34] Compared with sequential chemoradiation therapy, concurrent chemoradiation therapy significantly improved overall survival (hazard ratio, 0.84; 95% CI, 0.74 to 0.95; p = 0.004) with an absolute benefit of 5.7% (23.8% vs. 18.1%) at 3 years and 4.5% (15.1% vs. 10.6%) at 5 years (Fig. 39.2). This benefit was mainly due to less locoregional progression without any difference in the rate of distant metastases. Concurrent chemoradiation therapy increased acute esophageal toxicity (grade 3–4) from 4% to 18% with a relative risk of 4.9 (95% CI, 3.1 to 7.8; p < 0.001). There was no significant difference in acute pulmonary toxicity.

In summary, concurrent DDP-based chemoradiation therapy has been consistently shown to improve survival at the cost of manageable increased toxicity. Concurrent chemoradiation therapy that includes DDP is recommended as the standard therapy for patients with inoperable locally advanced NSCLC who are eligible for radiotherapy. Sequential chemoradiation therapy or radiotherapy alone is appropriate for frail patients who are unable to tolerate concurrent chemoradiation therapy.

Chemotherapy Drug Combinations

Several phase III trials of chemoradiation therapy with platinum (especially DDP) and second-generation anticancer agents, such as vindesine, mitomycin, etoposide, and vinblastine, have produced strong evidence of the effectiveness of these drugs, as described earlier. The evidence for combination therapy with platinum and third-generation agents for the treatment of locally advanced NSCLC has been less conclusive, although some trials have shown

Fig. 39.2. Survival curve comparing concurrent with sequential chemoradiotherapy (CRT). *CT,* chemotherapy; *HR,* hazard ratio; *OS,* overall survival; *RT,* radiotherapy. *(Modified from Auperin A, Le Péchoux C, Rolland E, et al. that such a combination produces significant response and survival when used to treat stage IV NSCLC. Additional data are needed to determine the optimal regimen. Several randomized trials are reviewed in the following sections (also see Tables 39.2 and 39.3).

Belani et al.[24] enrolled patients with unresectable locally advanced NSCLC in a three-arm phase II trial. Patients in arm 1 (sequential arm) received two cycles of induction chemotherapy with paclitaxel (200 mg/m^2) and carboplatin (area under the curve [AUC] = 6) followed by radiotherapy (63 Gy). Patients in arm 2 (induction and concurrent) received two cycles of induction chemotherapy with paclitaxel (200 mg/m^2) and carboplatin (AUC = 6) followed by weekly paclitaxel (45 mg/m^2) and carboplatin (AUC = 2) with concurrent radiation (63 Gy). Patients in arm 3 (concurrent and consolidation) received weekly paclitaxel (45 mg/m^2), carboplatin (AUC = 2), and radiotherapy (63 Gy) followed by two cycles of paclitaxel (200 mg/m^2) and carboplatin (AUC = 6). The median overall survival was 13.0 months, 12.7 months, and 16.3 months for arms 1, 2, and 3, respectively. The proportions of survivors in arm 1 at 1 year, 2 years, and 3 years were 57%, 30%, and 17%, respectively; in arm 2, 53%, 25%, and 15%, respectively; and in arm 3, 63%, 31%, and 17%, respectively. In this study, concurrent weekly paclitaxel, carboplatin, and thoracic radiotherapy followed by consolidation was associated with the best outcome but with greater toxicity.

Reduced (lower-dose) DDP and vinorelbine combination therapy is widely used as a standard treatment, but few prospective trials have been conducted. Zatloukal et al.[37] demonstrated the safety and efficacy of this combination in a trial of concurrent and sequential chemoradiation therapy for patients with locally advanced NSCLC. Fifty-two patients were randomly assigned to concurrent treatment and 50 patients to sequential treatment. The chemotherapy consisted of up to four cycles of DDP (80 mg/m^2) on day 1, and vinorelbine (25 mg/m^2 in the 1st and 4th cycles; 12.5 mg/m^2 during the 2nd and 3rd cycles) on days 1, 8, and 15, of a 28-day cycle. Radiotherapy (60 Gy) was given as five fractions per week for 6 weeks. In the concurrent arm, radiotherapy began on day 4 of cycle 2; in the sequential arm, it was started 2 weeks after completion of chemotherapy. Overall survival was significantly better in the concurrent arm (median survival, 16.6 months) than in the sequential arm (median survival, 12.9 months; p = 0.023, hazard ratio = 0.61; 95% CI, 0.39–0.93). The proportions of survivors were greater in the concurrent arm than in the sequential treatment arm at years 1, 2, and 3 (69.2%, 34.2%, and 18.6% vs. 53.0%, 14.3%, and 9.5%, respectively). Although the concurrent schedule was

associated with a higher toxicity, the adverse event profile was acceptable in both arms.

Two phase III trials comparing second-generation to third-generation chemotherapy in combination with concurrent thoracic radiotherapy were conducted in Japan. The West Japan Oncology Group conducted a three-arm randomized trial comparing a combination of mitomycin, vindesine, and DDP with irinotecan and carboplatin in one experimental arm and paclitaxel and carboplatin in the other.[38] The Okayama Lung Cancer Study Group also used mitomycin, vindesine, and DDP as a control regimen, which they compared with docetaxel and DDP.[39] No difference was noted among the regimens in terms of survival, but febrile neutropenia occurred more often in the control arm.

Lastly, a small trial was conducted in China to compare the DDP and etoposide combination with that of carboplatin and paclitaxel and concurrent radiotherapy (60 Gy). Results from this trial showed that 3-year survival was better after treatment with DDP and etoposide (33% vs. 13%).[40]

Pemetrexed has commonly been used recently in advanced nonsquamous NSCLC with a better outcome. The PROCLAIM study is a phase III trial of pemetrexed and DDP chemotherapy combined with concurrent radiotherapy, followed by consolidation pemetrexed or two additional cycles of a platinum-based regimen. Because pemetrexed can be given in full doses with radical radiotherapy, there was hope that it might result in lower rates of distant metastasis. However, the 2-year survival rates for the two arms were 52% without any significant difference regardless of the end points.[41]

Induction and Consolidation Therapy

Even with concurrent chemoradiation therapy for locally advanced NSCLC, local and distant disease recurrences are a common event, and most patients die of progressive lung cancer. Early administration of full-dose systemic chemotherapy has the potential to improve survival by treating micrometastases early and downstaging the primary tumor before chemoradiation therapy.

A Cancer and Leukemia Group B (CALGB) study randomized 366 patients with stage III NSCLC to immediate chemoradiation therapy (carboplatin, paclitaxel, and 66 Gy of radiotherapy) or induction chemotherapy with two cycles of carboplatin and paclitaxel before chemoradiation therapy.[42] Survival differences were not significant ($p = 0.3$), with a median survival of 12 months (95% CI, 10 months to 16 months) and 14 months (95% CI, 11 months to 16 months), respectively. The 2-year survival was 29% (95% CI, 22% to 35%) for immediate chemoradiation therapy and 31% (95% CI, 25% to 38%) for induction chemotherapy. The addition of induction chemotherapy to concurrent chemoradiation therapy added toxicity and provided no survival benefit compared with concurrent chemoradiation therapy alone. Similarly, a meta-analysis of individual patient data from six small randomized phase II trials did not show any difference between induction and adjuvant chemotherapy given before or after definitive chemoradiation therapy.[43] A recent trial randomized patients after concurrent chemoradiotherapy to two additional cycles of oral vinorelbine and DDP or best supportive care alone and failed to show any benefit of additional chemotherapy.[44] The Hoosier Oncology Group randomly assigned patients who had already received treatment with DDP, etoposide, and definitive thoracic radiotherapy to consolidation docetaxel or observation.[45] This trial was terminated early because of increased toxicity during docetaxel administration: 5.5% of patients died as a result of this drug. The median survival was 21.2 months in the docetaxel arm compared with 23.2 months in the observation arm ($p = 0.883$).

In summary, induction chemotherapy, adjuvant chemotherapy, and/or maintenance therapy currently are not recommended for patients with unresectable locally advanced NSCLC.

Chemoradiation Therapy for Older Individuals

Clinical trials rarely provide data on chemoradiation therapy for individuals older than 70 years. Atagi et al.[46] randomly assigned patients older than 70 with a good performance status to radiotherapy (60 Gy) and concurrent low-dose carboplatin (30 mg/m² per day, 5 days a week for 20 days) or to radiotherapy alone. Although greater hematologic toxicity was reported in the combined arm, late toxicities and treatment-related deaths were similar in both arms. Chemoradiation therapy produced a clear survival benefit: the 2-year survival rates were 46% and 35%, respectively (Fig. 39.3). For carefully selected older patients without severe comorbidities, chemoradiation therapy may be considered with careful management of toxicities.

In summary, for most patients with unresectable locally advanced NSCLC, concurrent chemoradiation therapy is the optimal treatment strategy with curative intent. Combination therapy with platinum and second-generation anticancer agents effectively prolongs survival. The superiority or noninferiority of third-generation anticancer drugs has not been shown in phase III trials. Results from smaller studies show that these drugs may modestly increase median survival and 5-year survival. Furthermore, it is difficult to translate the results observed in stage IV to stage III patients treated with a combined approach.

MOLECULARLY TARGETED THERAPEUTIC AGENTS

Recent discoveries in molecular biology have led to the identification of numerous molecular pathways that may be responsible for cancer cell development, progression, and growth; these pathways may also have a role in cancer cell resistance to radiotherapy or other cytotoxic agents. Therefore, these pathways are being explored as potential targets for augmentation of radiotherapy or chemotherapy response. Since the 1990s, there has been an explosion of new molecularly targeted agents for use in lung cancer treatment.

The expanding list of molecular targets for NSCLC includes epidermal growth factor (EGF) and its receptor (EGFR), vascular endothelial growth factor (VEGF) and its receptor (VEGFR), the fusion of echinoderm microtubule-associated protein-like 4 and anaplastic lymphoma kinase (*EML4–ALK*), *B-Raf*, *PIK3CA* gene, *ErbB2* (*Her2*) amplification or mutant genes, mammalian target of rapamycin, and various other molecules that regulate different steps in their signal transduction pathways.[47] Although preclinical data would indicate that these molecules are viable targets that could be exploited to improve therapeutic efficacy, not all agents have produced clinical benefits. A handful of targeted agents have been approved for cancer treatment. Clinical trials of other agents are being conducted to determine their efficacy in combination with other cytotoxic agents, including ionizing radiotherapy. Some potential agents target a single molecular signaling pathway, whereas others are able to target multiple molecular signaling pathways. The most clinically advanced agents target the EGFR, VEGF/VEGFR, and ALK1 pathways.

Epidermal Growth Factor Receptor

EGFR targeting exemplifies the approach of combining radiotherapy with molecularly targeted therapy. EGFR plays an important role in tumor growth and response to cytotoxic agents, including ionizing radiotherapy. Upregulation of EGFR expression occurs in many types of cancer and is often associated with more aggressive tumors, poor prognosis, and tumor resistance to treatment with cytotoxic agents including radiotherapy.[48,49] Preclinical data provide a strong rationale for combining EGFR inhibitors with radiotherapy.

Cetuximab is a chimeric mouse anti-EGFR monoclonal antibody. Although it was a study of patients with head and neck squamous cell carcinoma that confirmed the benefit of cetuximab with radiotherapy, the agent has been also been studied extensively in patients with NSCLC.[50] In 2011, CALGB and RTOG reported the results from phase II studies.[51,52] In the CALGB study, two novel chemotherapy regimens in combination with concurrent radiotherapy were evaluated. Patients in the first group received concurrent carboplatin and pemetrexed with thoracic radiotherapy (70 Gy). In the second group, patients received the same regimen plus cetuximab. Patients in both groups received four cycles of pemetrexed as consolidation therapy. The overall survival at 18 months was 58% without cetuximab and 54% with cetuximab. Treatment of NSCLC with the combination of thoracic radiotherapy, pemetrexed, carboplatin, and with or without cetuximab was shown to be feasible and fairly well tolerated.[51]

In the RTOG study, patients were treated with a combination of paclitaxel, carboplatin, and cetuximab with radiotherapy (63 Gy). All patients received a loading dose of cetuximab (400 mg/m^2) 1 week before radiotherapy, and patients received carboplatin, paclitaxel, and cetuximab for two additional cycles after completion of radiotherapy. The median survival was 22.7 months, and the 2-year survival rate was 49.3%.[52] Because of these very promising results, cetuximab was studied in the RTOG 0617 trial in which patients were randomly assigned to receive or not receive cetuximab in addition to concurrent chemoradiotherapy; however, no difference in survival was observed between the two arms. In a separate planned retrospective analysis, the EGFR expression could be evaluated on 203 patients; for patients expressing the EGFR, there was a statistical benefit with a higher survival rate, whereas for those not expressing EGFR, a negative trend was observed.[19] In the Raditux trial, patients received 66 Gy in 24 fractions plus daily DDP with or without cetuximab. The survival rates were very similar but the EGFR expression was not evaluated. More grade 3 lung toxicity was seen in the cetuximab arm (0% vs. 10%).[53]

Gefitinib and erlotinib are two tyrosine kinase inhibitors (TKIs) that are especially active in case of mutation and have been tested with radiotherapy. The Southwest Oncology Group (SWOG) performed a large phase III trial in which patients with stage III NSCLC were treated with standard chemoradiation therapy, and after consolidation with docetaxel for three cycles, the patients were randomly assigned to maintenance therapy with placebo or gefitinib. At interim analysis, overall survival was worse in the gefitinib maintenance arm (23 months vs. 35 months), and therefore the study was closed.[54] It is clear from this study that maintenance therapy with TKI after definitive chemoradiation therapy should be avoided in an unselected patient population.

CALGB 30106 was a phase II study designed to evaluate the addition of gefitinib to sequential or concurrent chemoradiation therapy in patients with unresectable NSCLC.[55] Patients were categorized as poor risk (performance status of 2 or higher, weight loss of 5% or more) or good risk (performance status of 0 or 1, weight loss less than 5%). All patients received induction chemotherapy with two cycles of carboplatin and paclitaxel plus gefitinib. (Gefitinib was removed from induction regimen in May 2004 when the SWOG trial did not demonstrate a benefit to adding gefitinib to chemotherapy.) Patients in the poor risk group received thoracic radiotherapy (66 Gy) with concurrent gefitinib. Patients in the good risk group received the same radiotherapy and gefitinib, but also received weekly carboplatin and paclitaxel. Consolidation gefitinib was given until disease progression. In the poor risk group, progression-free survival was 13.4 months, and median survival was 19 months. In the good risk group, progression-free survival was 9.2 months, and median survival was 13 months.

As many as 13 of 45 tumors had activating *EGFR* mutations, and 2 of 13 had T790M mutations. Seven of 45 tumors had *KRAS* mutations. When the results were analyzed by these molecular phenotypes, no significant difference in outcome was noted. Given the promising results for patients at poor risk, further studies will investigate the effectiveness of treating such patients with radiotherapy and gefitinib after induction chemotherapy; however, this regimen may not be beneficial for patients at good risk.

The findings from CALGB 30106 are consistent with studies of erlotinib and chemoradiation. Choong et al.[56] reported on a phase I study of erlotinib with chemoradiation. Patients in one group received induction chemotherapy with carboplatin and paclitaxel followed by carboplatin, paclitaxel, radiotherapy, and erlotinib. The second group of patients received DDP, etoposide, radiotherapy, and erlotinib followed by docetaxel. In both arms, the erlotinib dose was increased from 50 mg to 150 mg in three stages. The median survival in each group was 13.7 months and 10.2 months, respectively. Overall survival and progression-free survival were improved for patients in whom a rash developed. This study demonstrated the tolerability of such a regimen, but given the disappointing survival data, the need for improved patient selection criteria for EGFR-based treatments is clear.

Patient selection is likely to play an important role in the design of future studies of EGFR-targeted agents. For example, these agents have shown benefits for patients with *EGFR* mutations and studies may need to separate patients with activating *EGFR* mutations from patients with the general wild-type *EGFR*. A repeat evaluation of biomarkers after chemoradiation therapy may help to determine which subset of patients would benefit from additional therapy with anti-EGFR agents. Therefore molecular profiling, along with patient selection based on criteria such as *EGFR* mutation status, has become an important factor in predicting efficacy of anti-EGFR regimens. Future studies of anti-EGFR treatments used in combination with radiotherapy should also incorporate stringent patient selection criteria to maximize treatment benefit. The efficacy of combined treatment with EGFR inhibitors and radiotherapy may vary by tumor type and molecular profile, as well as the sequencing of the treatments.

Antiangiogenesis Agents

Inhibitors of angiogenesis have undergone extensive preclinical testing and some agents have been tested in clinical trials. Despite concerns that an antiangiogenic agent would enhance hypoxia, thereby impairing the efficacy of radiotherapy, the first preclinical study with a specific inhibitor of angiogenesis, angiostatin, showed a synergistic effect with radiotherapy.[57] Jain[58] proposed a model of tumor vasculature normalization that explains this effect. In this model, proangiogenic factors from tumors can cause abnormal neovascularization, and inhibition of tumor angiogenesis transiently normalizes the tumor vasculature. This has the counterintuitive effect of decreasing tumor hypoxia and improving the effectiveness of radiotherapy. Preclinical studies support this hypothesis, as have results from a phase I study with locally advanced rectal cancer.

Similar to the EGFR inhibitors, antiangiogenic compounds can be broadly classified as monoclonal antibodies directed against antiangiogenic molecules or their receptors (e.g., bevacizumab) or TKIs with narrow or broad-spectrum activity against one or more of these receptors (e.g., sorafenib, sunitinib, pazopanib). Studies of bevacizumab for the treatment of NSCLC have also included radiotherapy.

Efforts to improve the therapeutic ratio by adding bevacizumab to chemoradiation therapy have failed in multiple studies of patients with both small cell lung cancer (SCLC) and NSCLC. This regimen was associated with increased incidence of tracheoesophageal fistula in both SCLC and NSCLC.[59] Therefore patient selection factors such as location of the tumor and tumor histology, as well as the timing of bevacizumab integration with radiotherapy, need to be considered in the design of future studies.

Thalidomide has also been found to have potent immunomodulatory effects and antiangiogenic properties.[60] ECOG 3598 was a randomized study comparing chemoradiation therapy with or without thalidomide for patients with locally advanced NSCLC. Patients received carboplatin and paclitaxel, with or without thalidomide for two cycles, followed by weekly carboplatin and paclitaxel with radiotherapy, with or without thalidomide. In the thalidomide group, patients could be treated with adjuvant thalidomide for up to 2 years. There was no difference in progression-free survival or overall survival with addition of thalidomide.[61] Although this outcome might suggest that this treatment combination is not effective, the negative studies may also indicate the need for better patient selection when using specific agents.

Anaplastic Lymphoma Kinase Inhibitors

The *EML–ALK* fusion oncogene has become a very important potential biomarker for patients with NSCLC. Several ALK inhibitors have been identified; crizotinib is the most developed and has produced impressive responses. However, data have not indicated that ALK inhibitors have a radiosensitizing or synergistic effect when administered concurrently in combination with radiotherapy

Immune Checkpoint Inhibitors (PD-1/PD-L-1)

Interesting observations were made with the use of nivolumab and ipilimumab in stage IV patients or in experimental work with an abscopal response after radiotherapy using stereotactic radiotherapy to a metastatic site.[62] Currently, phase III trials are ongoing to evaluate the safety (the concern is risk of radiation pneumonitis) and the efficacy.[63]

In summary, as of 2016, no trial has proven the benefits of adding a molecularly targeted agent to the combined modality regimens in an unselected patient population. Currently, studies adding erlotinib or crizotinib for treatment of patients who are known to have EGFR mutation or ALK translocation are underway by NRG/Alliance in the United States.

The discovery of new biomarkers, advances in molecular therapeutics and imaging technology, and a better understanding of effective integration of chemotherapy and radiation treatments are making personalized medicine for NSCLC feasible. As more precise biomarkers are identified, the use of such personalized strategies will become routine. In addition, immunomodulatory therapy may play a larger role in the treatment of NSCLC. Initial studies of immunomodulatory agents in combination with cytotoxic agents have provided promising early results. Incorporation of such agents into a concurrent chemoradiation therapy is being investigated.

LOCOREGIONAL TREATMENT WITH SURGERY OR RADIOTHERAPY

The role of surgery in the multimodality treatment of stage III NSCLC is an open question and the subject of much discussion. In some cases, surgery has been performed after induction chemotherapy, whereas in some other cases it is an initial approach for minimal stage IIIA NSCLC followed by adjuvant chemotherapy, with or without postoperative radiotherapy. As survival outcomes following chemoradiation therapy have improved, the role of surgery has been challenged.

Randomized Trials of Surgery

Three large randomized trials conducted in North America and in Europe have compared surgery with radiotherapy (Table 39.4).[64–66] The selection criteria and the design of these trials differed: in the North American and German trials, patients had proven N2 that was considered to be resectable at the time of enrollment, whereas

N2 disease was considered to be unresectable in the European Organisation for Research and Treatment of Cancer (EORTC) trial. The terms "resectable" or "unresectable" may be partially subjective and depend on the surgeon's judgment.

In the EORTC trial, 579 patients with a stage IIIA disease were treated first by three cycles of a platinum-based chemotherapy before being randomly assigned to surgery or 6 weeks of radiotherapy (60 Gy).[65] Only 332 patients with an objective response to chemotherapy were included in the trial. Among the surgical patients, 40% received additional postoperative radiotherapy. Pneumonectomy was performed in 47% of patients. The 30-day postoperative mortality rate was 4% for the whole series and 7% after a pneumonectomy, with no significant difference between right-sided or left-sided procedures. A complete resection was achieved in 50% of the surgical patients and a pathologic complete response occurred in 5%; downstaging to ypN0 or N1 was achieved in 41% of patients. In the radiotherapy arm, 80% of the patients received a dose of 60 Gy in 30 fractions to 32 fractions over 40 days to 46 days. Overall compliance with radiotherapy was 55%. Eighty-six percent of patients started radiotherapy within 10 weeks of the 1st day of the final chemotherapy. No difference was observed between the two arms in terms of survival; the 5-year survival rate was approximately 15%. With regard to the first site of progression, locoregional relapse was more frequent after radiotherapy than after surgery (55% vs. 32%).

In the US Intergroup trial, individuals were enrolled if they had T1–T3 tumors and pathologically confirmed N2 disease, if resection seemed technically feasible, and if they were good surgical candidates.[64] Patients were randomly assigned to preoperative chemoradiation therapy or an exclusive schedule of chemoradiation therapy. The chemotherapy regimen consisted of DDP (50 mg/m²) on days 1, 8, 29, and 36 and etoposide (50 mg/m²) on days 1–5 and 29–33 delivered concurrently with thoracic radiotherapy (45 Gy delivered over 5 weeks). CT images of the chest were evaluated 2 weeks to 4 weeks after the induction regimen in the surgical arm and during the 5th week in the radiotherapy arm. If disease had not progressed, surgery was performed or radiotherapy was pursued to 61 Gy. Two additional cycles of chemotherapy were planned for after surgery or radiotherapy.

Of the 202 patients in the surgical arm, 177 patients were eligible for thoracotomy; 144 had a complete resection and 121 began the consolidation chemotherapy. The operative mortality was high, especially after a right-side pneumonectomy (26%). Compliance with the additional two cycles of chemotherapy was 55% in the surgical arm and 74% in the radiotherapy arm, rates that are similar to those reported in adjuvant chemotherapy trials. No significant difference in survival was found between the two arms: the 5-year survival rate was 20.3% and 27.2% for the radiotherapy and surgical arms, respectively. In a retrospective unplanned exploratory analysis, a matched pair analysis was performed: compared with radiotherapy, lobectomy led to significantly better survival but pneumonectomy did not.

The German trial was closed after enrolling half of the patients; 246 patients with proven N2 disease in either stage IIIA or B received three cycles of induction chemotherapy with DDP and paclitaxel followed by concurrent chemoradiotherapy, 45 Gy, two times a day with DDP and vinorelbine.[66] In the last week of radiotherapy, patients were reevaluated and those deemed resectable were randomized between surgery and additional chemoradiotherapy to receive 65 Gy to 71 Gy. The majority of patients had stage IIIB disease (171 patients). After induction, 65% of patients were found to present a resectable tumor and were randomized. An R0 resection for cure was performed in 81%. No difference in survival was observed between the two arms with 5-year survival rates of 44% for the trimodality and 40% for the chemoradiotherapy.

The last two important phase III trials addressed the issue of the induction treatment, radiochemotherapy, or chemotherapy only. In the trial by Thomas et al.,[67] 524 patients were randomly assigned to induction chemotherapy followed by surgery and postoperative radiotherapy (chemotherapy arm) or induction chemotherapy followed by an accelerated course of chemoradiation and then surgery (chemoradiation therapy arm). This trial included more than 500 patients with stage IIIA or B disease. The number of complete resections was similar between the groups: 84 patients in the chemotherapy arm and 98 in the chemoradiation therapy arm. Of the patients assigned to a treatment group, operations were performed on fewer than 60%. Complete pathologic response was achieved in 17 patients in the chemotherapy arm and in 59 in the chemoradiation therapy arm but this outcome did not translate to a survival benefit: 5-year survival rate was approximately 15% in both arms. A biased interpretation of these results might be that radiotherapy produces no benefit; however, it should be noted that the chemotherapy arm did include postoperative radiotherapy and that this trial was designed to compare thoracic radiotherapy as part of the induction treatment and as adjuvant treatment. The Swiss trial included 232 patients with stage IIIA and compared induction with three cycles of chemotherapy (DDP and docetaxel) with the same induction followed by sequential radiotherapy (44 Gy in 22 fractions for 3 weeks) prior to surgery.[68] No statistical difference was observed between the two arms; however, there was a lower rate of pathologic complete response in the chemotherapy arm.

Authors of a meta-analysis of seven phase III trials comparing preoperative chemotherapy with surgery alone for stage IIIA disease found that chemotherapy produced a 6% absolute increase in survival, increasing 5-year survival from 14% to 20%.[69] Nevertheless, local failure remains a key issue: in the Swiss Group for Clinical Research phase II trial, local relapse subsequently developed in 60% of patients.[70] All the trials included in the meta-analysis were conducted in the 1990s, using the staging procedure and radiotherapy techniques available at that time; nevertheless, they provide interesting information on the possible role of surgery and radiotherapy.

Advantages and Disadvantages of Surgery

The discussion of the advantages of surgery assumes that N2 disease has been identified before the operation through a complete staging procedure and careful evaluation of mediastinum using PET–CT, endobronchial ultrasound, or mediastinoscopy if needed. The discussion does not apply to positive nodes discovered at the time of thoracotomy.

In addition to increasing survival, surgery can improve local control. In both the US Intergroup and the EORTC trials, surgery led to a 50% improvement in local control. Theoretically, the bulk of the disease is less an issue with surgical resection than with radiotherapy, with larger tumor volume being a limitation on the efficacy of radiotherapy. Unfortunately, the report from the Intergroup trial provided no information on the tumor volume. An incomplete resection is a futile thoracotomy because salvage treatments have limited efficacy. When a complete resection cannot be performed, salvage radiotherapy is delayed and toxicity increases.

Surgery enables a complete pathologic evaluation of tumor extent. The choice to add adjuvant or neoadjuvant chemotherapy is already known very often at the time the treatment decision is made. For patients with severe emphysema or chronic obstructive pulmonary disease, an operative procedure may allow for lung parenchyma expansion, leading to better lung functions: patients with chronic obstructive pulmonary disease have greater forced expiratory volume (FEV_1) after lobectomy.[71] Because complications, including hemorrhage or abscess, occur frequently after radiotherapy, surgery may be beneficial in cases of infection or cavitations inside the tumor.[72]

A major drawback of surgery is its association with substantial morbidity and mortality, especially in the case of pneumonectomy because of its association with lower pulmonary function and high rate of complications. The mortality rate after neoadjuvant treatment has ranged from 0% to 26%, and postoperative mortality rises from 7% at 30 days to 12% at 90 days. The 90-day mortality is 9% for left pneumonectomy and 20% for right pneumonectomy,[73] although some teams report lower mortality rates even for right-sided pneumonectomy, especially after a careful functional evaluation. Nevertheless, pneumonectomy impairs quality of life and can lead to late complications.[74] Planning to include an operative procedure in a multimodality treatment approach could lead to a delay in starting radiotherapy. For example, if a restaging procedure is performed 2 weeks to 4 weeks after two or three cycles of induction chemotherapy and a decision is then made not to perform surgery, the long delay between the last chemotherapy and the start of thoracic radiotherapy could allow tumor regrowth.[75]

The preoperative chemotherapy regimens currently available lead to a low rate of pathologic complete response and downstaging in less than half of patients. Induction chemoradiation therapy has produced better rates of pathologic complete response and downstaging. However, this did not change the survival outcomes reported in the German study, a meta-analysis, or two other trials.[67,68,76,77] There is consensus that preoperative chemoradiation therapy is reasonable for superior sulcus tumors if there is no evidence of mediastinal node involvement.[78,79] Furthermore, a radiologic response after induction with concurrent chemoradiation therapy does not always correlate with the pathologic response, as some residual mass may be fibrosis.

Considerations for Choosing Surgery or Radiotherapy

Use of radiotherapy is less restricted by comorbidities and tumor extent than is the use of surgery, and surgical morbidity is avoided. However, radiotherapy is associated with acute toxicity such as radiation-induced acute esophagitis, especially with concurrent chemoradiation therapy. Limitations of radiotherapy include limited organ tolerance in the lung, spinal cord, and heart and lower

TABLE 39.5 Survival Rates According to the Type of Nodal Involvement in Selected Surgical Series

efficacy for patients with bulky disease. The choice between radiotherapy and surgery for an individual patient should be based on several factors. A primary consideration is the extent of N2 disease and the clinical presentation. Andre et al.[80] identified four negative prognostic factors: clinical N2 diagnosed on CT before surgery, involvement of multiple station levels, a pT3 or T4 classification, and the lack of induction chemotherapy. The 5-year survival rate dropped from 34% for patients with one-level N2 discovered at surgery to 3% for multiple-level clinical N2. Similarly, Casali et al.[81] reported that the 5-year survival rate decreased from 24% to 15% when N2 nodes were diagnosed before surgery. When induction chemotherapy is used, mediastinal downstaging and the number of positive nodal stations are crucial factors: Decaluwé et al.[82] reported that the 5-year survival rate decreased from 37% for patients with single-level persistent disease to 7% for patients with multilevel persistent disease (Table 39.5).

Good survival outcomes in surgery trials are often attributed to the operation. When interpreting these results, however, it is important to remember that only a small proportion of patients are candidates for surgery, and not all patients who receive an induction treatment subsequently have surgery. Indeed, factors such as tumor response and mediastinal downstaging are generally evaluated after induction treatment to decide whether surgery should be performed. Results are better for patients with a tumor that responds to induction than for patients with a tumor that does not respond, which has been shown for other types of tumor as well. In the EORTC trial,[65] only patients who had a response were included in the study and no difference was observed between surgery and radiotherapy. Prognostic factors such as tumor response and downstaging are often confused with predictive factors used to select a course of, for example, surgery or radiotherapy. Because the prognosis is poor for patients with unfavorable tumor response and a greater number of involved stations, the risk of surgery should be avoided.

When selecting a treatment approach, other factors to consider are the patient's overall condition including comorbidities, cardiovascular function, and the available clinical expertise in both fields. For surgeons, the key issue is the ability to perform a complete resection; as noted previously, any result other than complete resection is a futile thoracotomy. All attempts should be made to avoid a pneumonectomy as this procedure decreases short- and long-term quality of life. The risk of death after this procedure increases with time and strongly depends on the side of surgery; the 6-month mortality rate is as high as 24% for right pneumonectomy.[83] For the radiation oncologist, the primary issue is the ability to deliver an effective dose of radiotherapy, taking into consideration the tolerance of organs at risk.

Tumor bulk is an interesting parameter to consider. The tendency is to consult a surgeon if the tumor is small and a radiation oncologist if the tumor is large. However, the efficacy of radiotherapy is directly correlated with the number of cells in the tumors, and results are better for a lower number of cells than for

a larger tumor with hypoxic regions. Another unanswered question is the role of surgery when the volume of normal tissue to be irradiated is too large and the risk of radiotherapy-induced toxicity is too high. For patients who are not candidates for surgery, concurrent chemoradiation therapy is the favored approach, raising the question of optimal treatment for fragile or an older individual. Last, the search continues for a biomarker to help with selecting the most appropriate locoregional treatment.

The guidelines from the American College of Chest Physicians include the following statement: "neoadjuvant therapy followed by surgery is neither clearly better nor clearly worse than definitive chemoradiation therapy."[84] The authors obviously favored a multidisciplinary approach but the heterogeneity of patients in trials limits the strength of the recommendation.

BRAIN METASTASES AND PROPHYLACTIC CRANIAL RADIATION

Brain metastases in patients with NSCLC are frequent complications that affect survival and quality of life, especially for patients with locally advanced disease. Chemoradiation therapy has been associated with increased frequency of brain metastases, causing relapse to occur first in the brain.[88–89]

The incidence of relapse with brain metastases in patients with locally advanced NSCLC after locoregional treatment ranges from 12% to 54%.[86,89–96] The risk of brain metastases has been associated with stage,[95] tumor size,[96] histology,[92] length of survival from diagnosis,[94–97] female sex,[98] age less than 60 years,[93,99] and type of locoregional therapy.[88,92,97,100] The authors of several studies of multimodality therapy for locally advanced NSCLC have reported an excellent median survival of 20 months to 43 months and a 3-year survival rate of 34% to 37%.[88,93,100–104] The brain was a common site of metastases in these studies. Overall, brain metastases have occurred in 22% to 55% of patients, and the frequency of brain as first site of relapse has ranged from 16% to 43%.

Prophylactic cranial irradiation has been evaluated for the treatment of locally advanced NSCLC in several retrospective and prospective studies.[86,88,89,91,104–110] The results have demonstrated that prophylactic cranial radiation reduces the incidence or delays the onset of brain metastases (Table 39.6). In a phase III trial, Cox et al.[107] randomly assigned 281 patients to receive prophylactic cranial radiation (20 Gy in 10 fractions) or no prophylactic cranial radiation. Prophylactic cranial radiation reduced the frequency of brain metastases in patients with NSCLC from 13% to 6% (p = 0.038), but there was no significant difference in median survival between the groups. Umsawasdi et al.[108] reported results from 97 patients with locally advanced NSCLC treated with chemoradiation therapy who were randomly assigned to

prophylactic cranial radiation (30 Gy in 10 fractions) or no prophylactic cranial radiation. Prophylactic cranial radiation significantly decreased the incidence of brain metastases compared with not receiving the treatment (4% vs. 27%, p = 0.002). No survival benefit was observed for the treated group due to adverse effects from other relapses. An RTOG prospective randomized study compared prophylactic cranial radiation (30 Gy in 10 fractions) and no brain treatment in patients with nonsquamous NSCLC.[89] Brain metastases developed in 18 (19%) of 94 patients randomly assigned to no prophylactic cranial radiation with eight (9%) of 93 patients who received the treatment (p = 0.10). No survival difference was found between the treatment arms. Pottgen et al.[109] randomly assigned 106 patients with stage IIIA NSCLC to prophylactic cranial radiation (30 Gy in 15 fractions) or no prophylactic cranial radiation and found that the treatment significantly reduced the probability of brain metastases as the first site of metastases (7.8% at 5 years vs. 34.7%; p = 0.02). There was no significant difference in neurocognitive performance between the groups.

The largest prospective study on prophylactic cranial radiation is the RTOG 0214, which involved 340 patients with stage III NSCLC who had definitive locoregional treatment.[110] Patients were randomly assigned to prophylactic cranial radiation (30 Gy in 2 Gy per fractions) or no prophylactic cranial radiation. This study was closed early because of slow accrual. Although the 1-year overall survival rate was similar between the groups (75.6% vs. 76.9% in the treatment and observation groups, respectively), the 1-year incidence of brain metastases was significantly different (7.7% vs. 18.0% for the treatment and observation groups, respectively, p = 0.004). There were no significant differences in global cognitive function measured with the Mini-Mental Status Examination or quality of life after prophylactic cranial radiation, but memory had declined significantly at 1 year as measured with the Hopkins Verbal Learning Test.[111] A last recent phase III trial included 156 patients operated on for a stage III–N2 NSCLC. After postoperative adjuvant chemotherapy, the patients were randomly allocated between prophylactic cranial radiation (30 Gy in 10 fractions) and observation. A reduction in brain metastases (10 in the treatment arm and 29 in the observation arm) and longer progression-free survival were observed without any difference in survival.[112]

In summary, prevention of symptomatic relapse with brain metastases in patients with locally advanced NSCLC may improve quality of life and overall survival. Studies have shown that prophylactic cranial radiation significantly decreases brain metastases among patients with locally advanced NSCLC. However, prophylactic cranial radiation is not recommended as a standard therapy, because available data do not provide evidence of survival benefit or sufficient information about late toxicity.

OUTCOME MEASUREMENTS

Although various metrics can be used to evaluate treatment outcomes, overall survival is the most relevant end point. The wide range of reported survival outcomes within the stage III group reflects differences in prognostic characteristics and comorbidities as well as variations in treatments. The International Association for the Study of Lung Cancer collects data from trials, registries, and cases series in which patients have been treated with different modalities. When the data were analyzed, the 5-year survival rate was 19% for clinical stage IIIA, 7% for stage IIIB, 24% for pathologic stage IIIA, and 9% for stage IIIB.[113] The 5-year survival rate has also been reported in several influential trials (Table 39.7).[34,64,65,67,114] We should highlight the ongoing improvement in survival seen in trials over the last decades leading to 2-year survival rates over 50% with chemoradiation therapy.[19,41]

Progression-free survival and pattern of failures are less accurate end points. After chemoradiation therapy, it is often difficult to assess the tumor response because of radiotherapy-induced fibrosis; therefore, what researchers call local control is actually the lack of tumor progression. In a meta-analysis by Auperin et al.,[34] the proportion of patients with local and distant progression at 3 years after concurrent chemoradiation therapy was 28% and 40%, respectively. Thus more effective treatments are necessary to address two important problems: unsatisfactory locoregional control and high risk of development of distant metastases.

Another important end point is quality of life in terms of physical and mental health. Currently available treatments have a major effect on patients' ability to function, particularly after a pneumonectomy. Studies should be designed to better evaluate the toxicity related to surgery, radiotherapy, and chemotherapy. The quality of mental and physical health does not always change in parallel: emotional well-being may improve after treatment, despite declines in physical functioning. Deterioration is usually observed during and after treatment. Fatigue, dyspnea, coughing, and pain may last for months or even years. A correlation has been observed between quality-of-life scores and tumor response or even tumor extent. Comorbidities, extent of surgery, multimodality treatment, and continued smoking have a negative effect on the quality of life.[74,115] Smoking cessation should be encouraged in conjunction with any form of treatment with curative aim.

CONCLUSION

The treatment of clinical stage III locally advanced NSCLC should be carried out by a multidisciplinary team that includes medical oncologists, pulmonologists, surgeons, imaging specialists, and radiation oncologists. Multimodality therapy should be selected based on the patient's performance status, age, histology, tumor size and location, pulmonary and other organ function, and comorbidities.

Novel anticancer agents and new molecularly targeted drugs, as well as advances in radiation technology, are expected to improve outcomes in the near future. Despite substantial advances in the treatment of locally advanced NSCLC, it remains a deadly disease for most patients. Future treatment success depends on developing and improving therapeutic strategies.

40 Radiotherapy in the Management of Small Cell Lung Cancer: Thoracic Radiotherapy, Prophylactic Cranial Irradiation

Sara Ramella and Cécile Le Péchoux

SUMMARY OF KEY POINTS

- In patients with clinically nonmetastatic small cell lung cancer (SCLC), positron emission tomography–computed tomography (PET–CT) as well as brain imaging is suggested to classify tumor stage.
- To classify stage, it is recommended to use the Veterans Administration system (limited disease [LD] vs. extensive disease [ED]) as well as the International Union for International Cancer Control TNM Classification of Malignant Tumors seventh edition (2009), which recommended tumor, node, and metastasis (TNM) staging based on analysis of the International Association for the Study of Lung Cancer database. The prognostic value of clinical and pathologic T and N staging in patients with SCLC is confirmed in the eighth edition. For the M descriptors, more research is warranted.
- In patients with nonmetastatic SCLC or LD, combined chemoradiation is the standard. Concomitant chemoradiotherapy gives the best results and is preferred to sequential chemoradiotherapy, but the latter can be an option in fragile patients. Compliance with alternating regimens may be difficult, but promising results have been published.
- In fit, nonmetastatic SCLC patients, early chemoradiotherapy is recommended. In more fragile patients, for whom good compliance with early concomitant chemoradiotherapy cannot be expected, there is no survival advantage with early chemoradiation.
- A randomized phase III trial showed no difference between once-daily (66 Gy/33 fractions per 6.6 weeks) and twice-daily radiation (45 Gy/30 fractions per 3 weeks) given along with chemotherapy for patients with LD-SCLC.
- In patients with nonmetastatic SCLC who achieve a complete or partial response to initial therapy, prophylactic cranial irradiation (PCI) at the dose of 25 Gy in 10 daily fractions is recommended. It should not be administered concomitantly with chemotherapy.
- In metastatic SCLC, PCI is also recommended among patients with any response to chemotherapy based on a randomized trial and the meta-analysis. The same regimen (25 Gy/10 fractions per 2 weeks) or a more hypofractionated regimen (20 Gy/5 fractions per 1 week) may be administered. A recent Japanese study showed a decrease in brain metastasis rate but failed to demonstrate survival advantage with PCI in patients with extensive stage SCLC, but mature data are awaited.

- Patients should be informed of potential adverse effects on neurocognitive functioning that may be caused by PCI especially in elderly patients to balance the benefit of PCI on survival and risk of brain metastases.
- In patients with ED-SCLC who have completed chemotherapy and achieved a response, a course of consolidative thoracic radiotherapy (TR) is suggested by the results of a randomized trial. A subgroup analysis has shown that among patients with partial response in the chest, but not complete response, consolidation TR had an impact on survival.

Small cell lung cancer (SCLC) represents less than 20% of all lung cancers. It is an aggressive tumor, and only a third of patients have limited stage disease at diagnosis. As SCLC has a high propensity for early metastatic dissemination, chemotherapy has been and still is the cornerstone of treatment, but SCLC is also very sensitive to radiotherapy (RT).

Patients often have bulky mediastinal disease at presentation.[1] After staging procedures, SCLC was classically presented as LD or ED according to the Veterans Administration Lung Cancer Study Group Classification.[2] LD was defined as confined to a hemithorax and the regional lymphatic nodes (mediastinum, ipsilateral, and contralateral hilar regions, and supraclavicular fossa), thus theoretically encompassable with an RT field. Although this classification has been used for many years, the International Association for the Study of Lung Cancer has recommended the use of the new TNM classification for nonsmall cell lung cancer (NSCLC) for SCLC as well.[3] The seventh and the future eighth TNM classifications split patients into a larger number of prognostically homogeneous subgroups, which could better define those patients for whom thoracic RT (TR) might be beneficial.[3,4] Recent advances in the management of SCLC are principally attributed to the improved knowledge of the indications for RT, both in nonmetastatic (or limited) and in metastatic (or extensive) diseases. By contrast, in the last two decades, chemotherapy progress has reached a plateau. The integration of TR with systemic chemotherapy in SCLC as well as PCI is really a "unique success story in the field of radiation oncology and highlights the potential for effective local therapy to impact overall outcomes."[5]

This relative "success story" started with the publication in the early 1990s of an individual patient data-based meta-analysis of randomized trials comparing combined chemoradiotherapy with chemotherapy alone, which demonstrated an absolute overall survival (OS) benefit of 5.4% in favor of combination therapy (3-year OS of 8.9% vs. 14.3% in the chemoradiation arm). Pignon and colleagues[6] collected and analyzed individual data from 13 trials involving 2140 patients with LS-SCLC: the relative risk of death in the chemoradiation group, as compared with the chemotherapy alone group, was 0.86 (95% confidence

CHAPTER 40 Radiotherapy in the Management of Small Cell Lung Cancer: Thoracic Radiotherapy, Prophylactic Cranial Irradiation **375**

40

interval [CI], 0.78–0.94; p = 0.001). This equated to a 14% reduction in death with the addition of radiation. Warde and Payne[7] published similar findings in a literature-based analysis of 11 randomized trials. They showed that the addition of TR to chemotherapy led to an overall benefit of 5.4% on 2-year survival, and an improved 2-year intrathoracic tumor control (from 16.5% in the chemotherapy arm alone to 34.1% in the combined modality arm), resulting in a benefit in local control of about 25%. The combination of chemotherapy and RT became a standard in the early 1990s after the publication of these two meta-analyses. Subsequently, these benefits have been confirmed by other studies. The current state-of-the-art treatment for SCLC patients with nonmetastatic disease involves cisplatin (or carboplatin in more fragile patients)–etoposide chemotherapy combined with chest RT, as reported in guidelines worldwide.[8–10]

It is possible, however, that the two reported meta-analyses underestimate the results that can be obtained with platinum-based chemotherapy and contemporary RT as only a few studies included in the meta-analyses used platinum-based chemotherapy and concurrent chemoradiation, which are considered nowadays as part of the optimal treatment approach.

There are indeed different ways of combining chemotherapy and TR: they can be administered concurrently, sequentially, or in an alternating fashion. Furthermore, the issue of timing of RT has also been addressed in randomized trials: whether radiation should be given early or late in the overall course of treatment has long been a subject of debate.[11] Sequential schedules allow the delivery of full-dose chemotherapy followed by full-dose RT; tumor shrinkage can be observed after systemic therapy, but repopulation and selection of resistant cellular clones may lead to treatment failure.[1] The alternating schedule has a good toxicity profile, although from a practical point of view, it may be a complicated approach; the good results obtained in a French Study group randomized trial could not be reproduced by a larger European Organization for Research and Treatment of Cancer (EORTC) study.[12,13] The concomitant approach has the radiobiologic advantage of reducing the overall treatment time, which is a particularly relevant issue in SCLC treatment, although it is associated with an increased risk of acute toxicity, especially esophagitis. Even so, this latter approach has now become the standard of care.

Two phase III trials have studied alternating schedules: an EORTC study, which compared an alternating chemoradiation regimen with a sequential regimen,[13] and the "Petites Cellules" study,[14] which compared an alternating regimen with a concomitant chemoradiation approach. It should be noted that none of these trials used platinum-based chemotherapy. Results were poor in both trials, with no difference in terms of OS between the two arms (median 15 months vs. 14 months in the first study; 13.5 months vs. 14 months in the second one).

The Japan Clinical Oncology Group (JCOG) performed a phase III trial comparing a sequential and concurrent chemoradiation approach.[15] A total of 231 patients with LD-SCLC were randomly assigned to receive four cycles of cisplatin plus etoposide every 3 weeks followed by accelerated hyperfractionated TR at the dose of 45 Gy in 3 weeks (sequential arm) or the same four cycles of chemotherapy administered every 4 weeks with the same modality of TR starting on day 2 of the first cycle of chemotherapy (concurrent arm). The results favored the concurrent schedule with a median survival of 27.2 months versus 19.7 months of the sequential arm, even if the difference was not significant (p = 0.097).

TIMING QUESTION

Several phase III trials have examined the question of timing, that is, administration of early versus late RT during the course of combined chemotherapy and RT; however, the issue remains controversial.[16–21] To try to clarify the issue, several meta-analyses were conducted between 2004 and 2007.[22–26] The definition of early and late TR differs in these literature-based meta-analyses. The first two meta-analyses were published in 2004 by Fried et al.[22] and Huncharek and McGarry[23] on more than 1500 patients each. Both studies showed an advantage for early RT. In the first study, late TR was defined as beginning 9 weeks after initiation of chemotherapy or after completion of the third cycle of chemotherapy.[22] This meta-analysis showed a statistically significant benefit of 5% of early TR over late TR in terms of 2-year OS (relative risk [RR], 1.17; p = 0.03). Moreover, both studies reported that the best results could be achieved if platinum and etoposide were administrated concomitantly with early RT. In a meta-analysis published by De Ruysscher et al.,[24] early RT was defined as beginning within 30 days after the start of chemotherapy. The 2-year and 5-year OS rates were not significantly different (odds ratio [OR], 0.84; 95% CI, 0.56–1.28 vs. OR, 80; 95% CI, 0.47–1.38). However, when the only trial that delivered concurrent nonplatinum-based chemotherapy was excluded, the results were significantly in favor of early RT, with a 5-year survival rate of 20.2% for early versus 13.8% for late RT (OR, 0.64; 95% CI, 0.44–0.92; p = 0.02). Based on the same published data of four randomized trials, De Ruysscher et al.[25] hypothesized that the start of any treatment until the end of RT (SER) was important to consider in SCLC, taking into account both overall duration of RT and timing of TR. They concluded that a shorter time between the initiation of chemotherapy and the subsequent completion of RT was prognostic for survival. There was a significantly higher survival rate in the shorter SER arms; a 5-year OS rate of 20% was reached when the SER was less than 30 days (RR, 0.62; 95% CI, 0.49–0.80; p = 0.0003). Moreover, each additional week of the SER resulted in an overall absolute decrease in the 5-year survival rate of 1.8%. Acute toxicity, and particularly severe esophagitis, is related to timing and SER with a higher incidence in case of early RT and shorter time between start and end of therapy (OR, 0.63; 95% CI, 0.40–1.00; p = 0.05 and OR, 0.55; 95% CI, 0.42–0.73; p = 0.0001, respectively). This SER concept should certainly be further evaluated and considered in designing future studies as repopulation of cells seems to be a major cause of failure. As emphasized by Brade and Tannock[1] in an editorial, repopulation of cells between dose fractions is important for recovery in normal tissue, but repopulation of surviving tumor cells also occurs and offsets tumor cell kill. Repopulation triggered by neoadjuvant chemotherapy may inhibit the effectiveness of subsequent RT.

The same team published an update of their literature-based meta-analysis including 11 trials; there was no difference in 2-year survival, but once again excluding the only nonplatinum-based trial, the benefit of early RT became statistically significant (OR, 0.73; 95% CI, 0.57–0.94; p < 0.05).[26]

Another interesting observation that emerges from these studies is related to treatment compliance. Two studies with the same design and therapeutic regimen have been included in this meta-analysis: the NCI-C trial and the London trial.[20,21] The survival advantage observed for the early RT group in comparison with the late one (21 months vs. 16 months; p < 0.05, respectively) reported by the NCI-C trial was not confirmed by the London trial (14 vs. 15 months, respectively). However, in the latter study, patients randomized to early chest radiation received significantly less chemotherapy than in the late arm (69% in the early group and 80% in the late one, p = 0.03). In the NCI-C study, the percentage of intended total dose completed was the same for the early and late groups (both 86%). Similar disappointing survival results have also been reported by the Hellenic trial;[17] when analyzing compliance, a significant reduction in completion of planned chemotherapy was reported in patients who had early RT (71% in the early group and 90% in the late

group, $p = 0.01$). Hence, it would seem that only patients who can receive early RT as planned according to the protocol benefit from it. This issue has been thoroughly addressed in an individual data-based meta-analysis that concluded that there was no difference in terms of OS between "earlier or shorter" versus "later or longer" TR when all trials were analyzed together.[11] However, "earlier or shorter" delivery of TR with planned chemotherapy significantly improved 5-year OS at the expense of more acute toxicity, especially esophagitis. The authors highlight that the hazard ratio (HR) for OS is significantly in favor of "earlier or shorter" RT where there was a similar proportion of patients who were compliant with chemotherapy in both arms (HR, 0.79; 95% CI, 0.69–0.91) and in favor of "later or longer" RT among trials with different compliance to chemotherapy (HR, 1.19; 95% CI, 1.05–1.34; interaction test, $p < 0.0001$). Thereby, the absolute gain between "earlier or shorter" and "later or longer" TR in 5-year OS for similar compliance trials was 7.7% (95% CI, 2.6% to 12.8%) and was –2.2% (–5.8% to 1.4%) for different compliance trials. As expected, "earlier or shorter" TR was associated with a higher incidence of severe acute esophagitis.

Finally, a large retrospective study examined the National Cancer Database to assess practice patterns and survival for TR timing in relation to chemotherapy in 8391 nonmetastatic SCLC patients. This study suggested that early initiation of TR was associated with improved survival (5-year survival rate of 21.9%) compared with late initiation (5-year survival rate of 19.1%, $p = 0.01$), particularly when hyperfractionated radiation was utilized (28.2% vs. 21.2%, $p = 0.004$).[27]

Sun et al.[28] published a randomized trial of 219 patients, who were allocated to receive four cycles of cisplatin and etoposide with radiation beginning with the first cycle or the third cycle. It was not included in any of the meta-analyses. Patients received a total dose of 52.5 Gy in 25 daily fractions of 2.1 Gy over 5 weeks. Late RT was not inferior to early RT in terms of complete response rate, which was the main end point (early vs. late: 36.0% vs. 38.0%, respectively). After a median follow-up of 59 months, OS was similar in the two groups (rates at 2 years and 5 years after randomization in the early vs. late radiation arms were 50.7% vs. 56.0% and 24.3% vs. 24.0%, respectively). Thus as recommended by European and North American guidelines, patients with nonmetastatic disease, with good performance status (PS) and good compliance should be treated with concurrent chemoradiotherapy.[8–10] TR should be administered early in the course of treatment, in fit patients, for whom a good compliance may be expected, preferably beginning with cycle one or two of chemotherapy. According to the study of Sun et al.,[28] TR could be administered concomitantly to the third cycle with equivalent results. Nevertheless, this observation should be confirmed in another study because one should be cautious when extrapolating results issued from Asian population studies to non-Asian patients in lung cancer. Chemotherapy should consist of four cycles of a platinum agent and etoposide.

FRACTIONATION AND DOSE

Historically, modest total doses of daily fractionated radiation (1.8–2 Gy daily to 40–50 Gy) were used because of the observed responsiveness of SCLC to radiation. Although the clinical response rates with these total doses are high, durable local control is poor.[29–31] The hypothesis that hyperfractionated radiation therapy might be more effective than normofractionated schedules is based on in vitro marked radiosensitivity even to small doses of radiation, and on the high kinetics of SCLC proliferation and its repopulation between two fractions of treatment.[32] The in vitro observation of the lack of a shoulder on the cell survival curve for SCLC cell lines provides some of the rationale for

the hyperfractionated schedule, in which the dose per fraction is 1.5 Gy. Two phase III trials comparing conventional RT with hyperfractionated accelerated twice-daily RT schemes have been published.[33,34] In both trials, concomitant cisplatin plus etoposide chemotherapy was delivered with twice-daily RT; however, in the first trial RT was delivered after three cycles of chemotherapy, whereas in the second one RT started upfront during the first cycle of chemotherapy. In the NCCTG study,[33] the overall treatment time was similar in the conventional and hyperfractionated arms because of a 2.5-week split at the midpoint of treatment, and this could be the cause of the lack of difference in local progression (33% in the once-daily arm vs. 35% in the twice-daily arm) and OS (20.6 months in both arms). In the Intergroup trial 0096/ECOG 3588,[34] 417 patients were randomly assigned to receive a total of 45 Gy of concurrent TR, given either 1.5 Gy twice daily over a 3-week period or the conventional once daily over a period of 5 weeks. A significant difference in OS was reported in the last trial (19 months in the once-daily arm vs. 23 months in the twice-daily arm, $p = 0.04$) with a benefit in 2-year and 5-year survival rates (41% vs. 47% and 16% vs. 26%, respectively). As expected, grade III esophagitis was more frequent in the investigational arm (27% vs. 11%). An individual patient data meta-analysis on hyperfractionated and accelerated regimens in lung cancer has been conducted, which included trials comparing conventional fractionation with altered fractionation schedules in both SCLC and NSCLC.[35] This meta-analysis showed a significant OS benefit from accelerated or hyperfractionated RT in patients with NSCLC. The effect of altered fractionation on OS was similar among patients with SCLC, but not statistically significant (HR, 0.87 [95% CI, 0.74–1.02, $p = 0.08$]). The absolute benefit on OS was 1.7% at 3 years (from 29.6% to 31.3%) and 5.1% at 5 years. An interesting interaction between modified regimen and PS was reported (PS 0: HR, 0.81; PS 1: HR, 0.86; PS 2: HR, 2.22), underlining once again the correlation between survival benefit derived from altered fractionation regimens and the importance of patients being fit enough to undergo a more intensive regimen.

Despite the results of the Intergroup trial, showing that the 45-Gy twice-daily regimen could improve survival, accelerated hyperfractionated RT has not been widely adopted in general clinical practice. The reasons are possibly related to the logistical difficulties of delivering twice-daily RT, the increase in acute toxicity (especially esophageal), and possibly to the fact that the control arm used rather low doses of RT. However, the most important lesson that came from INT 0096 is the demonstration that intensified RT with concomitant chemotherapy could have an impact on survival.

A recent randomized phase II Norwegian trial compared two schedules, one using twice-daily fractionation (45 Gy in 30 fractions) and the other once-daily (42 Gy in 15 fractions) so that the overall radiation treatment time was the same. Although survival favored the twice-daily regimen in this small trial, it was not statistically significant (median 25.1 months vs. 18.8 months, $p = 0.61$). Response rates were significantly higher with the twice-daily regimen, with no difference in severe toxicities between schedules.[36] The way to intensify local therapy can be summarized in two strategies: total dose escalation and further exploration of altered fractionation schedules (i.e., applying concomitant boost).

Modern data on RT dose escalation come from several Cancer and Leukemia Group B (CALGB) studies starting with a phase I trial to determine the maximum tolerated dose of the twice-daily regimen and of the once-daily treatment delivered concomitantly to the fourth cycle of platinum-based chemotherapy.[37] The total recommended dose was 45 Gy for twice-daily RT, and 70 Gy for conventional fractionation. These promising results led to several phase II trials, which all confirmed the feasibility of delivering 70 Gy with concomitant chemotherapy.[38]

CHAPTER 40   Radiotherapy in the Management of Small Cell Lung Cancer: Thoracic Radiotherapy, Prophylactic Cranial Irradiation   **377**

40

The concomitant regimen (carboplatin and etoposide based) was administered after two cycles of chemotherapy with paclitaxel and topotecan. The median survival was 23 months in patients who had a weight loss over 5% compared with 31 months in patients with weight loss less than 5% before diagnosis. In a pooled analysis of limited-stage SCLC patients treated with two cycles of induction chemotherapy followed by concurrent platinum-based chemotherapy and RT, the authors analyzed 200 patients from three consecutive CALGB L-SCLC phase II trials (39808, 30002, and 30206) using high-dosage once-daily RT with concurrent chemotherapy.[39] The median follow-up was 78 months. Grade 3 or greater esophagitis was 23%. The median survival for pooled population was 19.9 months, and the 5-year rate was 20%. The 2-year progression-free survival was 26%. The authors concluded that 2-Gy daily RT to a total dosage of 70 Gy is well tolerated, and with similar outcome to twice-daily RT administered with chemotherapy. However, this hypothesis should be confirmed in a randomized trial, which is ongoing (NCT00433563).

The second method for intensifying local treatment was applied by Radiation Therapy Oncology Group (RTOG) researchers conducting some clinical studies with a hybrid approach, consisting of once-daily RT at standard fractionation in the first part of treatment followed by twice-daily RT to counter repopulation. The RTOG applied this dose escalation method from a total dose of 50.4 Gy to 64.8 Gy.[40] The esophagitis rate was lower than in the INT 0096 trial (18% in comparison with 27%), and so were the median and 2-year survival rates (19 months and 36.6% in comparison with 23 months and 47%, respectively).

To establish the optimal dose and fractionation, two phase III trials have been undertaken comparing two modalities of concurrent chemoradiation: hyperfractionated accelerated RT (45 Gy in 3 weeks as given in the INT 0096 study) and once-daily RT at higher dosage (66–70 Gy in 6.5 weeks) corresponding to a higher biologic effective dose but with superior overall treatment time.

The Intergroup trial CALGB 30610/RTOG 0538 (NCT00632853) started as a three-arm study. It was decided that the experimental arm with the higher rate of toxic events would be discontinued. Arm B was then closed in 2013. This trial is continuing as a two-arm study comparing arm A (twice-daily RT of 45 Gy) with arm C (once-daily RT of 70 Gy).

- Arm A: twice-daily RT up to a total dose of 45 Gy delivered concurrently to the first cycles of four cisplatin and etoposide chemotherapy regimens;
- Arm B: hybrid approach applied concurrently to the same chemotherapy regimen (this arm has been discontinued after a preplanned interim analysis);
- Arm C: once-daily RT at standard fractionation up to a total dose of 70 Gy with the same chemotherapy regimen.

The second phase III trial is the CONVERT intergroup study (concurrent once-daily vs. twice-daily RT; NCT00433563), which is a United Kingdom–led study comparing twice-daily and once-daily RT. The results of the CONVERT study were presented at the American Society of Clinical Oncology Annual Meeting, in 2016.[41] The study enrolled 547 patients with proven SCLC from 73 centers in seven European countries and Canada between 2008 and 2013. Patients were randomized to receive either concurrent twice-daily radiation therapy (45 Gy in 30 twice-daily fractions over 3 weeks) or concurrent once-daily radiation therapy (66 Gy in 33 once-daily fractions over 6.5 weeks), both starting with the second cycle of chemotherapy on day 22. Four or six cycles of cisplatin–etoposide were given according to the investigator's prespecified choice. Patients with any response were offered prophylactic cranial radiation. At a median follow-up of 45 months, 2-year and 3-year survival rates and median survival were 56%, 43%, and 30 months, respectively, for the twice-daily radiation therapy versus 51%, 39%, and 25 months for the once-daily radiation therapy (HR, 1.17; 95% CI, 0.95–1.45; p = 0.15). Toxicities were comparable; grade 3/4 esophagitis rate was 19% in the twice-daily arm and 18% in the once-daily arm. The results of CONVERT support the use of either regimen for standard-of-care treatment of nonmetastatic SCLC with good PS. The authors insisted that survival in both arms was higher than previously reported probably because of better patient selection.

To summarize, the evidence strongly supports concurrent chemotherapy and RT for patients with LS-SCLC. The available data also suggest that RT should begin early in good performance patients; the RT fractionation programs that satisfy these parameters have been associated with better survival.

RADIATION TREATMENT VOLUMES

The two major issues regarding treatment volume in SCLC can be summarized as follows:

- Is it appropriate to use the postchemotherapy target volume after induction chemotherapy in cases where RT is delayed?
- Do we need to electively treat clinically uninvolved regional lymph nodes?

An evolution in target volume definition can be recognized over the last two decades. In the early 1990s, emerging evidence demonstrated that smaller radiation target volumes did not adversely affect tumor control in the management of LD-SCLC.[42,43] In fact, more than 80% of failures occurred in-field, suggesting that inadequate radiation doses rather than inadequate volumes were the primary cause of intrathoracic recurrence.[44] Therefore the prevailing issue of recent research has been to reduce the treatment field size while increasing the radiation dose and sparing surrounding organs at risk. The analysis of the site of recurrence after chemoradiation may help define the optimal treatment volume. In the randomized study by Kies et al.[42] published in 1987, patients achieving a partial response or stable disease after induction chemotherapy were randomized to receive RT either to the prechemotherapy volume or to the postinduction reduced tumor volume. The local recurrence rate was not significantly different in the two arms (32% vs. 28%). Liengswangwong et al.[43] and Arriagada et al.[30] came to the same conclusions in their studies. Consequently, treating the residual tumor after induction chemotherapy may be sufficient. However, it should be underlined that most patients treated in these older studies had no chemotherapy-based treatment planning. More recent trials have explored the role of involved-field RT. In 2008, a report from the International Atomic Energy Agency explored whether one should electively treat all mediastinal nodes, or selectively include those with some clinical risk for harboring disease, or perhaps omit elective nodal irradiation (ENI) altogether.[45] This review revealed how limited the evidence was for defining the place of ENI in SCLC at that time. The authors suggested the need for prospective clinical trials and recommended that, given the lack of strong evidence regarding ENI in LD-SCLC, the use of ENI should be considered on a case-by-case basis.

More recently, prospective clinical trials have explored this issue and have reported on isolated mediastinal relapse, defined as failure in an initially uninvolved lymph node region in the absence of local recurrence or distant metastasis. A small prospective study (37 patients) from the Netherlands Cancer Institute reported only two out-of-field isolated nodal failures (5.3%) with an excellent 5-year survival of 27% using involved-field RT as part of combined modality treatment.[46] In another small study from the United Kingdom (38 patients), where patients were

treated omitting ENI based on CT imaging,[47] no isolated nodal failure was reported. Eight patients were found to have an intrathoracic recurrence: two within the planning target volume only, four within the planning target volume and distantly. There were only two cases of thoracic nodal relapse (6.5%), and both were accompanied by distant metastases. The Maastricht group outlined the possible importance of PET–CT in defining treatment volumes in SCLC. In the first prospective study,[48] with the gross tumor and nodal volume being defined by CT imaging, they reported an isolated nodal failure in 3 of 27 patients (11%), all in the supraclavicular region. Thus the omission of ENI on the basis of CT scan resulted in a higher-than-expected rate of isolated nodal failure in the ipsilateral supraclavicular fossa. However, the authors stated that because of the small sample size, no definitive conclusion could be drawn, and recommended to continue use of ENI outside of clinical trials. However, they started a small prospective trial evaluating selective nodal irradiation based on ^{18}F-2-deoxy-D-glucose (FDG)-PET for LD-SCLC.[49] Of the 60 patients enrolled, 39 (65%) developed a recurrence, but only two patients (3%) experienced isolated nodal failure. These findings are in contrast with the previous experience of CT-based selective nodal irradiation.[46]

In 2012, Xia et al.[50] examined the pattern of failures in 108 patients included in two successive trials and treated with combined involved-field RT and chemotherapy. They reported an isolated nodal failure rate in 5 patients (4.6%) treated with involved-field RT and chemotherapy using CT imaging for target definition, all in the ipsilateral supraclavicular area. Moreover, another four supraclavicular nodal failures with simultaneous distant metastases were also observed. To try to clarify the role of prophylactic irradiation of the supraclavicular area, a retrospective analysis on 239 patients has been conducted by Feng et al.[51] The supraclavicular metastasis incidence was 34.7%; multivariate analysis showed that upper mediastinal involvement (level 2 or 3) was significantly associated with supraclavicular metastasis. Thus such patients with upper mediastinal involvement could theoretically benefit from prophylactic irradiation of the supraclavicular lymph nodes. The lesions located in the right upper lobe had a higher incidence of supraclavicular involvement. In patients with supraclavicular involvement, 36% had bilateral or contralateral lymph node metastases and the frequency of contralateral involvement was higher for left-sided tumors than for those on the right.

The available data suggest that FDG-PET scans are more accurate than CT in the primary staging of SCLC and subsequently may lead to a reduction in the rate of isolated nodal failure.[9,52–55] A systematic review suggests that compared with conventional staging, PET can alter management in at least 28% of SCLC patients, resulting in the addition of life-prolonging RT in 6% and averting unnecessary RT with associated toxicity in 9%.[52] The cost analysis revealed that the PET-based strategy and the conventional methods do not seem significantly different, but PET may reduce health-care costs through avoidance of inappropriate TR.[53] A planning study on FDG-PET–based selective mediastinal node irradiation in 21 LD-SCLC patients showed a change in the PET treatment plan compared with the CT-based plan in 24% of cases.[54]

In a retrospective study by Shirvani et al.[55] examining the role of FDG-PET–based treatment planning before intensity-modulated RT combined with chemotherapy in 60 patients with SCLC and omitting ENI, a low rate of isolated nodal failure was found (2%). The authors concluded that ENI could be safely omitted in patients who underwent staging with PET–CT and treatment with intensity-modulated RT. Recently, a continuation of the work by Van Loon et al.[49] has been published by Reymen and colleagues,[56] expanding the initial series of 59 patients to 119 patients treated with concomitant chemotherapy and accelerated hyperfractionated RT, with only CT-PET–positive

or pathologically proven nodal sites being included in the target volume. Isolated elective nodal failure occurred only in two patients (1.7%) as in other studies using PET–CT for treatment planning. Median follow-up was 38 months, median OS was 20 months (95% CI, 17.8–22.1 months), and 2-year survival was 38.4%. In multivariate analysis, only total gross tumor volume (corresponding to postchemotherapy tumor volume and prechemotherapy nodal volume) and PS significantly influenced survival ($p = 0.026$ and $p = 0.016$, respectively).

A comparison of treatment outcomes between involved field and ENI in LS-SCLC was conducted retrospectively in a Korean study of 80 patients.[57] The two groups had similar overall and progression-free survival; however, for patients who had no PET scan, survival was significantly longer in patients who had ENI. All the isolated nodal recurrences were observed in patients who had no PET scan in their initial workup.

In a retrospective study of 253 patients treated in one institution over more than 10 years, the authors focused on locoregional failures. The cumulative locoregional failure rate was 29% and 38% at 2 years and 5 years, respectively. About 30% of local and regional failures were in-field, so most failures were marginal or out-of-field. Thus, according to these authors, it may be possible to prevent locoregional failure with improved RT target definition and careful consideration of the initial extent of disease.[58]

In conclusion, if patients do not have PET staging, the extension of the initial disease should be carefully evaluated to reduce the risk of isolated nodal failure and impaired survival outcome, and elective irradiation of the supraclavicular region should be considered. Subsequently, involved-field irradiation for limited stage SCLC can be considered with pretreatment PET–CT scan implementation. The two phase III trials investigating once-daily versus twice-daily RT will hopefully contribute to clarify volume issues. They do not recommend ENI, but require that both FDG-PET–avid lymph nodes and enlarged regional lymph nodes by CT criteria (regardless of FDG-PET activity) are included in the radiation treatment volume.

CHEMOTHERAPY REGIMEN COMBINED WITH RADIOTHERAPY

Since the early 80s, etoposide combined with cisplatin or carboplatin has been the cornerstone treatment of SCLC. Several new chemotherapy combinations have been explored in LD, with some of them seeming promising, especially paclitaxel and irinotecan.[59–64] However, none has shown superiority in terms of efficacy or tolerance compared with the platin-based and etoposide regimen, which remains the widely accepted standard. The JCOG published a randomized trial investigating the efficacy of irinotecan plus cisplatin in patients with nonmetastatic disease (JCOG0202).[63] The hypothesis that irinotecan and cisplatin could improve OS compared with etoposide plus cisplatin as demonstrated in ED by the same group could not be confirmed.[65] Of 281 patients enrolled, 272 received induction etoposide plus cisplatin and accelerated hyperfractionated RT (45 Gy) and 258 were randomly assigned to consolidation chemotherapy with etoposide–cisplatin or irinotecan–cisplatin (3 cycles). However, even if there was no significant difference in terms of survival between the two arms—35.8% in the etoposide–cisplatin arm and 33.7% in the investigational irinotecan plus cisplatin arm, respectively (HR, 1.09 [95% CI, 0.80–1.46]; $p = 0.70$)—the 5-year OS rate was among the best reported so far in phase III studies. Median survival was 3.2 years in the etoposide–cisplatin arm and 2.8 years in the irinotecan plus cisplatin arm. As outlined by the authors, this result might be partly attributable to selection of patients, but also to quality control of RT that may have an impact on outcome, as shown in a recent meta-analysis.[66] A phase II trial

CHAPTER 40   Radiotherapy in the Management of Small Cell Lung Cancer: Thoracic Radiotherapy, Prophylactic Cranial Irradiation   **379**

40

was also performed in the United States, with a different design consisting of two cycles with cisplatin and irinotecan followed by once-daily chest irradiation (70 Gy) administered concurrently with carboplatin etoposide (CALGB 30206). The 2-year survival was 31%, so it did not meet the survival target for further development.[64]

If many therapeutic strategies have been disappointing in SCLC, there are promising strategies such as immunotherapy. Several studies in patients with lung cancer have suggested a possible favorable association between the increased presence of immunologically active cells in the tumor and survival, suggesting that immunotherapy may be a viable approach for patients with SCLC. Early clinical trials with nivolumab and ipilimumab have shown activity in a broad range of cancers, including SCLC.[67]

There is an ongoing randomized phase II study (NCT02046733) investigating the efficacy and tolerability of the standard treatment (chemotherapy and RT) alone, compared with the standard treatment followed by immunotherapy (nivolumab and ipilimumab) in patients with limited SCLC, and more trials are ongoing in ED.

EXTENSIVE DISEASE: THORACIC RADIOTHERAPY

The majority of metastatic (or ED) SCLC patients respond to induction chemotherapy, but more than 50% of patients will eventually experience intrathoracic failure.[8,9,68,69] The hypothesis to add RT to chemotherapy is based on possible improvement in local control and survival benefits by controlling residual disease that is resistant to chemotherapy. Moreover, in a patient population with incurable malignancy, maintenance of local control to minimize/delay symptoms as long as possible may be considered as an important clinical objective. The role of radiation therapy in extensive SCLC was traditionally reserved for patients who required local palliation, and typically was not considered part of the standard of care in the absence of mediastinal symptoms. In 1999, Jeremic et al.[70] published a randomized study to evaluate whether TR as consolidation treatment could improve the poor results observed in ED-SCLC. Patients were randomized to either six cycles of chemotherapy of cisplatin–etoposide or six cycles of the same chemotherapy with 54 Gy of hyperfractionated TR. Patients who had a complete response outside the thorax after three cycles of chemotherapy and an at least partial response in the thorax benefited from subsequent concurrent chemotherapy and radiation. Median survival time (17 months vs. 11 months, $p = 0.041$), 5-year survival rate (9.1% vs. 3.7%, $p = 0.041$), and median time to local recurrence (30 months vs. 22 months, $p = 0.062$) were all improved in the RT group. This trial was conducted in a single institution and underpowered so the issue remained controversial.

There are two very recent trials that have investigated the role of extracranial RT in addition to PCI following platinum-based chemotherapy in patients with ED-SCLC. The Dutch Lung Cancer Study Group has activated an international randomized controlled trial of TR versus observation for patients with ED-SCLC who responded to chemotherapy. The trial coordinated by Slotman et al.[71] accrued 483 patients (Chest Radiotherapy in Extensive Stage SCLC Trial [CREST]). In CREST, patients were randomized to receive TR (30 Gy in 10 fractions within 2 weeks) plus PCI or PCI only. While there was no difference between groups in the primary end point of 1-year OS, a significant difference was observed in OS at 2 years in a secondary analysis (13% vs. 3%, with and without chest radiation, respectively, $p = 0.004$). The HR for OS was 0.84 with a 95% CI just passing through 1.00 (0.69–1.01; $p = 0.066$). The study also showed that TR led to a significant improvement in progression-free survival ($p < 0.001$) and a nearly 50% reduction in the risk of intrathoracic progression ($p < 0.001$). A subsequent analysis has shown that TR

improved OS significantly as well as progression-free survival in patients who had residual intrathoracic disease after chemotherapy.[72] In these patients, the difference in OS was statistically significant ($p = 0.03$; HR, 0.81; 95% CI, 0.66–0.98; stratified). In patients who achieved a complete intrathoracic response, no benefit of TR was observed. Within the RTOG, a randomized phase II trial was activated to determine the role of consolidation extracranial RT (thoracic and other extracranial metastatic sites) plus PCI after a response to systemic chemotherapy (RTOG 0937; clinical trials.gov NCT01055197).[73] Extensive stage SCLC patients with up to three extrathoracic sites were randomized to PCI only or PCI plus consolidative RT to the thorax and residual distant metastases to a total dose of 45 Gy in 15 fractions within 3 weeks. The primary end point was 1-year survival, and a total of 154 patients were to be enrolled. However, as the planned interim analysis seemed to show that the study crossed the futility boundary, the trial was closed to accrual after inclusion of 91 patients. Observed 1-year OS was 60.1% (95% CI, 41.2% to 74.7%) in the PCI arm and 50.8% (95% CI, 34% to 65.3%) in the PCI plus consolidative RT arm ($p = 0.21$). The authors concluded that the observed OS exceeded predicted OS in both arms, and consolidative RT to the thorax and extracranial metastases delayed progression of disease but did not improve 1-year OS.

PROPHYLACTIC CRANIAL IRRADIATION

Brain metastases are frequent in SCLC and responsible for serious impairment of patients' survival and quality of life.[74] Approximately 15% of patients have brain metastasis at the time of diagnosis, and this rate is even higher with more accurate imaging, such as magnetic resonance imaging (MRI). Moreover, about half of patients in complete remission after treatment for LD-SCLC will develop brain relapse.[75] In the early 1980s, PCI was therefore introduced to prevent brain metastasis. Most of the randomized trials testing PCI showed a significant decrease of brain metastasis incidence in favor of PCI; however, none of them individually could demonstrate a significant improvement in OS. Thus a meta-analysis was undertaken, based on individual data of almost 1000 patients in complete remission included in seven randomized phase III studies.[76] Thoracic complete remission corresponded to at least normalization of chest x-ray in most trials. In this meta-analysis, 85% of the patients had LD- and 15% had ED-SCLC; administered PCI dose ranged from 8 Gy in one fraction to 40 Gy in 20 fractions. At 3 years, there was an absolute decrease of 25.3% in the cumulative incidence of brain metastasis (59% in the control arm vs. 33% in the PCI arm, $p < 0.001$) and an absolute increase in survival of 5.4% from 15.3% in the control group to 20.7% in the treatment group ($p = 0.01$). Interestingly, an indirect comparison of four total dose groups (8 Gy, 24–25 Gy, 30 Gy, and 36–40 Gy) showed a significant trend ($p = 0.02$) toward a decrease in the risk of brain failure with higher PCI dose. The authors also identified a trend ($p = 0.01$) toward a lower risk of brain metastasis with earlier administration of PCI after start of the treatment. Therefore PCI became part of the standard of care for complete and good responders based on CT scan evaluation. More recently, in a retrospective study based on the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program, which involved almost 8000 patients, Patel et al.[77] have reported similar results, with a significant improvement in both overall and cause-specific survival in favor of PCI. The 5-year OS rate was 19% among patients who had PCI versus 11% among patients who had no PCI ($p \leq 0.001$).

Other challenges raised by the meta-analysis are optimal timing and optimal dose for PCI. The PCI Collaborative Group has published an intergroup trial addressing the question of dose–effect to prevent the development of brain metastases in

patients with LD who achieved a complete response (i.e., at least a normal chest radiograph).[78] It compared a standard dose of 25 Gy in 10 fractions with a higher dose of 36 Gy (36 Gy/18 fractions or 36 Gy in 24 twice-daily fractions). It is noteworthy that to evaluate a possible increased neurologic toxicity, quality of life and neurologic assessments both before and after PCI were performed. Toxicities and treatment delivery were not different between the two arms. Patients who received the high-dose had a nonsignificant decrease in brain metastases compared with patients who received the standard dose. The rate of brain metastasis at 2 years was 29% and 23% in the high-dose and standard-dose groups, respectively (p = 0.18). For unclear reasons, OS was significantly decreased among patients in the high-dose PCI group (HR for death, 1.2 [95% CI, 1.00–1.44]). The importance of fractionation in terms of efficacy, tolerance, and possible neurologic sequelae could be determined by a phase II/III trial (RTOG 0212), which compared three schedules: 25 Gy in 10 fractions; conventional fractionation (36 Gy in 18 fractions); and hyperfractionated accelerated RT (36 Gy in 24 twice-daily fractions).[79] At 1 year after PCI there was a significant increase in the occurrence of neurotoxicity in the 36-Gy cohort (p = 0.02). Logistic regression analysis revealed increasing age to be the most significant predictor of chronic neurotoxicity (p = 0.005).

Another important issue is whether elderly people should have PCI, as the rate of elderly patients with SCLC is increasing, and about 50% of nonmetastatic patients are 70 years or older. Using the same SEER database, the authors identified 1926 patients aged 70 years or older who were diagnosed with LD between 1988 and 1997; amongst them, 138 patients (7.2%) received PCI. Median age was 75 years, ranging from 70 years to 94 years; in this group of patients, 2-year and 5-year OS rates (33.3% and 11.6%, respectively) were significantly better among patients who received PCI than in patients who did not receive PCI (23.1% and 8.6%, respectively; p = 0.028). On multivariate analysis, PCI was found to be an independent predictor of OS in patients aged 80 years or less.[80] However, this potential benefit has to be balanced against the potential neurocognitive sequelae of PCI that are known to increase with age.[74] PCI at 25 Gy in 10 fractions is now recommended for LD-SCLC good responders.[8–10] A recent review has also examined the role of PCI in SCLC in specific subgroups such as resected or elderly patients.[74]

PROPHYLACTIC CRANIAL IRRADIATION IN EXTENSIVE DISEASE

Even if the PCI meta-analysis, which included 15% of patients with ED, supported PCI in ED for complete responders, the question remained unanswered for patients with partial response.[76] Furthermore, most clinicians were reluctant to administer PCI in metastatic patients. The EORTC thus decided to undertake a phase III trial randomizing exclusively patients with ED who had partial or complete response to first-line treatment. They would be randomly assigned PCI (20–30 Gy) or no PCI.[81] Patients in the PCI arm were mostly treated with a short-course schedule: among the 143 irradiated patients, 89 received 20 Gy in 5 fractions, and the others were treated with various fractionation schedules (30 Gy in 10 fractions, 30 Gy in 12 fractions, or 25 Gy in 10 fractions). The results of this study were strongly in favor of PCI: not only did PCI significantly reduce the risk of symptomatic brain failure, but it also significantly improved OS. The cumulative risk of symptomatic brain metastases at 1 year was 14.6% in the PCI arm and 40.4% in the control arm (p < 0.001), and the 1-year survival rate was 13.3% in the control arm and 27.1% in the PCI arm (p = 0.003). Because of the low median survival in this setting, long-term toxicity is not of major concern, and the short-course schedule (20 Gy in 5 fractions) should

be favored. However, less hypofractionated schedules (such as the schedule applied to LD) could be offered to patients with higher life expectancy. This study has had major implications and contributed to the modification of the standard of treatment for patients with metastatic SCLC.[8–10]

However, preliminary results of a Japanese phase III trial are in disagreement with the findings of the EORTC study.[82] The design was quite similar, but the inclusion criteria as well as the main objective differed. In the Japanese study, all patients had brain MRI before randomization and had follow-up with brain MRI every 3 months. The primary end point of the Japanese study was OS, and the study investigated whether PCI (25 Gy in 10 fractions) could affect survival compared with no PCI, as reflected by an HR of 0.45. The secondary end point was time to brain metastasis (assessed every 3 months by brain MRI). The planned sample size was 330 patients, but after a planned interim analysis, patient enrollment was stopped because of futility. Of the 224 patients enrolled from 2009 to 2013, 163 patients were analyzed. The cumulative risk of developing brain metastases at 1 year was significantly lower in the PCI group (32.2%) than in the control group (58.0%; p < 0.001). Median survival was 10.1 months in the PCI group compared with 15.1 months in the control group (p = 0.091). Therefore the results of this trial confirmed once again that PCI reduced the risk of developing brain metastases, whether symptomatic or asymptomatic. However, it did not show a benefit in terms of survival. The researchers concluded that PCI did not confer any survival benefit for patients with extensive SCLC when absence of brain metastases was confirmed by MRI before enrollment and asymptomatic brain metastases were detected early and treated. There was a nonsignificant trend for longer survival in patients who did not receive PCI compared with those who did. The fully published results of this trial are awaited, so in the meantime some guidelines recommend PCI for all patients who respond to treatment, while others say that close surveillance may also be proposed in metastatic patients.

Even if there are strong data showing that PCI reduces the incidence of brain metastasis and improves OS in SCLC, its indications should also be considered in the light of its potential neurotoxicity.

In the 1980s, several studies had reported neurologic and intellectual impairment or abnormalities on brain CT scan potentially related to PCI that were of concern to clinicians.[74,83–85] Acute toxicity is generally manageable and mostly involves alopecia, headache, fatigue, nausea, and vomiting. Long-term toxicity is of concern, because irreversible sequelae such as severe memory loss, intellectual impairment, or even dementia, ataxia, or seizures have been reported in retrospective studies and attributed to PCI. However, most of these studies were small, retrospective, and of questionable methodology. For example, baseline evaluations were lacking in most of them. Since then, it has been clearly demonstrated that many patients with SCLC have neurologic and cognitive impairments prior to the administration of PCI.[75,86–88] They may be due to effects of chemotherapy on the brain, a paraneoplastic syndrome, aging, an immunologic dysfunction, or even microscopic cranial metastases leading to frontal–subcortical cognitive abnormalities. Other factors related to treatment have been implicated in increasing the risk for chronic neurotoxicity, including a daily fraction size over 3 Gy per fraction and concomitant administration of chemotherapy during PCI. In a retrospective study with no neurologic baseline evaluation, Shaw et al.[89] found that the actuarial risk of severe or worse brain toxicity was 2% at 2 years and 10% at 5 years posttreatment and only occurred in those who received daily fraction sizes of PCI of at least 3 Gy. It should be outlined that in two randomized trials,[75,87] a prospective evaluation was performed in the group of patients treated with PCI and in patients who had no PCI. They did not show

any significant difference in neurologic functions between the PCI and no-PCI groups, with a follow-up limited to 30 months. However, these neurologic evaluations did not focus on neuro-cognitive functions. Quality of life was evaluated in one of the larger studies,[87] and there was no significant difference between the PCI and no-PCI groups, at baseline, at 6 months, and at 1 year; however, compliance was not optimal. More recently, in a retrospective study, so as to evaluate the benefits and the possible risks of PCI, Lee et al.[90] developed a model taking into account the OS and the quality of life, which is related to the frequency and the severity of PCI-related late neurotoxicity, in patients who have achieved complete response. The authors were then able to determine the quality-adjusted life expectancy. They concluded that quality-adjusted life expectancy was greater with PCI, but, as the OS increases, frequency and severity of neurotoxicity should be as low as possible to keep this benefit.

In the Intergroup study evaluating the optimal PCI dose in patients with nonmetastatic SCLC, a mild deterioration was observed across time of communication deficit, fatigue, intellectual deficit, and memory (all $p < 0.005$).[91] This study also confirmed the importance of age as a cofactor of neurocognitive decline. All patients included in the RTOG 0212 study had a thorough neurocognitive assessment in their follow-up, similar to the one used in another RTOG randomized trial (RTOG 0214) evaluating PCI in NSCLC. Gondi et al.[92] thus evaluated tested and self-reported cognitive functioning after PCI for lung cancer among 410 patients who had PCI and 173 patients who had no PCI. PCI was associated with a higher risk of decline in self-reported cognitive functioning at 6 months (OR, 3.60; $p < 0.0001$) and 12 months (OR, 3.44; $p < 0.0001$). Memory was evaluated with the Hopkins Verbal Learning Test-Recall, which is a well-validated assessment of list-learning memory, including encoding, retrieval, and retention of new information. A decline over time at 6 months and 12 months was also associated with PCI ($p = 0.002$) but was not closely correlated with decline in self-reported cognitive functioning, so the authors concluded that these tests may evaluate distinct elements of the cognitive spectrum.

Because alteration of the limbic circuit, and more specifically the hippocampus, may contribute to memory and neurocognitive deficit, recent studies have analyzed the precise location of brain metastases to explore whether whole-brain irradiation with hippocampal avoidance could be envisaged in the future.[93–95] Very few patients with SCLC brain metastases were included in these studies, so further research is needed to evaluate whether brain irradiation with hippocampal avoidance might be effective in patients with SCLC brain metastases. Several studies have now been launched, evaluating PCI with hippocampus sparing.[74] Another approach that is being explored is close surveillance with MRI and administration of stereotactic RT to new brain metastases.[96] More data are needed, and the fully published results of the trial of Seto et al.[82] will bring us further information concerning this approach in ED-SCLC.

Thus in conclusion, patients should be informed of these potential adverse effects on neurocognitive functioning that have to be put in balance with the benefit of PCI on survival and brain metastasis.[74,76,78,81,90,97] Median age of patients included in the meta-analysis and patients included in the Intergroup study and EORTC RTOG studies was 60 to 62.[76,78,81,92] Therefore for elderly patients, this balance of benefit to risk should be highlighted.

PCI remains the standard of care in all SCLC patients who have a good response to treatment. The optimal dose is 25 Gy/10 fractions in patients with nonmetastatic disease; for patients with metastatic SCLC, the same PCI dose or a dose of 20 Gy/5 fractions can be delivered.

41 Palliative Radiotherapy for Lung Cancer

Andrea Bezjak, Alysa Fairchild, and Fergus Macbeth

SUMMARY OF KEY POINTS

- Palliative radiotherapy is an effective and well tolerated treatment for palliation of thoracic and other symptoms in patients with lung cancer (both nonsmall cell lung cancer and small cell lung cancer).
- There is ample high-quality evidence from many randomized trials that short courses (one or two fractions only) of thoracic radiation provide high rates of symptomatic relief.
- There is ongoing controversy about whether moderate dose radiation schedules are superior to shorter courses in terms of symptom control or survival benefit; they do result in more toxicity.
- Single-fraction palliative radiation is recommended for uncomplicated bone metastases, with high rates of pain relief.
- Dexamethasone at a low dose administered on the day of single-fraction radiation for bone metastases and for 4 subsequent days significantly reduces the incidence of pain flare with tolerable side effects.
- Stereotactic radiotherapy is emerging as an option for management of patients with vertebral body metastases; trials are in progress to compare it with conventional palliative radiation.
- Brain metastases are common in patients with lung cancer; options for management include whole-brain radiotherapy, stereotactic radiation, surgical resection, observation, or best supportive care. Prediction tools can be helpful in identifying patients who have better versus poorer prognosis, in order to guide most appropriate therapy.

Despite substantial advances in earlier diagnosis, with prompt staging and management, and with the improved results of lung cancer treatment, metastatic disease is either present at the time of diagnosis or will develop after initial curative treatment in many patients with lung cancer. A minority of patients with metastases outside the thorax may be candidates for more aggressive multimodality treatment, such as patients with a solitary brain metastasis. However, virtually all patients with stage IV disease and indeed the majority with stage III disease will not be cured, despite the increase in therapeutic options including targeted therapy and systemic chemotherapy that may indeed extend survival and improve or control their cancer for a period of time.

For most patients with metastases, success would be defined as prolonged survival with good quality of life; good performance status; few symptoms of disease; and then, when all options have been exhausted, a peaceful and comfortable death. As a result, the aims in treating patients with incurable disease are prolonging survival, maintaining or improving quality of life, and controlling any cancer-related symptoms with minimum toxicity and inconvenience. Palliative radiotherapy was one of the first treatments to provide symptom improvement for patients with either locally advanced thoracic or metastatic disease, and it continues to have a favorable therapeutic index. The side effects are often minor, and the benefit in terms of symptom improvement is substantial. This finding has been well documented for patients with symptomatic intrathoracic disease and for patients with bone metastases. The evidence for the effectiveness of palliative radiotherapy for patients with lung cancer with brain metastases has been debated in the literature, but it is still the mainstay of treatment for these patients. Palliative radiotherapy is also widely used for metastases at other sites, such as lymph nodes, skin or subcutaneous nodules, adrenal metastases, liver metastases, and orbital or retinal metastases, although there is little formal evidence, other than clinical experience, for its use. Local symptoms may be improved regardless of the histologic subtype of tumor. Small cell lung cancer (SCLC) responds quite rapidly to radiotherapy, and symptoms will improve in most patients. Even though the biology of SCLC, with its tendency to grow rapidly and metastasize, means that chemotherapy is usually the treatment of choice, palliative radiotherapy undoubtedly has a place in treatment management and should not be overlooked. In patients with nonsmall cell lung cancer (NSCLC), the response to palliative radiation is more variable, although symptom response does not directly correlate with radiographic responses and can be seen quite early; e.g., hemoptysis can resolve 12 hours to 24 hours after large-dose-per-fraction radiotherapy, and similarly bone pain may respond in that time frame as well, particularly after single-fraction radiotherapy. Whether response is related to radiation effect on cancer cells, or tumor vasculature, or the surrounding cell matrix with apocrine and metacrine effects or other factors, is far from understood. Elucidating the precise mechanism by which palliative radiotherapy leads to symptom palliation would be a major advance in management of patients with incurable cancers.

This chapter covers the indications for palliative radiotherapy, dose fractionation, planning issues, outcomes including symptoms, quality-of-life benefits and potential effects on prolonging survival, toxicity, and potential repeat treatment issues in patients with lung cancer with either thoracic (lung or mediastinal lymph nodes) or metastatic disease, specifically bone, brain, and other symptomatic sites. Most of the evidence relates to NSCLC, but as mentioned, SCLC would be expected to have a greater symptomatic response to palliative radiotherapy, although a less certain overall benefit in terms of length of disease control.

PALLIATIVE RADIOTHERAPY FOR THORACIC SYMPTOMS

The aim of palliative radiotherapy is to relieve symptoms as completely and as durably as possible. But, as with any palliative treatment, there is a trade-off between the burden of the treatment itself—inconvenience and acute and potentially long-term side effects—and the benefits in terms of symptom relief, quality of life, and, perhaps, improved survival. Evidence-based clinical practice guidelines published in 2012 detail the evidence and recommendations for the role of radiotherapy in thoracic symptom palliation; there is also evidence that international patterns of practice differ.[1,2]

Indications

Palliative thoracic radiotherapy is indicated whenever a patient has disease that is not potentially curable and has troublesome symptoms that can be attributed to growth of the primary tumor and/or mediastinal node disease. These findings need to be integrated into the whole care of the patient and any systemic therapy that is ongoing or being planned. Thoracic palliative radiotherapy is most often used when a patient is unfit for chemotherapy because of poor performance status or comorbidities and there is no appropriate targeted therapy, or when symptoms persist or recur during or after systemic therapy. Additionally, for patients with NSCLC, because the response to radiotherapy is faster and more reliable than to chemotherapy, there are often occasions when local symptoms mean that it is better to treat patients with radiotherapy first and consider systemic treatment later. For patients with SCLC, palliative radiotherapy is probably only indicated as a first-line treatment in emergency situations such as severe stridor or if the patient is considered too unwell to tolerate systemic chemotherapy, but is often useful when there is symptomatic recurrence and resistance to chemotherapy.

Most of the common symptoms from intrathoracic disease are well palliated by radiotherapy. These include cough, hemoptysis, and chest pain. The response rates range from 50% to 90%,[3] with the highest complete response rates seen for hemoptysis. Breathlessness appears to be less well palliated as it may be also caused by a number of other factors, such as obstructive airways disease, cardiac disease, lymphangitis carcinomatosa, or pleural effusion. Moreover, when there is a tumor in an airway causing lung, lobar, or sublobar atelectasis, the lung may not always reexpand even if the tumor shrinks and the airway is opened up, especially if there has been infection or a coexisting pleural effusion. However, any patient who presents with stridor or computed tomography (CT) evidence of a tumor threatening a major airway should be considered for urgent radiotherapy, as even modest shrinkage of a tumor causing obstruction of a large airway can provide considerable symptom relief. Superior vena cava obstruction (when due to tumor compression rather than thrombus) may also be relieved by palliative radiotherapy, although when severe, more rapid improvement may follow a stenting procedure. However, if a patient has both superior vena cava obstruction and airway compromise, the placement of a superior vena cava stent would not palliate the airway compromise, whereas palliative radiotherapy could improve both; thus, the pros and cons regarding placement of a stent followed by radiotherapy rather than palliative radiotherapy alone need to be carefully considered.

Sometimes it may be considered appropriate to treat patients prophylactically before symptoms develop. There no good evidence that this approach improves outcomes. The authors of one randomized clinical trial carried out in the United Kingdom before widespread use of chemotherapy for patients with NSCLC found that in a group of asymptomatic patients randomly assigned to no immediate palliative radiotherapy, 56% died without having had radiotherapy and that there was no substantial difference in symptom control or survival between patients who received immediate or as required palliative radiotherapy, neither at an early time point nor a later 6-month time point.[4]

Palliative radiotherapy may be delivered either by external beam or as intracavitary; i.e., endobronchial brachytherapy.

External-Beam Radiotherapy

Most palliative radiotherapy to the chest can be delivered simply with uncomplicated fields and short courses of mega-voltage radiotherapy. Because this treatment is palliative and the aim is to improve the patient's symptoms and improve quality of life, unnecessarily complex and prolonged courses of treatment should be avoided, especially in patients with a poor performance status and limited life expectancy.

Radiotherapy Planning

Usually simple parallel opposed anterior/posterior beam arrangements are sufficient, and although recent CT images are useful to assess the extent of disease, complex CT planning should not be needed. The fields should be designed to cover the extent of the tumor causing the troublesome symptoms, but should be kept as small as possible to minimize toxicity (Fig. 41.1), especially as many patients with advanced lung cancer have coexisting chronic obstructive pulmonary disease and therefore already compromised pulmonary function. Widespread sites of disease that are unlikely to be causing symptoms, such as involved but relatively small nodes in the mediastinum, should not necessarily be included. More complex field arrangements may occasionally be needed if there is a risk of overlap with previously treated areas or it is considered essential to minimize the dose to the spinal cord (see later).

Radiotherapy Regimens

The regimens for palliative radiotherapy evolved pragmatically over the past 20 years before they were subjected to any rigorous evaluation in randomized controlled trials (Table 41.1). A number of randomized controlled trials have compared various regimens for palliation and these have been summarized and reviewed in two systematic reviews.[3–5] These reviews included 14 randomized controlled trials meeting the selection criteria (more than 3000 patients) but use different approaches to incorporating different dose/fractionation regimens in a meta-analysis. For patients with a poor performance status (2–4) there is no evidence that longer, more fractionated regimens provide better palliation or longer survival than shorter regimens, such as 10 Gy in a single fraction or 16 or 17 Gy in two fractions over 1 week. For patients with a good performance status (0 or 1) the evidence is more uncertain, but it is possible that higher dose, more fractionated regimens (such as 36 to 39 Gy in 12 or 13 fractions) provide more durable symptom control and longer survival than lower dose regimens, but at the expense of more toxicity, especially esophagitis (see later). However, the increase in 1-year survival is likely to be modest—assuming a 1-year survival of 45% in this group of patients with better prognosis, the increase is likely to be around 10%, similar to that achieved with cisplatin-based chemotherapy.

However, although shorter courses of palliative radiotherapy are almost certainly as effective as more prolonged ones for most patients, especially patients who are less well, there appears to be a reluctance to use such regimens in many parts of the world.[1] This reluctance may be because of unfamiliarity, lack of exposure during training, concerns about the risks associated with using large fractions (see later) and the ability to retreat after larger doses per fraction, or unrealistic expectations about the anticipated life expectancy of the patient and possible survival benefits from longer courses. But this reluctance is also influenced by departmental policy and a widespread belief that what is commonly prescribed is indeed the best, and sometimes is also influenced by financial considerations. It is therefore important to consider the burden placed on patients and their families or caregivers from a prolonged course of treatment with repeated hospital visits, when useful palliation can be provided by only one or two fractions.

Side Effects

Typically, palliative thoracic radiotherapy is well tolerated with few toxicities, none of which is likely to be life-threatening. This

TABLE 41.1 Commonly Used Palliative Radiotherapy Regimens for Thoracic Radiation

Dose (Gy)	No. of Fractions	No. of Days	BED (Gy10)
10	1	1	20
16	2	8	29

to normal lung in those circumstances. In cases of symptomatic radiotherapy pneumonitis, corticosteroids may improve the symptoms of cough and dyspnea, but need to be tapered gradually in order to prevent relapse.

Larger fraction palliative radiotherapy may be associated with specific side effects that have been described by a number of authors.[6–8] In the first 24 to 48 hours after treatment, up to 50% of patients may experience nausea, brief episodes of acute chest pain, or fever and rigors. These side effects are rarely severe and usually do not last long, but may cause patients anxiety and distress unless they are warned and given appropriate medication. Acute changes in peak expiratory flow rate have also been described, and caution is needed in patients with substantial airway obstruction.[9] A short course of corticosteroids such as prednisolone given for a few days during radiotherapy may be helpful.

Spinal cord damage (radiation myelopathy) was recorded in a few cases in the clinical trials following the use of 17 Gy in 2 fractions and 39 Gy in 13 fractions.[10] Care should therefore be exercised when using these regimens, and steps should be taken to avoid the spinal cord or reduce the dose, especially in patients with a relatively good prognosis and when lower energy radiation (e.g., from cobalt 60) with a less favorable dose distribution is used.

Repeat Radiation

Occasionally, recurrent tumor in the chest causes symptoms in patients who had a good response to palliative radiotherapy. The patient may have had systemic treatment in the meantime, but disease has progressed despite treatment or subsequently after treatment. The clinical question then arises as to whether it is safe and appropriate to consider a further course of palliative radiotherapy. The major risk from repeat radiation is radiation myelitis, possibly leading to paraparesis, if the spinal cord is included in both treatment volumes and the total dose exceeds tolerance. A further risk is radiation pneumonitis if large volumes of the residual normal lung are included in the retreatment fields.

Repeat radiotherapy is never an easy decision and several factors need to be considered:

- clinical benefit gained (degree of improvement and duration) with the first treatment and the likelihood of substantial tumor and symptomatic response from repeat radiotherapy
- patient's likely prognosis
- risk of radiation myelitis, given the original dose fractionation and the proposed second dose to the spinal cord
- volume of lung in the proposed retreatment field, especially if the beams are arranged to avoid the spinal cord.

Inherent in all these considerations is great uncertainty, and, in particular, little is known about the cumulative risk to the spinal cord and whether recovery takes place following initial treatment. However it is reasonable to make some pragmatic judgments

Fig. 41.1. Illustration of thoracic palliative radiotherapy plan. (A) Baseline diagnostic CT scan. (B) CT simulation image of palliative radiotherapy plan delivering 20 Gy in five daily fractions via a four-field technique (*red,* GTV; *turquoise,* PTV; *orange,* spinal canal; *dark blue,* esophagus). finding is in marked contrast with the potentially severe and persistent toxicity caused by chemotherapy. The most common side effects of palliative thoracic radiotherapy are fatigue and esophagitis. The severity of esophagitis is generally dose-related, and in most patients it is easily managed and resolves within a week or so. Radiation pneumonitis may occur if large fields and higher doses are used, and care should be taken to minimize the dose

[a]Depending on performance status.

about the balance of risk and benefit and to discuss these openly with the patient and his or her relatives. If after being fully informed, the patient is prepared to accept what is probably for most patients with a limited prognosis a quite small risk of myelitis, versus an uncertain but likely symptomatic benefit, then repeat radiotherapy may be appropriate. Clearly, the health-care provider should only proceed with repeat radiotherapy once clear consent processes have been completed.

Brachytherapy

Endobronchial brachytherapy using iridium-192 is an established method of treating tumors in the main bronchi. It involves bronchoscopy and insertion of a small catheter, which is connected to a device that sends the radioactive source to pre-specified positions along the tube that correspond to the location of the tumor; the radioactive sources remain in prespecified positions for a few minutes, as needed to deliver the prescribed dose of radiation. The advantage of this technique is that a high dose can be delivered locally to the tumor but it is not effective if there is bulky extraluminal tumor or complete obstruction of the bronchus.

The authors of a Cochrane review summarized the clinical trial evidence and concluded that brachytherapy is less effective than external-beam palliative radiotherapy as first-line treatment.[11] Its use should therefore be restricted to patients who have symptomatic recurrent tumor, which is mainly within the lumen of the bronchus.

Palliative Chemoradiation Therapy

Many patients with symptomatic incurable NSCLC may be candidates for both palliative chemotherapy and radiotherapy; the usual approach is to sequence the therapy, typically starting with palliative radiotherapy for local symptoms, as the expected symptomatic response rates are overall higher than with palliative chemotherapy. This finding has been confirmed in a randomized phase III study of palliative radiotherapy with or without chemotherapy; toxicity was greater and patient outcomes were not better with the addition of concurrent chemotherapy (fluorouracil [5FU]).[12] In 2013, Strøm et al.[13] published the results of a randomized trial that compared chemotherapy alone (cisplatin and vinorelbine) with concomitant chemoradiation in which 45 Gy in 15 fractions was given along with cycle 2, in patients with "poor prognosis" stage III NSCLC. Survival was significantly better in the patients receiving chemoradiation, (1-year survival 53.2% vs. 34.0%; $p < 0.01$), even those aged over 70 years and with bulky disease,[14-16] but with increased toxicity. The survival benefit was

not, however, seen in those with World Health Organization Performance Status.[2] Although these results are interesting, they come from only one underpowered trial and should be treated with caution. It would certainly not be appropriate to extrapolate them to the management of those with stage IV disease.

BONE METASTASES

Bone metastases will develop in as many as 40% of patients with lung cancer at some point.[17] The prevalence of bone metastases has increased because of longer survival related to advances in systemic therapy, but the median survival of 13 weeks in patients with lung cancer with bone metastases is poor in comparison to that of other tumors.[18] Bone metastases are the most common cause of cancer-related pain,[19] and up to 75% of patients experience symptoms that impair their quality of life. As patients with lung cancer and bone metastases have incurable disease, treatment intent is palliative; treatment goals are pain relief, preservation of mobility and function, prevention of skeletal-related events, and optimized quality of life.

Bone metastases can be described as complicated or uncomplicated; complicated generally refers to impending or established pathologic fracture, previous surgery, impending or established spinal cord compression, impending or established nerve-root compression, neuropathic pain, previous radiotherapy, or associated soft-tissue mass. Skeletal-related events are usually defined as pathologic fracture, spinal cord compression, hypercalcemia, or the need for surgery or radiotherapy.[20] Management costs of bone metastases secondary to lung cancer are substantial and primarily driven by treating skeletal-related events.[20]

The selection of the optimal method of palliative radiotherapy depends on symptom burden, extent of disease, life expectancy, performance status, comorbidities, toxicity, risk of skeletal-related events, prior treatment, whether metastases are (un)complicated, and patient wishes and would be best assessed and determined by an interdisciplinary team. Table 41.2 lists the indications and the usual fractionation schedules recommended.

International Bone Metastases Consensus End Points

Although many phase III trials assessed the palliative benefit of radiotherapy in patients with painful bone metastases, caution is required when interpreting and generalizing the results of older studies because of variable definitions of response, including what constitutes complete and partial relief.[21,22] The International Bone Metastases Consensus Working Party has defined a uniform set of eligibility criteria, end point measurements, repeat
Fig. 41.2. Example of parallel-opposed pair technique delivering 8 Gy in one fraction to a painful right scapular metastasis (*red,* gross tumor volume; *turquoise,* planning tumor volume).

radiation guidelines, and statistical analysis for clinical trials to increase consistency in reporting.[21]

Indications for External-Beam Radiotherapy: Uncomplicated Bone Metastases

External-beam radiotherapy provides durable and timely symptom relief while minimizing toxicity, resource utilization, and the number of visits to the cancer center, but would not be expected to confer a survival benefit. Tumors do not have to be completely eradicated in order to improve symptoms, and therefore doses lower than that required for lesion ablation are used for palliation. Moreover, the treatment of asymptomatic bone metastases may be deferred unless there is a risk of a serious adverse event such as spinal cord compression.

Authors and investigators of more than 20 randomized controlled trials, two systematic reviews, and four meta-analyses have shown that single-fraction palliative external-beam radiotherapy provides equivalent pain relief to multiple fractions in patients with a variety of tumors (up to 25% in lung cancer).[22–25] The most recent meta-analysis included 25 studies comprising 2818 patients who were randomly assigned to single-fraction radiotherapy and 2799 to multiple-fraction radiotherapy.[22] The overall response rate to single-fraction radiotherapy was 60%, and the complete response rate was 23% (intent-to-treat), which was comparable to the 61% and 24% rates for patients who received multiple-fraction radiotherapy. There were no differences in acute toxicity, pathologic fracture (3%), or spinal cord compression (2% to 3%). None of the meta-analyses separated out treatment effects by histology, and there is no convincing evidence that outcomes differ by primary site.[22] Single-fraction radiotherapy has been repeatedly recommended as the standard of care for uncomplicated bone metastases (Table 41.2) Fig. 41.2 demonstrates a radiotherapy plan using an anterior and posterior beam to deliver 8 Gy in one fraction to a painful right scapular metastasis.

Despite this strong evidence, there has so far been reluctance to adopt single-fraction schedules as standard practice in many countries.[26] In a large prospective study conducted in the United States, 25 in 1574 patients with lung cancer and metastatic disease who received palliative bone radiotherapy, only 6% received single-fraction radiotherapy. Patients who were younger than age 55 years, had had surgery at a metastatic site, or had received chemotherapy were more likely to receive radiotherapy. Patients treated in integrated networks (e.g., health maintenance organizations) received on average 3.4 fewer fractions ($p = 0.001$) and 4 Gy less dose ($p = 0.049$), although the overall rates of

radiotherapy delivery were similar.[27] Suggested reasons for this reticence include country of training, membership affiliation, institutional structure, available pain management teams, wait times for radiotherapy consultation or delivery, reimbursement levels, and departmental policy.[20,26–28]

Indications for External-Beam Radiotherapy: Complicated Bone Metastases

Impending Pathologic Fracture

An impending pathologic fracture is defined as a bone metastasis that has a substantial likelihood of fracture under normal physiologic loads. Patients with an impending pathologic fracture may benefit from surgery, radiotherapy, or both, but no randomized trials have reported a comparison of these modalities. Provided that the surrounding bone can support the implanted hardware,[29] prophylactic stabilization reduces pain and avoids the serious consequences of fracture, although postoperative recovery may delay continuation of systemic therapy.[28] Generally, postoperative radiotherapy follows. A proportion of patients will not be candidates for operative intervention or will refuse. In that case, radiotherapy alone can be delivered.[30]

Established Pathologic Fracture

If a pathologic fracture has occurred, surgery with suitable reconstruction is indicated, especially for lower limb bones in patients with a good prognosis.[31] Surgery cannot prolong survival but improves stability, activities of daily living, function, pain, and quality of life.[31,32] Most guidelines recommend fractionated radiotherapy if surgery is not indicated (Table 41.2), although goals of care and expected lifespan may result in the decision to prescribe single-fraction radiotherapy. In an apparently solitary, histologically confirmed metastasis, especially after a long disease-free interval, doses on the higher end of the spectrum (e.g., 30 Gy in 10 fractions) may be prescribed, although there is no conclusive evidence that this improves local control.

Postoperative Radiotherapy

Postoperative radiotherapy is used to promote bone healing by suppressing tumor growth, preventing destabilization of the prosthesis by maintaining the structural integrity of the bone in which the implant is fixed.[33] Postoperative radiotherapy decreases pain, increases the frequency of normal use of the extremity, prevents disease progression, minimizes the need for revision procedures, and reduces the risk of refracture.[34] Following intramedullary nailing, all implanted hardware should be included in the radiation portal to decrease the risk of seeding (Fig. 41.3). Treatment is generally started within 2 to 4 weeks after surgery, once the wound has healed satisfactorily. Although commonly a multiple-fraction schedule is prescribed (Table 41.2),[34] patients with postoperative clinical deterioration may be considered for single-fraction radiotherapy.[33]

Neuropathic Pain

Although neuropathic pain from bone metastases does not usually respond well to standard analgesics,[35] it does respond to radiotherapy.[36] Roos et al.[36] compared 8 Gy in a single fraction with 20 Gy in five fractions for 245 patients with any primary site; 31% had lung cancer. Pain relief was seen in 53% of patients who had single-fraction radiotherapy and in 61% of patients who had multiple-fraction radiotherapy (intent-to-treat) at 2 months. The median time to treatment failure was longer in the fractionated arm (3.7 vs. 2.4 months), but did not reach significance. The authors recommended 20 Gy in five fractions; however, patients

Example of postoperative radiotherapy delivered after surgical decompression, vertebrectomy, tumor resection, and stabilization for a T11 pathologic fracture secondary to nonsmall cell lung cancer. Using a five-field technique, 20 Gy was delivered over five daily fractions to encompass a planning tumor volume *(turquoise),* which included the pathologic fracture, adjacent involved T10 vertebral body, and surgical bed including hardware *(yellow contour)*. (A) axial image; (B) sagittal image; and (C) coronal image.

with decreased performance status, shorter expected survival, or substantial comorbidities should receive single-fraction radiotherapy (Table 41.2).

Quality of Life

As the main treatment goal of radiotherapy is symptom control, the most appropriate way to assess response (pain, other quality-of-life aspects) is by patient-reported outcomes.[37] Measuring quality of life was recommended for all bone metastases clinical trials by 91% of experts in an international survey.[21] Authors of many recent studies have reported health-related quality of life and functional interference after palliative radiotherapy for bone metastases. In general, patients whose pain improves after radiotherapy also experience substantially improved physical and role function.[38–40] Improvements extend to associated symptoms, such as insomnia and constipation, and responders describe better emotional functioning, general activity, normal work, and overall quality of life by 2 months.[38–41] Neither anatomic location nor radiotherapy dose predicts the degree of improvement.[40,41] Differences in the likelihood of functional response by primary site have been suggested; in one study, 27% of patients with lung cancer had responded by 2 months, compared with 70% of patients with breast and prostate cancer.[40]

Indications for Hemibody External-Beam Radiation

Hemibody radiation is an effective treatment for widespread symptomatic bone metastases,[42] particularly for patients with poor performance status, although it used to be practiced more often in the past. It may be delivered to the upper half (base of skull to iliac crest; 6 Gy in one fraction), lower half (iliac crest to ankles; 8 Gy in one fraction), or middle of the body (diaphragm to pubic symphysis; 6 Gy in one fraction). Hemibody radiation

provides pain relief in 70% to 80% of patients, often within 24 to 48 hours, and may decrease future requirements for opioids and local external-beam radiotherapy.[43–45]

Indications for Stereotactic Radiosurgery

Stereotactic radiosurgery is administered as a radioablative dose to a lesion in a highly conformal manner, typically in a single or a few fractions. It is presently being investigated for certain clinical circumstances, such as repeat treatment of bone metastases near the spinal cord.[46] There are possible advantages with stereotactic radiosurgery:[47]

- Smaller volumes of normal tissue radiated
- Higher degree of preservation of organ function
- Radiobiologic benefits due to the high dose per fraction
- Improved local control

However, these advantages may be outweighed by cost, need for specialized equipment, and laborious set-up and treatment. Randomized trials comparing conventional external-beam and stereotactic radiotherapy for bone metastases are ongoing. Gerszten et al.[47] prospectively evaluated outcomes of single-fraction radiosurgery delivered to 87 patients with spinal bone metastases secondary to lung cancer. Of the 87 patients, 70 patients had previous maximum external-beam radiotherapy. The mean tumor dose was 20 Gy in one fraction, delivered over an average of 90 minutes. No patient experienced radiotherapy-related neurologic deficits. A total of 65 of 73 patients were treated primarily for pain and had long-term improvement.[47] Enrollment of fit patients in clinical trials at centers with sufficient experience should be encouraged.[47-49]

Side Effects of External-Beam Radiotherapy

Acute side effects are generally mild and self-limiting or controllable by conservative measures. Most begin 1 to 2 weeks after treatment, although some, such as nausea, begin within hours. They may not peak until after the end of radiotherapy and usually resolve in 2 to 3 weeks. As radiotherapy is a localized treatment, all the potential side effects except fatigue are site-specific. Late effects, which may appear months or years after treatment, are uncommon, usually permanent, and should be managed by a radiation oncologist. Although the possibility of late toxicity in patients with incurable malignant disease must be considered, many patients will not live long enough to be at risk. Side effects and recommended management strategies have been reviewed.[50]

Pain flare is a common side effect in patients who have undergone external-beam radiotherapy for bone metastases. Pain flare is a short-lived worsening of pain in the treated area, can occur in up to 44% of patients within a week after starting radiotherapy, and lasts for a median of 3 days.[51,52] It is not clear whether pain flare is more common after single fractionation. In one study, the authors found that patients with lung cancer were less likely to experience pain flare (23%) compared with patients with breast and prostate cancers.[53] In a recently reported double-blind, placebo-controlled randomized trial, dexamethasone 8 mg orally starting on the day of single-fraction radiotherapy and for 4 consecutive days afterward significantly decreased the rate of pain flare with tolerable side effects.[54]

Integration of External-Beam Radiotherapy With Other Modalities

External-Beam Radiotherapy and Minimally Invasive Techniques

Percutaneous vertebroplasty and kyphoplasty are minimally invasive outpatient surgical techniques for restoring stability to lytic spinal bone metastases, as well as improving pain and mobility and preserving quality of life, functional independence, and performance status; when used in the pelvis and elsewhere, the technique is referred to as osteoplasty.[55,56] These treatments are an option for patients with medical comorbidities, mechanical component to their pain, even if multilevel spinal disease but cannot be used in the setting of a soft-tissue mass.[57] There is no evidence that adding external-beam radiotherapy improves clinical outcomes,[48] although both can decrease pain refractory to other modalities.[55,58]

External-Beam Radiotherapy and Systemic Therapy

Chemotherapy addresses systemic as well as bone disease. It can improve pain and quality of life and prolong survival in patients with bone metastases, but may be hazardous for heavily pretreated patients with extensive bone marrow disease. Response rates and duration are usually lower than that of radiotherapy, drugs can be expensive, there may be a long interval before onset of relief, and side effects are also systemic. Concurrent radiotherapy and chemotherapy have not been extensively investigated in patients with bone metastases although it is common for patients with bone metastases to receive these modalities sequentially.

Bisphosphonates may prevent or delay skeletal-related events in lung cancer.[59,60] Because bisphosphonates and external-beam radiotherapy have different dose-limiting toxicities, bisphosphonates could provide background control alongside acute local pain relief provided by radiotherapy.[61,62] Vassiliou et al.[63] published their experience of concurrent radiotherapy (30–40 Gy) and monthly intravenous ibandronate in 45 evaluable patients with multiple primary sites; 29% had lung cancer. All groups had substantial reductions in pain and opioid requirements, and improved performance status and physical functioning. At 3 months, the complete response rate was 69% and the partial response rate was 31%. Radiographic bone density and lesion healing were substantially increased at all time points. No patient required repeat treatment, and only one pathologic fracture occurred in a patient with lung cancer. Other studies evaluating the combination have been reviewed by Vassiliou et al.;[63] no randomized data are available.[61] External-beam radiotherapy and concurrent bisphosphonates have been recommended by one guideline.[30] They are also a consideration where radiotherapy is contraindicated.[62]

Denosumab is a fully human monoclonal antibody, which specifically targets the receptor activator of nuclear factor kappa B ligand, an osteoclast regulatory factor. It may delay the onset of bone metastases and treat established bone destruction.[64] In patients with bone metastases due to NSCLC, denosumab may increase median overall survival compared with zoledronic acid (9.5 vs. 8 months).[65] Denosumab is recommended as an option for preventing skeletal-related events in adults with bone metastases from solid tumors if bisphosphonates would otherwise be prescribed or after bisphosphonates have become ineffective.[17,59,66] However, there is no high-quality evidence available on combined denosumab and radiotherapy.

Repeat Radiotherapy

Repeat radiotherapy may be considered when other treatments are either ineffective or not indicated.[67,68] Rates of repeat treatment in the most recent meta-analysis were 20% after 8 Gy in one fraction compared with 8% after multiple-fraction radiotherapy ($p < 0.00001$).[22] One reason more patients receive repeat treatment after SF radiation is because they can; many radiation oncologists are reluctant to deliver repeat treatment after ≥30 Gy, particularly if the spinal cord is in the volume.[52] An intergroup study randomly assigned 850 patients who had received previous radiotherapy and had painful bone metastases to receive radiotherapy at 8 Gy in one fraction or 20 Gy in five fractions. The

intention-to-treat response rate at 2 months after 8 Gy (28%) was no lower than that after 20 Gy (32%); by per-protocol analysis, rates were 45% and 51%, respectively. There were no differences in rates of pathologic fracture, spinal cord compression, or quality of life, but adverse events at day 14 were substantially worse after multiple fractions.[69] Studies that report time to maximum response after external-beam radiotherapy have found it commonly takes 4 to 6 weeks. Therefore, repeat treatment should be delayed until this time, which also allows response to the first course to be assessed and pain flare to have resolved.[21]

Spinal Cord Compression

Spinal cord compression will develop in 5% of all patients with cancer, and lung cancer is ultimately diagnosed in 15% to 30% of patients with spinal cord compression as their presenting event.[70-72] The median survival from diagnosis of spinal cord compression due to lung cancer is poor: it is less than 2 months in one study.[73] Urgent magnetic resonance imaging (MRI) of the entire spine should be undertaken on the least suspicion of neurologic symptoms or signs, especially in a patient with known vertebral metastases.

Definitive treatment (surgery or radiotherapy) within 24 hours is recommended to optimize symptom control, preserve neurologic function and ambulation, decrease tumor bulk, and maximize quality of life.[74] The spinal service should be consulted for an opinion if a tissue diagnosis is required; there is a solitary level of compression; there is spinal instability or bony fragments within the spinal canal; the patient cannot have radiation (e.g., because of previous radiation at that level); neurologic deterioration occurs during or after maximal dose radiotherapy; there is radiotherapy-resistant histology; there is rapid symptom progression; or there is acute onset paraplegia.[74]

In general, factors associated with a better prognosis include longer time to development of motor deficits, ambulatory ability before and after therapy, radiotherapy-sensitive histology, and a single site of compression, treated in a timely fashion.[30,75]

Best supportive care including opioids, venous thromboembolism prophylaxis, and rehabilitation are reviewed in a 2008 United Kingdom guideline.[74] There is good evidence that corticosteroids are effective. Unless contraindicated, all patients should receive a loading dose of 10 mg to 16 mg of dexamethasone, followed by 16 mg daily in divided doses thereafter.[74] After radiotherapy, the dose can be tapered. If neurologic function deteriorates, the dose should be increased temporarily.[74]

Impending Spinal Cord Compression

Retrospective studies suggest that radiotherapy may preserve neurologic function in patients with spinal metastases with radiographic signs that suggest the spinal cord is at risk.[76] In the absence of good evidence on dose, fractionated radiotherapy should probably be offered (Table 41.1).[21,76]

Established Spinal Cord Compression

Surgery and postoperative radiotherapy is superior to radiotherapy alone for symptomatic patients with an expected survival of more than 3 months and a single level of compression, resulting in significantly better ambulation rates, retention of ambulation and continence, maintenance of functional and motor scores, and lower doses of steroids and analgesics.[77] This combined-modality approach has therefore been recommended for spinal cord compression or spinal instability (compression fracture, dislocation, or retropulsed bone fragments), in patients with sufficient performance status and life expectancy, by many international bodies.[30,52,74] Because patients with SCLC often have

a short lifespan, surgery is less often considered.[78] If surgery is not indicated or declined, radiotherapy alone should be offered,[49] which is still the most common treatment for epidural spinal cord compression.[49,73] The most appropriate radiotherapy schedule is still being debated (Table 41.1). This debate is likely due to the scarcity of good data exploring dose schedules in common use. Patients with spinal cord compression were excluded from most clinical trials investigating radiotherapy for uncomplicated bone metastases. Two randomized Italian phase III trials investigated short-course and single-fraction treatment in patients with poor prognosis.[79,80] No significant differences were found for relief of back pain, ability to walk after radiotherapy, bladder function, duration of motor improvement, toxicity, or survival between short-course regimens.[80] There were no differences between short-course and single-fraction radiotherapy except for median duration of response, which was longer for 8 Gy in two fractions.[79] The authors of a series of retrospective studies from a large multicenter database have reported similar immediate functional and neurologic outcomes and survival with short- and longer-course radiotherapy. However, longer-course radiotherapy is probably associated with better local control and less in-field recurrence.[75] Although a patient with a poor prognosis who is paraplegic will not benefit from radiotherapy in terms of neurologic status, delivery of external-beam radiotherapy for pain control should be considered. Postoperative radiotherapy should be offered to all patients with a satisfactory surgical outcome once the wound has healed.[74]

Repeat Radiotherapy for Spinal Cord Compression

Recurrent spinal cord compression in a previously radiated region may be treated with further radiotherapy, provided the patient responded well to the previous course and the interval has been greater than 3 months. Highly conformal radiotherapy techniques such as stereotactic radiosurgery provide a method of salvage treatment in patients with limited metastases and good performance status and can be considered to reduce the cumulative spinal cord dose.[74,75,81] Although stereotactic radiosurgery could be undertaken for patients who have recurrent pain at a previously radiated spinal segment, it cannot be used in an emergency setting such as frank spinal cord compression.[81] Surgical decompression could be undertaken in the setting of maximal previous radiotherapy.[70]

BRAIN METASTASES

Brain metastases are a common site of metastatic disease in patients with lung cancer, whether occurring at the time of diagnosis (as neurologic symptoms are frequently the presenting symptoms that prompt testing that leads to a diagnosis of lung cancer) or later. Some patients are living longer because of better systemic therapy and increasing recognition of treatable mutations, but many chemotherapeutic agents do not penetrate the blood–brain barrier well enough to eradicate micrometastatic disease. Thus, the incidence and prevalence of brain metastases in patients with lung cancer are increasing. There is also a subgroup of asymptomatic patients with a low burden of brain metastatic disease found during routine MRI, as part of staging or restaging. They may have only one or a few small metastases and may be candidates for stereotactic brain radiotherapy (gamma-knife or linac-based treatment) or surgical resection for larger lesions that are surgically accessible, especially if the lesions are symptomatic and causing mass effect. However, management of patients with a good performance status who have a relatively low burden of disease and a solitary brain metastasis is not truly palliative in its intent, but is aimed at eradicating intracranial metastatic disease and prolonging life. Admittedly, there is only anecdotal evidence that such aggressive treatment

leads to permanent eradication of all cancer. This section covers palliative management, such as, management of symptomatic patients who have multiple brain metastases.

Brain metastases that are found because of symptoms of raised intracranial pressure, such as headaches and nausea, or because of seizures or focal neurologic deficits usually cause substantial morbidity and affect the patients' physical and mental functioning and performance status. The presence of multiple symptomatic brain metastases is a sign of poor prognosis. The most appropriate management of symptomatic patients will depend on a number of patient and tumor factors. Many options are available:

- End-of-life care alone
- Corticosteroids alone
- Corticosteroids and a short course of whole-brain radiotherapy (WBRT)
- A combination of WBRT and focal stereotactic brain radiotherapy
- Surgical resection of the symptomatic lesion for palliation, usually followed by WBRT

The important clinical decision is to identify the most favorable group, such as, patients who might benefit from a more aggressive approach, with the aim of prolonged neurologic control, and the unfavorable group, patients who have poor prognosis for whom the goal might be short-term palliation and end-of-life care. Most patients will fall into an intermediate prognosis group, for whom WBRT and corticosteroids are the mainstay of management.

Selection of Patients Who Are More Likely to Benefit From Treatment

Several methods have been developed to aid clinicians and clinical trialists for identifying patients who are likely to have a better prognosis and might benefit from a more aggressive treatment. The best known method is the Radiotherapy Oncology Group (RTOG) Recursive Partitioning index (RPA), developed from pooling of data from several RTOG phase III trials.[82] These trials did not include only patients with lung cancer, although in most trials of brain metastases, lung cancer is the most common primary tumor. The best group, RPA class I, consisted of patients who had reasonable performance status (Karnofsky score greater than 70), a controlled primary tumor, age younger than 65 years, and brain as the only site of metastases. Further analyses of the RTOG clinical trials have led to the development of the Graded Prognostic Assessment (GPA),[83] which considers more categories of age and performance status and includes the number of brain metastases (1, 2–3, greater than 3), with the best prognosis in patients that are younger, with excellent performance status and a solitary brain metastasis.

Further publications by the same group have refined the GPA and have created disease-specific (DS)-GPAs.[83] To illustrate, the lung cancer DS-GPA includes performance status, age, presence of extracranial metastases, and the number of brain metastases, whereas the melanoma and renal cell carcinoma DS-GPA only includes performance status and the number of brain metastases. Several authors have compared the various prognostic indices for brain metastases. Rodrigues et al.[84] performed a systematic review of nine published and validated brain metastases prognostic indices including the RTOG RPA, the GPA and DS-GPA, Rotterdam, Basic Score for bone metastases, Golden Grading System, and RADES I and II. These authors compared the indices with respect to a range of characteristics and reported that although none is ideal, all had some clinical usefulness. The authors concluded that RTOG RPA was the best validated to date. In another report, these prognostic indices were used on two institutional databases of 500 patients treated either with stereotactic radiotherapy (381 patients) or WBRT (120 patients).[85] Comparisons were made using novel metrics (net reclassification improvement index, integrated discrimination improvement index, and decision curve analysis). Different indices performed better on different metrics; overall best results were with RTOG RPA, Golden Grading system, RADES I, and Rotterdam, but the GPA was best in identifying poor prognosis patients. Thus, any of these indices could and should be used in clinical practice and clinical trials to identify a subgroup of patients with good prognosis who would benefit from a more aggressive approach to their brain metastases, a subgroup with a poor prognosis, and an intermediate group who should be considered for whole-brain radiotherapy.

Whole-Brain Radiotherapy: Dose Fractionation and Planning

Palliative radiotherapy for patients with multiple brain metastases, where the goal is palliation, consists of WBRT, with two parallel opposed lateral fields, covering the entire brain but sparing the eye and minimizing dose to the salivary glands and oropharyngeal mucosa, in order to reduce the toxicity. Traditionally, planning was not CT-based but used clinical mark-up, relying on the anatomic landmarks of the superior orbital ridge and the external auditory canal to delineate the inferior border of the WBRT field as they are appropriate surrogates for the base of skull; a field that cleared the scalp in all other borders would encompass the entire content of the intracranial fossa while avoiding the eyes and other organs at risk. However, the anterior- and inferior-most parts of the brain and especially the meninges were being underdosed or not covered, and the precise level of cervical spine that was included in the radiotherapy field was hard to evaluate and especially hard to match with any future cervical spine radiotherapy fields. Thus, many centers have moved to CT-based planning, where those issues, including dose delivered to the lens, the most radiation-sensitive structure in the eye, could be better estimated, although this may not be of relevance to many patients who have short life expectancies and will not live long enough for radiotherapy-induced cataracts to develop. This finding led to an appreciation of the dose inhomogeneity with traditional planning, and attempts to create more homogeneous doses, with segments, or even with intensity modulated radiotherapy. Intensity modulated radiotherapy is a sophisticated radiotherapy technique, frequently used for high-dose radiotherapy planning, which can allow sparing of particularly sensitive structures such as the hippocampus in an attempt to reduce the risk of memory impairment after WBRT,[86] or sparing of the scalp to avoid the otherwise universal (albeit temporary) side effect of alopecia. However, whether the use of these sophisticated and typically more expensive technologic advances is appropriate for palliative radiotherapy is debatable; it hinges on the goals of care and a realistic estimate of the patient's life expectancy.

There have been many randomized trials in which the authors have attempted to define the most appropriate dose and fractionation of palliative WBRT, and others in which the authors have investigated the addition of chemotherapy or radiosensitizers to improve the therapeutic ratio of WBRT. The standard radiotherapy schedules are considered to be 30 Gy in 10 daily fractions over 2 weeks and 20 Gy in 5 fractions over 1 week. Although the five fractions over 1 week is a biologically lower dose (although it is not one-third less, as the fraction size is higher and overall duration lower, which increases its biologic potency), head-to-head comparisons have not shown better outcomes with the higher dose. In a Cochrane review on WBRT for multiple brain metastases, the authors summarized 39 randomized trials (more than 10,000 patients), some of which were studies on altered fractionations (e.g., hyperfractionated or accelerated radiotherapy), WBRT

with and without radiosensitizers, WBRT with or without radiosurgery boost, or radiosurgery with or without WBRT.[87] Their conclusion was that no alternative regimen was better than standard radiotherapy (30 Gy in 10 fractions or 20 Gy in fractions) in terms of overall survival, neurologic function, or symptom control.

Outcomes

One of the challenges in assessing the effectiveness of palliative management of patients with brain metastases is the lack of consensus on what constitutes palliation. The investigators of many clinical trials have focused on overall survival, even though that may be influenced by the presence of extracranial disease. Others have tried to assess neurologic progression-free survival and neurologic control, most frequently through radiographic response rates rather than the patients' actual symptoms or functioning. There have been attempts to measure palliation, by assessing control of the presenting neurologic symptoms, steroid dose, and the patient's performance status—all factors probably most relevant to assessing whether patients have actually benefited from radiotherapy.[88] Using those criteria, only a minority of patients in clinical practice appear to derive palliative benefit from WBRT.[89] This finding is partly due to the fact that a proportion of patients with a poor prognosis die within 6 to 8 weeks of a diagnosis of brain metastases and thus do not live long enough to derive a clear palliative benefit,[90] and partly because neurologic symptoms improve with corticosteroids, a fact that is well recognized but poorly documented.[91] There is clear evidence that corticosteroids themselves cause toxicity, especially with prolonged use[92]; but there is no good evidence for the use of high doses, such as dexamethasone 16 mg per day, when lower doses, such 4 or 8 mg per day, may be as effective and less toxic.[93] One approach to mitigate corticosteroid-related side effects is to personalize the starting dose depending on the degree of edema and symptom response; to taper rapidly to a low dose, such as 2 mg or 4 mg of dexamethasone per day; and then consider whether a complete wean is appropriate, depending on the patient's prognosis and symptom burden. To answer the question of how best to manage the palliation of patients with brain metastases who have a poorer prognosis, investigators in the United Kingdom have completed a phase III, multicenter randomized controlled trial in which patients with optimal supportive care with or without WBRT (20 Gy in five fractions) are compared. The primary outcome was quality-adjusted life years, with survival, performance status, and symptoms as the secondary outcomes. This study has recently been reported as not showing a benefit to WBRT over best supportive care.[94,95]

Toxicity of WBRT

The main acute side effects of WBRT are fatigue and, sometimes, headaches, nausea, and vomiting, related to an increase in intracranial pressure presumably due to the cytotoxic and other effects of radiotherapy causing edema; these side effects are usually prevented by giving adequate doses of corticosteroids. Occasionally, patients will have swelling of the parotid gland, usually after the first or second fraction. Subacute side effects include ongoing fatigue, as well as alopecia, skin reaction (dryness, redness, hyperpigmentation), and possibly transient reduced hearing due to a combination of middle ear fluid accumulation and dry wax in the auditory canal. With the usual palliative dose regimens, there should be no permanent effect on hearing, as the radiotherapy doses delivered are well within tolerance of nerves.

The main late effect of concern is impaired cognitive function. For a long time, this effect was not appreciated, probably because of the poor prognosis of those who are treated with palliative WBRT. Studies have brought attention to this important quality-of-life issue, demonstrating impairments in memory and other cognitive function using standardized tests, although data have been debated in terms of their generalizability and have led to divergent conclusions. Reduction of delayed neurotoxicity is an area of active investigation.[95] The use of pharmacologic agents such as memantine or hippocampal sparing radiotherapy to preserve cognitive function[96,97] are covered in more detail in Chapter 43.[96,97]

Alternative Management Approaches

As outlined at the beginning of the section on brain metastases, if the goal of treatment is eradication of neurologic disease in a patient with minimal or no extracranial disease, stereotactic radiotherapy or surgical resection, with or without WBRT, may be considered. Authors of studies and practice patterns in some areas of the world, notably the United States, have championed the avoidance of WBRT in order to reduce the negative cognitive impact. Small randomized trials of stereotactic radiotherapy for brain metastases demonstrated better neurologic and cognitive outcomes and improved survival in patients randomly assigned to stereotactic radiotherapy.[98] It was not clear whether the differences were indeed due to the therapeutic benefit of stereotactic radiosurgery, given that additional brain metastases developed in patients who were treated with stereotactic radiosurgery initially but continued to be treated aggressively, typically with further stereotactic radiosurgery. In contrast, patients randomly assigned to initial WBRT were deemed to be closer to the end of life and were not offered further therapy upon progression. Thus, a larger proportion of patients in that arm were closer to the last months of their life when the primary outcome of this trial, cognitive function at 4 months after randomization, was assessed. Their poor performance on that test may have been a reflection of the terminal state of disease, rather than the direct effect of WBRT.

Additional larger randomized studies are being conducted to try to determine whether withholding of WBRT will indeed lead to better overall neurologic outcomes, when taking into account both tumor recurrence, further therapy, and neurologic and functional outcomes. Until then, countries and centers are quite divided in their opinions on what is the best strategy; it would not be unusual if the controversy were to continue even after data from randomized controlled trials are available. Unfortunately, it is hard to completely separate the views of what is the most important end point from training and local practice, financial incentives and disincentives, and, in some jurisdictions, patient expectations and demands; these findings further fuel the current debate, which of course extends to management of patients with brain metastases well beyond lung cancer.

Repeat Treatment

In the past, patients with brain metastases had a short life expectancy, and repeat treatment was rarely contemplated. Investigators from several centers have reported that repeat WBRT may be considered for patients who have shown a good and prolonged response to previous radiotherapy, although what is considered a prolonged response is not well defined. Current practice is to consider stereotactic radiotherapy for progression in solitary metastases, and although there is no randomized level evidence for that approach, stereotactic radiotherapy is a relatively well-tolerated treatment that might provide better local control. Whether this finding will result in overall clinical benefit is largely dependent on other patient selection factors and needs to be balanced against the

risks of short- and long-term toxicity. There may indeed be a role for repeat WBRT,[98,99] but the toxicity of such a second course, especially in terms of cognitive function, should be considered.

PALLIATIVE RADIOTHERAPY TO OTHER AREAS

Palliative radiotherapy is also widely used for SCLC and NSCLC metastases to other sites, such as lymph nodes, skin or subcutaneous nodules, adrenal metastases, liver metastases, and orbital or retinal metastases. There are virtually no formal studies evaluating the effectiveness of palliative radiotherapy for those sites, as it would take a long time for any center to accrue patients with those specific metastatic sites to a study. However, principles of palliative radiotherapy apply—if one can identify with reasonable confidence which site of tumor involvement is causing a symptom, and can target that tumor with a radiation field that delivers a certain dose with minimal/modest toxicity, one should expect a therapeutic benefit, typically within days or a few weeks at most, especially if large doses per fraction are employed. With some application of clinical judgment, good history taking, physical examination, and judicious use of tests, symptom improvement should be possible to attain in a large proportion of patients. Thus, only patients who have multiple symptoms from multiple areas of involvement or an overall life expectancy of less than 3–4 weeks may be too far progressed to benefit from palliative radiotherapy. Many other patients with SCLC and NSCLC may indeed derive a considerable palliative benefit from short courses of palliative radiotherapy directed to sites of symptomatic disease.

CONCLUSION

Palliative thoracic radiotherapy is an extremely valuable option in the management of patients with both SCLC and NSCLC. There is good evidence for its effectiveness in controlling most symptoms and for its relative lack of toxicity and it can be used safely in patients who are frail and unwell. Many patients can be treated safely with one or two large fractions and do not need to travel daily to the hospital for treatment.[100] For some patients with a good performance status, an option that may give more durable symptom control and the possibility of a modest survival benefit at the expense of more esophagitis is a higher dose regimen, such as 36 Gy to 39 Gy in 12 or 13 fractions.

Although there has in the past been well-conducted research into the most effective dose regimens of palliative radiotherapy, there has been little if any research into the most effective way of integrating palliative radiotherapy with systemic treatments to ensure that patients whose disease is almost certainly incurable get the most durable and least toxic symptom control. For instance, if a patient has metastatic disease and symptomatic intrathoracic disease, what sequence of treatments is most effective? Or, if a patient has major intrathoracic disease, does palliative radiotherapy given before or immediately after systemic treatment improve the degree and duration of the palliation of thoracic symptoms?

Ideally, the care of patients with advanced symptomatic lung cancer should be managed by a multidisciplinary team so that all relevant treatments can be used to their best effect. Such teamwork is increasingly common, especially in well-organized oncology centers. However, with the increasing use of a variety of systemic treatments in patients with advanced disease, the value of palliative thoracic radiotherapy may be underestimated and patients denied a useful and relatively nontoxic treatment option.

42 Acute and Late Toxicities of Thoracic Radiotherapy: Pulmonary, Esophagus, and Heart

José Belderbos, Laurie Gaspar, Ayse Nur Demiral, and Lawrence B. Marks

SUMMARY OF KEY POINTS

- The acute and late toxicity of radiotherapy (RT) for lung cancer usually involves the lungs, esophagus, and heart.

Lung

- Post-RT, there are multiple biochemical and molecular events involving type II pneumocytes, surfactant protein transudation into alveolar spaces, with subsequent inflammation with associated capillary obstruction, and then much later tissue fibrosis.
- The risk for clinical lung injury has been associated with various dosimetric factors (e.g., mean lung dose), clinical factors (e.g., preexisting pulmonary comorbidities), and cytokines (e.g., IL-6, IL-8, and TGF-β1).
- Prednisone is typically effective in treating patients with troublesome symptoms of radiation peumonitis.

Esophagus

- Acute esophageal injury is common and is manifest by pain with swallowing, reflecting mucosal injury. Late injury is typically manifest as partial obstruction or fistula.
- Various dosimetric and clinical factors (e.g., concurrent chemotherapy) have been associated with acute and late injury.
- Acute symptoms are treated with dietary changes, proton pump inhibitors, analgesics, local anesthetics, promotility agents, intravenous fluids, and/or nasogastric tube or gastrostomy tube insertion. Late esophageal stenosis or fistulae may require repeated dilatations or stents.

Heart

- Radiation can accelerate atherosclerosis of "large vessels" (often seen only many years/decades post-RT) and/or cause subclinical microvascular injury (within months of RT). Pericardial inflammation and thickening may also occur.
- Additional work is needed to better understand the radiation dose/volume/risk relationships and clinical relevance of heart injury in patients with lung cancer.

The organs most commonly at risk of injury during and shortly after thoracic radiotherapy for lung cancer are the lungs and esophagus. Injury to the heart is usually a late effect and is conditional on the patient living long enough for it to become clinically evident.

PULMONARY TOXICITY

Pathophysiology

Radiation pneumonitis (RP) can be divided into three stages—latent, acute, and late.[1] Following radiation there is a latent phase in which there is no apparent symptomatic or radiologic changes. However, microscopically there is degranulation and loss of type II pneumocytes, loss of surfactant, swelling of the basement membrane, and protein transudation into the alveolar spaces. Due to an influx of macrophages and fibroblasts, there is a release of cytokines such as transforming growth factor-beta (TGF-β), interleukin (IL)-2, fibronectin and growth factors such as IGF-1, platelet-derived growth factor, and tumor necrosis factor-alpha (TNF-α). During the acute phase there can be imaging changes and clinical symptoms. The chest x-ray or computerized tomography (CT) scan may show the typical changes of a diffuse infiltrative process corresponding to the radiation field (Fig. 42.1). The symptoms are classically a nonproductive cough, fatigue, shortness of breath, and/or fever. This acute phase occurs within 6–7 months of the delivery of radiation, with a peak incidence of 2–3 months. Microscopically there is a continued inflammatory response with capillary obstruction and an increase in leukocytes, plasma cells, macrophages, fibroblasts, and collagen fibers. The alveolar septa appear thickened and the alveolar space smaller. In the late phase of RP, the imaging will show dense consolidation and volume loss of lung tissue. Some of the acute symptoms such as fever, cough, and fatigue often resolve although it would not be uncommon to have chronic shortness of breath. Pathologically, there is fibrosis of the endothelium and an increase in the thickness of the alveolar septa with obliteration of many alveolar spaces.

The trachea and bronchi are lined with pseudostratified ciliated columnar epithelial cells and mucus-producing goblet cells. A mild to moderate dry cough is common during the acute phase of lung radiation due to depletion of the mucosa. This cough usually resolves shortly after 60–66 Gy radiation therapy, and severe late complications are relatively unusual. In 88 stage III nonsmall cell lung cancer (NSCLC) patients treated to 66 Gy or higher, Lee et al.[2] observed bronchial stenosis in three patients between 2–7 months, representing 11% of all late complications. Miller et al.[3] reported an actuarial rate of treatment-related bronchial stenosis at 1 and 4 years of 7% and 38%, respectively. Radiation dose was suspected to be a factor, with bronchial stenosis observed in 4% and 25% of patients treated to 74 Gy and 86 Gy, respectively. The correlation of mainstem bronchial stenosis with doses of 73 Gy or more was confirmed in a further study by Kelsey et al.[4] This narrowing of the bronchi occurred as early as 3 months following radiation. The caliber of the trachea on the other hand was unchanged following even high doses of radiation.

Grading of Lung Toxicity

Radiation-induced pulmonary toxicity after radical radiotherapy or chemoradiation is complex to score in lung cancer patients because it is difficult to distinguish from tumor progression and exacerbation of preexisting pulmonary comorbidities. The Common Terminology Criteria for Adverse Events (CTCAE) grading system, in common use worldwide for scoring of toxicity, has been modified over the years (http://www.eortc.be/services/doc/ctc/).

The Radiation Therapy Oncology Group (RTOG) had its own grading system initially but has adopted the CTCAE over the last 10 years. An important difference between the RTOG and CTCAE grading system is that the RTOG differentiates between acute (pneumonitis) and late (fibrosis) toxicity based upon the time interval (90 days) after treatment. The choice of
Fig. 42.1. CT scan before irradiation of a stage III NSCLC tumor in the right lung. The corresponding CT slices at 1, 3, and 6 months after 66 Gy in 24 fractions using IMRT and the dose distribution. At 3 months a lung volume reduction and infiltrative changes are seen corresponding to the delivered dose. At 6 months these changes disappeared. (A) CT scan before irradiation of a stage III NSCLC tumor in the right lung; (B) 1 month posttreatment; (C) 3 months posttreatment; (D) 6 months posttreatment; and (E) the dose distribution showing isodose lines of the radiation treatment plan. *CT*, computed tomography; *IMRT*, intensity-modulated radiation therapy; *NSCLC*, nonsmall cell lung cancer. *(Reprinted with permission from José Belderbos.)*

90 days is somewhat arbitrary as the active inflammatory phase of pneumonitis can persist beyond 90 days. Tables 42.1 and 42.2 summarize the RTOG grading systems as well as the CTCAE version for pneumonitis and pulmonary fibrosis.[4,5] In all these grading systems grade 5 toxicity is death (http://ctep.cancer.gov/protocolDevelopment/electronic_applications/ctc.htm#ctc_40).

Changes in Pulmonary Function Tests

The RTOG grading system was heavily dependent on the prescription of drugs or oxygen, which varies greatly from physician to physician. The CTCAE grading systems did away with that in the later versions, but still require subjective assessment of symptom severity, its effect on activities of daily living, and the indication for oxygen. More objective criteria to measure pulmonary toxicity have been sought such as changes in pulmonary function tests (PFTs).

Miller et al.[6] summarized the changes in PFTs in 13 patients who had been treated definitively with radiation therapy and were thought to have no tumor recurrence for 2 years or longer. These patients had been followed prospectively with PFTs approximately every 6 months. PFTs included spirometry with forced expiratory volume in 1 second (FEV_1) and forced vital

TABLE 42.1 Pneumonitis Grading Criteria

	Grade 1	Grade 2	Grade 3	Grade 4
RTOG	Mild symptoms of dry cough or dyspnea on exertion.	Persistent cough requiring narcotic or antitussive agents. Dyspnea with minimal effort but not at rest.	Severe cough, unresponsive to narcotic antitussive agent or dyspnea at rest. Clinical or radiologic evidence of acute pneumonitis. Intermittent oxygen or steroids may be required.	Severe respiratory insufficiency. Continuous oxygen or assisted ventilation.
CTCAE v4.0 2009	Asymptomatic; clinical or diagnostic observations only; intervention not indicated.	Symptomatic; medical intervention indicated; limiting instrumental activities of daily living.	Severe symptoms; limiting self-care ADL; oxygen indicated.	Life-threatening respiratory compromise; urgent intervention indicated (e.g., tracheotomy or intubation).

CTCAE, Common terminology criteria for adverse events; *RTOG,* Radiation Therapy Oncology Group.

TABLE 42.2 Pulmonary Fibrosis

	Grade 1	Grade 2	Grade 3	Grade 4
CTCAE v4.0 2009	Mild hypoxemia; radiologic pulmonary fibrosis <25% of lung volume.	Moderate hypoxemia; evidence of pulmonary hypertension; radiographic pulmonary fibrosis 25–50%.	Severe hypoxemia; evidence of right-sided heart failure; radiographic pulmonary fibrosis >50–75%.	Life-threatening consequences (e.g., hemodynamic/pulmonary complications); intubation with ventilatory support indicated; radiographic pulmonary fibrosis >75% with severe honeycombing.

CTCAE, Common terminology criteria for adverse events.

capacity (FVC), diffusing capacity for carbon monoxide (DLCO), and lung volumes. There was a decline in the 6-month median FEV_1, FVC, and DLCO that reverted to baseline by 1 year. This improvement at 1 year following radiation therapy was attributed to tumor response. However, there was then a yearly reduction in the median FEV_1, FVC, and the DLCO of 7%, 9.5%, and 3.5%, respectively. The changes in FEV1 and FVC were significant. Ten of these 13 patients developed some new respiratory symptoms that developed at 6 weeks to 21 months following treatment, with a median of 6 months. The authors attributed this progressive decline in PFTs to progressive/evolving radiation-induced lung injury, possibly due to the continuous cycle of tissue hypoxia resulting in an influx of proinflammatory cells that release cytokines that perpetuate the process.[7]

Observations such as this of progressive decline in lung function have resulted in a reluctance of some clinicians to prescribe high-dose radiotherapy to patients with poor pulmonary reserve. However, there is evidence that the extent of decline is linked to pretreatment function such that patients with poor PFTs pretreatment are at less risk of symptomatic lung toxicity or reduction in FVC or FEV_1 compared with patients with good spirometry.[8,9] These somewhat paradoxic observations suggest that poor PFTs should not by themselves be a contraindication to high-dose radiotherapy.

One prospective study of 185 patients given PFTs before and after thoracic RT found that the median maximal percentage reductions in FEV_1, uncorrected DLCO (not corrected for hemoglobin levels), and DLCO were 11.5%, 14.9%, and 15.3%, respectively.[10] Reductions in corrected and uncorrected DLCO were larger than that observed for FEV1. Reductions in uncorrected DLCO were associated with the mean lung dose (MLD) and percentage of perfused lung (measured by SPECT) receiving 30 Gy or more (V30). However, the changes in the SPECT scans were relatively smaller than the observed changes in PFTs in many patients. In a later analysis in an expanded group of patients, the correlation between the predicted drop in DLCO and subsequent pneumonitis was not considered high enough to be very clinically useful.[11]

Others have found a significant correlation between preradiation and postradiation therapy DLCO and pulmonary toxicity. In one large institutional retrospective study 85% of patients with NSCLC had a postradiation reduction of DLCO.[12] The mean reduction in pretreatment and posttreatment DLCO was 20%. The proportional drop in DLCO differentiated between patients who developed RP grade 1 versus grade II (common toxicity criteria [CTC] v3). This reduction in DLCO correlated with RP grade ≤1 versus ≥2 in patients who were age 65 years or more, had advanced stage (III–IV vs. I–II), were smokers, received chemotherapy, had V20 Gy ≥ 30% (the percentage of normal lung receiving 20 Gy or more), and had baseline DLCO or FEV_1 equal to or more than 60% of predicted. Patients who had higher proportional reductions in DLCO had significant higher rates of severe RP. However, the reductions in DLCO still varied widely between the grades of RP, making it less useful to use in routine clinical practice.

RADIATION PNEUMONITIS

RP typically presents between 1 to 7 months after treatment of external-beam radiotherapy. Clinical symptoms range from shortness of breath, unproductive cough, and occasionally mild fever to death from respiratory failure. RP is diagnosed in approximately 30% of the patients irradiated with radical intent.[13] In patients with respiratory comorbidity such as chronic obstructive pulmonary disease it is often difficult to distinguish whether an acute episode of cough and dyspnea is related to RP or an (postobstructive) infection, disease progression, or preexisting lung disease. RP has a considerable impact on the patient morbidity (quality of life) and less on mortality.

Cooperative group studies of concurrent chemoradiation therapy in stage III NSCLC using 2-dimensional (2-D) or 3-D CT planning have demonstrated grade 3 or higher RP rates in the range of 8% to 18% (Table 42.3).[14–18] The lack of clarity as to how toxicity was calculated or graded makes it difficult to compare rates of RP from study to study. The RTOG designed its dose escalation studies with an upper limit of 15% grade 3 or higher toxicity, most of which were pulmonary.[19,20] Other studies have accepted higher rates of toxicity.[2] In a large institutional experience in patients with stage III disease treated with concurrent chemoradiation with 3-D planning technique, where the incidence of pneumonitis was calculated on an actuarial basis, the risk of symptomatic pneumonitis was more than 30%.[21]

TABLE 42.3 Cooperative Studies Stage III NSCLC Concurrent Chemoradiation

Dosimetric Factors

Estimation of the probability of developing RP after treatment with high-dose RT is important for patients with inoperable lung cancer.[22] An important question is could the lung toxicity be predicted from the delivered dose and historical toxicity models? The total dose for an organ-at-risk after conventional fractionated radiotherapy is calculated as the biologic effective dose or normalized total dose in 2 Gy per fraction (NTD2Gy) according to the linear–quadratic model. Studies of the risk of RP relative to the radiation dose received to a certain volume of "normal" lung have used various theoretic models. These studies were only possible with the adoption of CT planning. In two of these models the dose–volume histogram is first reduced to a single parameter, which is subsequently related to the incidence of radiation pneumonitis. Single parameters are the MLD and the volume of the lung receiving more than a certain threshold dose (Vx). The MLD is defined as the average dose throughout the lungs (minus the gross tumor volume). One of the seminal articles by Graham et al.[23] that studied the risk for 99 lung cancer patients with the incidence of RP found that it was correlated with the percent of normal lung receiving 20 Gy or more (V20). In this analysis Graham subtracted the planning target volume (PTV) from the total bilateral lung volume. The PTV is the volume that contains the gross disease, areas thought to represent microscopic extension with an additional margin to account for daily set-up variation. This method of calculating the V20 was continued in several RTOG radiation dose escalation studies.[19,20] However, RTOG 0617, which is a phase III study comparing 60 Gy with 74 Gy with concurrent carboplatin/paclitaxel, calculated normal irradiated lung as the total lung minus the clinical target volume, i.e., the volume thought to contain only gross tumor and microscopic extension.[24] Wang et al.[24] demonstrated that the differences in the calculated mean lung dose or other dosimetric parameters varied greatly depending on which formula was used to define "normal lung." The choice of which of the various formulas to use can lead to significant variation in the prediction of subsequent pulmonary toxicity. The most conservative approach is to subtract only the gross tumor volume (or the internal target volume if using 4-D CT simulation technique). Multiple authors have recommended this approach since the choice of the clinical target volume or PTV margin is more variable from physician to physician.[24,25]

Marks et al.[25] reviewed over 70 articles that correlated dose–volume parameters with subsequent RP following conventionally fractionated radiation therapy of NSCLC. This review, part of the Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) initiative, cautioned that there was no MLD below which there was no risk of RP. There is also the issue of overestimating RP in these patients due to exacerbation of preexisting pulmonary comorbidities, or tumor progression producing similar complaints. The correlation of MLD and the risk of RP was not linear but had a mildly exponential increase that was more pronounced with increasing MLD. The risk of symptomatic RP with MLD of 20 Gy and 30 Gy was approximately 20% and 40%, respectively. A significant variation in the risk of RP with increasing normal lung volumes, i.e., V20, V30, etc., was reported within the 14 studies summarized by QUANTEC. For example, for V20 of 30% the reported symptomatic RP varied from less than 10% to approximately 50%. There was less variation among the 10 studies that correlated MLD and subsequent symptomatic RP.

In addition to looking at the radiation dose to the total normal lung, there may also be an association between the ipsilateral normal lung dose and the risk of RP. Ramella et al.[26] found that if the V20, V30, and MLD of the total lung volume did not exceed 31%, 18%, and 20 Gy, respectively, there was additional predictive value to the ipsilateral (affected) lung constraints. For example, if the ipsilateral V20 was 52% or less, the risk of RP was 9%, whereas if it was greater than 52%, the risk of RP was 46%. These dosimetric values were calculated by subtracting the PTV from the ipsilateral affected lung.

The use of intensity modulated radiation therapy (IMRT) has been reported to be associated with less pneumonitis compared with 3-D conformal radiotherapy, but it is difficult to understand why if normal lung parameters such as MLD or V20 are similar.[27] IMRT plans are characterized by a more conformal dose distribution and steeper dose fall off and result in a decrease of the V20 and MLD,[28] although the volume of lung receiving a low dose (V5) will be higher. It has been recommended that contralateral lung V5 be kept below 60% to reduce the risk of potentially fatal pneumonitis.[29]

RTOG 0617, a phase III study comparing 60 Gy versus 74 Gy for locally advanced NSCLC, stratified patients according to 3-D CT or IMRT treatment planning. Preliminary results of this study indicate that quality of life was superior in patients treated with IMRT.[30] There is unlikely to be a phase III study directly comparing 3-D CT and IMRT treatment planning. A population-based study of comparative effectiveness found similar rates of early and late pulmonary toxicity for both techniques.[31]

Fewer studies have been done to predict the risk of RP following treatment of limited SCLC. However, there is likely a similar correlation between the dosimetric factors and subsequent RP. For example, Tsujino et al.[32] looked at the risk of RP in patients with limited small cell lung cancer (SCLC) who were treated with cisplatin-based chemotherapy and concurrent thoracic radiation of 45 Gy given two fractions daily, over 15 treatment days. The 12-month cumulative incidence of symptomatic RP was 0%, 7.1%, 25%, and 42.9% in patients with a V20 of <20%, 21% to 25%, 26% to 30%, and >31%, respectively.

Clinical Factors

The impact of nondosimetric factors in predicting the risk of RP has been an area of intense study. Appelt et al.[33] analyzed the patient data used to make the QUANTEC recommendations to look for
Fig. 42.2. Nomogram to predict incidence of radiation pneumonitis. *(Reprinted with permission from Bradley JD, Hope A, El Naqa I, et al. A nomogram to predict radiation pneumonitis, derived from a combined analysis of RTOG 9311 and institutional data.* Int J Radiat Oncol Biol Phys. *2007;69(4):985–992.)*

clinical risk factors.[25] Factors found to significantly increase the risk of RP were preexisting pulmonary comorbidity, mid or inferior tumor location, current smoking, age older than 63 years, and sequential (as opposed to concurrent) chemotherapy.

Other studies have found that sequential or concurrent chemotherapy involving cisplatin/etoposide does not appear to increase the risk of RP.[17,34,35] RTOG 8808/ECOG 4588 was a three-arm phase III study comparing radiation only, 60 Gy in 2 Gy daily fractions (considered "standard"), or 69.6 Gy in 1.2 Gy fractions twice daily, or sequential cisplatin/vinblastine chemotherapy and standard radiation therapy.[35] The 18-month cumulative incidence of toxicity, primarily pulmonary, was almost 30% in the combined modality arm, as compared with 20% to 25% incidence in the radiation therapy–only arms. The statistical significance between the pulmonary toxicity in the various arms is not stated although the authors said the toxicity was acceptable. Most of the toxicity occurred within the first 3 to 6 months in all treatment arms, with a relative flattening of the incidence after 9 months.

Given the difference from study to study in the nondosimetric variables predicting the risk of pneumonitis, meta-analyses have been done. Vogelius et al.[36] reviewed the English language lung cancer literature between 1990–2010 in which RP was correlated with some patient or treatment variables. In the 31 studies analyzed, the statistically significant risk factors for increased RP were older age, mid-lower lung disease location, and presence of pulmonary comorbidity. The use of sequential rather than concurrent chemotherapy was found to increase the risk of RP

but the authors suspected this was likely due to patient selection rather than a "real" predictive factor. Interestingly, smoking at the time of treatment was found to protect against RP. Even a prior history of smoking was associated with a decreased risk of RP, although this did not reach statistical significance.

Patients with collagen vascular diseases (CVD) are likely at increased risk of RP. In an excellent review by Lee et al.[37] it appears that cytokines such as TGF-β are chronically elevated in such patients. There is often preexisting lung fibrosis. Radiation therapy may cause a patient with quiescent CVD to develop active CVD. These patients are also noted to have increased late toxicity as compared with patients without CVD. Lung fibrosis may extend outside of the high-dose region, so treatment volumes should be reduced when possible, although there is no reason to omit radiation therapy if it is indicated. Interestingly, tumors developing in patients with CVD may be more radiosensitive, prompting consideration of a radiation dose reduction of at least 10%.

Combined Dosimetric and Clinical Factors

Dosimetric and nondosimetric factors can be combined to increase the ability to predict RP. Bradley et al.[38] proposed a nomogram to predict RP based on mean lung dose and the tumor location, superior to inferior (Fig. 42.2).

Taking it one step further, Palma et al.[13] performed a meta-analysis of both dosimetric and nondosimetric factors based on individual patient data. The authors did a search of articles

published between 1993 and 2010, in which clinical and dosimetric factors of patients treated with concurrent chemoradiation therapy were available to be correlated with RP. These data were then utilized to conduct a recursive partitioning analysis (RPA) from a 557-patient dataset, and then the RPA was validated using another 279-patient dataset. Factors predicting greater risk of pneumonitis were carboplatin/paclitaxel chemotherapy (vs. cisplatin/etoposide), age greater than 65 years, V20, and MLD (Fig. 42.3).

Biomarkers

Inflammatory cytokines are made by many cells within the lung, including the alveolar macrophages, type II pneumocytes, T lymphocytes, and lung fibroblasts. The blood levels of these cytokines pre-RT, during, and post-RT have been an area of intense interest. For example, Chen et al.[39] found that circulating IL-6 levels pre-RT, during, and post-RT have been correlated with an increased risk of RP. In that study, TNF, another inflammatory cytokine, was not associated with an increased risk of RP.

TGF-β1 is a cytokine that has been extensively studied as a marker predictive of RP.[40,41] It was noted that patients with NSCLC have increased pretreatment levels of TGF-β1 and that increased levels were associated with a higher MLD and a higher incidence of RP. Several studies showed that the absolute levels of TGF-β1 were not as predictive of RP as the observation of an increasing ratio of pretreatment to intratreatment TGF-β1 for stage III NSCLC treated with definitive radiation, with or without chemotherapy.[42] The predictive value of the TGF-β1 ratio was even higher when combined with the MLD. The combination of a MLD of more than 20 Gy and a TGF-β1 ratio of more than 1 was associated with a 66% incidence of RP. Similarly, IL-8 levels pretreatment and then at weeks 2 and 4 of radiation therapy

were associated with RP.[43] Patients with RP grade 2 or higher tended to have higher baseline IL-8 levels and these had a slight downward trend during radiation therapy, as opposed to low and stable IL-8 levels in patients without RP. Combining IL-8, TGF-β1, and MLD into a single model led to an improved ability to predict RP as compared with either variable alone.

Certain polymorphisms of the VEGF gene have been correlated with the incidence and severity of RP.[44]

Recall Radiation Pneumonitis

Recall RP is when symptoms of RP are activated by administration of a drug sometime after completion of radiotherapy, with worse than expected RP. Recall RP has been associated with multiple chemotherapy drugs such as taxanes, gemcitabine, vinca alkaloids, doxorubicin, and epirubicin.[45–48] Tyrosine kinase inhibitors such as erlotinib and sunitinib have also been associated with radiation recall pneumonitis and increased risk of severe RP following palliative or definitive radiation therapy.[45,47,49,50]

Prevention and Management
Amifostine

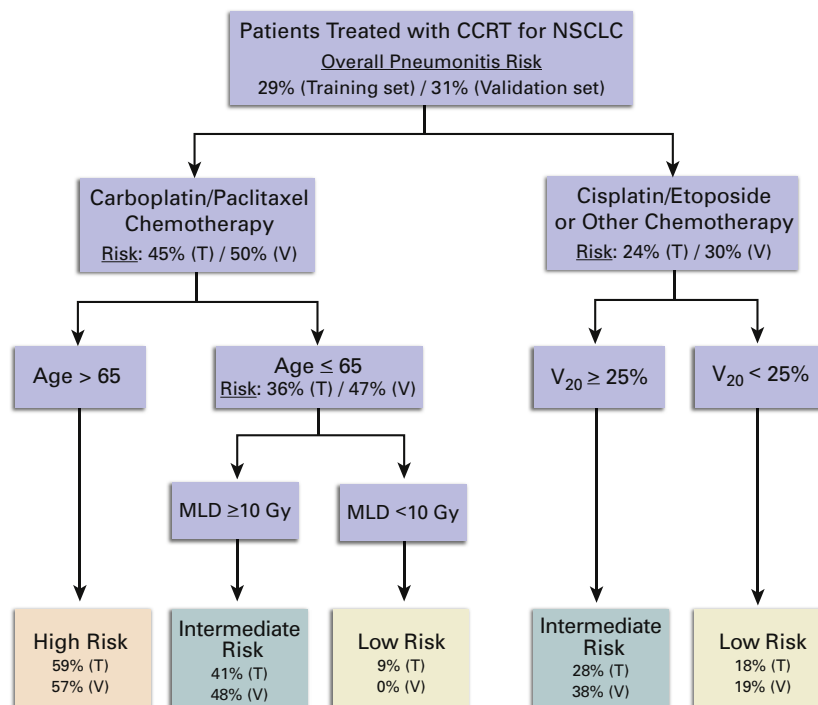
Amifostine, a thiol derivative, is a scavenger of free radicals generated during radiation therapy.[51] Other possible mechanisms of action include increasing the consumption of oxygen within the cells and condensation of DNA, making the strands more resistant to free radicals.[52] A small phase III study in stage III NSCLC patients given radiation and concurrent chemoradiation therapy (paclitaxel or carboplatin) found a significant decrease in the rate of symptomatic RP.[53] The rate of grade 3 or higher (RTOG grading system) in the amifostine versus nonamifostine arms was


Fig. 42.3. Recursive partitioning analysis of radiation pneumonitis risk in patients undergoing concurrent chemoradiation therapy (CCRT) for nonsmall cell lung cancer (NSCLC). Patients were randomly divided into a training set (T) and validation set (V). *MLD*, mean lung dose; *V20*, volume of lung receiving equal to or greater than 20 Gy. *(Reprinted with permission from Palma DA, Senan S, Tsujino K, et al. Predicting radiation pneumonitis after chemoradiotherapy for lung cancer: an international individual patient data meta-analysis.* Int J Radiat Oncol Biol Phys. *2013;85(2):444–450).*

56.3% and 19.4%, respectively ($p = .002$). However, a larger phase III study, RTOG 9801, investigated the ability of amifostine to reduce chemoradiation-induced esophagitis.[54] Amifostine did not reduce treatment-related esophagitis in that study when it was given daily with carboplatin/paclitaxel and concurrent thoracic radiation for stage III NSCLC. A subsequent report indicated that amifostine also did not reduce either median survival or late toxicities, including RP.[55]

Pentoxifylline and Vitamin E

The combination of pentoxifylline and vitamin E has been shown to decrease radiation-related soft-tissue fibrosis of the breast and extremities.[56–58] Pentoxifylline is a methylxanthine derivative developed and prescribed for impaired microcirculation. It improves blood perfusion by erythrocyte deformability and decreased blood viscosity. Pentoxifylline appears to decrease fibroblast, cellular matrix, and collagen production by blocking the activity of TNF, decreasing IL and oxygen radicals, and stimulating collagenase activity.[59] Vitamin E, a tocopherol, acts as an antioxidant and protects membrane phospholipids from oxidative damage by scavenging reactive oxygen species generated during oxidative stress. Vitamin E also inhibits TGF and collagen production.[59,60]

A small randomized study of pentoxifylline 400 mg versus placebo three times a day during radiation therapy for either lung or breast cancer demonstrated superiority in the pentoxifylline arm in the posttreatment patient-reported breathing function, DLCO, and imaging studies.[61] Larger studies should be done to validate this finding.

Steroids

Surprisingly, there has been little clinical research into the use of prophylactic steroids to reduce the incidence and severity of RP. A rodent study found that small doses of steroids three times a week for 15 weeks starting 10 to 11 weeks from delivery of thoracic radiation significantly delayed the onset of and death due to RP.[62] A prospective study in humans would be clinically relevant.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors have been studied in both animals and humans. The mechanism of its protective effect is not clear but may have something to do with the reduction in pulmonary arterial pressure, resulting in less severe edema.[63] Rodent studies established the rationale for angiotensin-converting enzyme inhibitors, such as captopril, in the reduction of acute pneumonitis following radiation therapy.[64] This effect was most notable at moderate doses of radiation therapy. Following very high doses of hemithoracic radiation, i.e., 80 Gy in 10 fractions, captopril had no significant protective effect. Retrospective studies also confirmed the apparent protective effect of ACE inhibitors on pulmonary toxicity following concurrent chemoradiation for stage III NSCLC.[65] A phase II cooperative group study (RTOG 0213) was initiated to test this hypothesis but closed due to poor accrual. The study was designed to test the ability of captopril to alter the incidence of pulmonary damage at 12 months from completion of radiation treatment in SCLC or NSCLC patients receiving at least 45 Gy.

TGF-β Tyrosine Kinase Inhibitors

There are no human clinical studies of inhibitors of TGF-β to reduce RP, but preclinical studies suggest potential utility. Flechsig et al.[66] found that a 4-week course of a tyrosine kinase inhibitor to TGF-β improved the survival of rodents following whole thoracic radiation.

Treatment of Radiation Pneumonitis

There are no prospective studies evaluating the effectiveness of treatment of RP. Most cases are self-limiting. Patients with troublesome symptoms from presumed RP are usually started on prednisone 50–60 mg per day for 1–2 weeks and then decreased slowly by 10 mg per week, assuming the symptoms are improved or stable.[19,30] Oxygen may be needed and a referral to a pulmonologist should be considered if the symptoms are severe or do not improve as anticipated.

ESOPHAGUS TOXICITY

Pathophysiology

Radiation-induced esophagitis is an inflammation of the esophagus, which develops 2 to 3 weeks after the initiation of radiation therapy. Radiation affects the part of the esophagus within the irradiated area. The normal esophageal mucosa undergoes continuous cell turnover and renewal. These mucosal cells are sensitive to irradiation-induced damage. Acute radiation esophagitis is primarily due to effects on the basal epithelial layer. This causes a thinning of the mucosa, which can progress to denudation.

In 1960, the onset of radiation effects in the esophagus was first studied in rats and displayed timelines and clinical findings.[67] Four days after radiation a submucosal infiltration of leucocytes was seen, mucosal necrosis was seen at 7 days, and a moderate inflammation of the muscularis of the esophagus and some submucosal telangiectasia was seen 10 days after radiation. By 20 days most of the rats showed reepithelization of the esophagus. However, in animals killed more than 3 months after exposure, defects in the muscle walls and atrophy of the epithelium were seen.[67]

Grading of Esophagus Toxicity

Esophagus toxicity is scored using the CTCAE (version 4.0). Grade 2 is scored in case of symptomatic dysphagia and altered eating and intravenous fluids may be indicated for a period shorter than 24 hours. Grade 3 esophagus toxicity is scored in case of symptomatic and severely altered eating/swallowing and the use of intravenous fluids, tube feedings, or total parenteral nutrition equal to or more than 24 hours. Grade 4 esophagus toxicity includes life-threatening consequences for the patients, and grade 5 is scored in case of death. The CTC scoring system, however, does not differentiate between early and late symptoms. The RTOG/EORTC scoring system differentiates between acute esophagus toxicity (AET), symptoms within 3 months after concurrent chemoradiation therapy, and late esophagus toxicity (LET), symptoms persisting or occurring more than 3 months after the end of treatment (Table 42.4). AET influences the quality of life of the patient and may result in treatment interruption, but generally resolves after treatment. Patients who develop esophagus stenosis, perforation, or fistula are categorized as severe LET (grade 3–5). Severe LET seriously affects the patients' quality of life or even leads to death. Although several models are available to predict the incidence and severity of AET, for LET

TABLE 42.4 Late Esophagus Toxicity Scoring From 3 Months After Treatment According to TOG/EORTC

Grade 0–1	Mild fibrosis; slight difficulty in swallowing solids; no pain on swallowing.
Grade 2	Unable to take solid food normally; swallowing semisolid food; dilatation may be indicated.
Grade 3	Severe fibrosis; able to swallow only liquids; may have pain on swallowing; dilatation required.
Grade 4	Necrosis/perforation fistula.
Grade 5	Death.

predictive models are sparse. So far, several studies have reported the incidence of severe LET using 3-D–conformal-radiotherapy (3DCRT) and IMRT (Table 42.5).[17,68–76] Using 3DCRT, the reported crude incidence of severe LET in concurrent RCT varies from 5% to 16%. Without solid evidence, several implications can be drawn from previous studies: severe AET is associated with severe LET.

Radiation Esophagitis

The improved survival of patients with locally advanced NSCLC who are treated with concurrent radiochemotherapy comes at a price of increased esophagus toxicity.[75,77–80] Due to overlap with the target volume because of involvement of mediastinal lymph nodes or mediastinal tumor invasion a part of the esophagus is often irradiated in lung cancer. Acute toxicity is manifested clinically as dysphagia, odynophagia, and substernal discomfort and usually occurs within 2 to 3 weeks after the initiation of radiation therapy. Patients may describe a sudden, sharp, severe chest pain radiating to the back. Patients with insufficient intake due to radiation esophagitis are at risk for premature discontinuation of therapy. Predicting the risk of esophagus toxicity makes it possible to take appropriate precautions, such as preventive medication or tube feeding. Identifying the low-risk patients for radiation esophagitis gives the opportunity to escalate the dose of radiotherapy to improve tumor control.

Dosimetric Factors

Estimation of the probability and severity of esophagus toxicity after concurrent chemoradiation treatment is crucial. This allows the individual prescription of tumor doses based on normal tissue complication probabilities. Several prediction models have been reported to estimate the risk of AET based on the planned dose distributions. Currently used models to predict AET in

lung cancer patients after intensity IMRT and concurrent chemotherapy were mainly derived from patients treated with 3-D chemoradiation.

When using IMRT and concurrent chemoradiation in patients with NSCLC, reported were a dose–effect relationship of AET in 185 patients,[81] severe LET in 171 patients,[68] and dose–volume parameters of the esophagus. Severe LET was defined as grade equal to or greater than 3 RTOG/EORTC (Table 42.6).[17,82–92] In these Dutch studies,[81,68] hypofractionated IMRT treatment up to 66 Gy in 24 fractions and concurrent daily low-dose cisplatin (6 mg/m^2 with a maximum of 12 mg) was administered in consecutive patients. Cisplatin was administered as a bolus injection 1 hour to 2 hours before each fraction. The dose distributions were first converted to normalized total doses to account for fractionation effects with an α/β-ratio of 10 Gy for AET and α/β-ratio of 3 Gy for LET. Equivalent uniform dose (EUD) to the esophagus and the volume percentage receiving more than x Gy (Vx) were evaluated by the Lyman-Kutcher-Burman model. A total of 22% patients with NSCLC developed AET toxicity greater than or equal to grade 3, and 6% severe LET was observed. The median time to AET grade 3 was 30 days, with a median duration of >80 days. The median onset time of severe LET was 5 months (range 3~12). All 11 patients expressed LET within 1 year. Eight patients developed esophagus stenosis (grade 3), which could be treated by dilatation. A fistula was diagnosed in three patients, and these patients were treated with intraluminal stent. All three patients with fistulae died from respiratory insufficiency caused by pneumonia shortly after the stent was placed (up to 3 months). Pathologically proven tumor progression was the cause of esophageal fistulae in three other patients (28, 31, and 31 months) and not scored as LET. Severe LET occurred in 7% of the patients (4 of 61) with grade 2 AET and 19% of the patients (7 of 37) with grade 3 AET. Severe LET was significantly ($p = 0.002$) associated with the maximum grade of AET. Patients with unrecovered AET had a significantly ($p < 0.001$) higher risk of developing

TABLE 42.5 Crude Incidence of Reported Severe LET in Patients With NSCLC Treated With Sequential and Concurrent Radiochemotherapy Regimens[7]

severe LET, compared with patients without AET or with a recovered AET. In the EUD, $n = 0.03$ model, all severe LET patients had a NTD greater than 70 Gy on the esophagus. In the EUDn-LKB model, the fitted values and 95% confidence intervals (CIs) were TD50 = 76.1 Gy (73.2~78.6), $m = 0.03$ (0.02~0.06) and $n = 0.03$ (0~0.08). In the Vx-LKB model, the fitted values and 95% CIs were Tx50 = 23.5% (16.4~46.6), $m = 0.44$ (0.32~0.60) and $x = 76.7$ Gy (74.7~77.5).

The V50 was identified as the most accurate predictor of grade ≥3 AET.[81] Werner-Wasik et al.[80] described in their review on esophagus toxicity that a higher dose, even on a small part of the esophagus, might be a risk factor for AET. They described several dosimetric parameters to be predictive in univariate analysis for grade 2 and grade 3 AET: V20 through V80. But most at risk for AET were esophagus volume doses receiving greater than 40 Gy to 50 Gy. The systematic review by Rose et al.[79] demonstrated that the Dmean, V20, V30, V40, V45, and V50 were the best-studied dosimetric predictors with high levels of association with AET. The dosimetric predictors of AET in Rose and colleagues' review are consistent with the predictor advocated by Kwint et al.,[81] namely, the V50.

A large multiinstitutional study on 1082 patients treated with 3DCRT, or IMRT concurrent with chemotherapy, analyzed acute radiation esophagitis.[93] The median radiotherapy dose was 65 Gy, and median follow-up was 2.2 years. Most patients (92%) received platinum-containing concurrent chemoradiation therapy regimens. The development of radiation esophagitis was common, scored as grade 2 in 348 patients (32.2%), grade 3 in 185 patients (17.1%), and grade 4 in 10 patients (0.9%). The high-dose volumes were the most important predictors for radiation esophagitis.[93] The V60 emerged as the best predictor for both moderate and severe AET. A low-risk subgroup was identified with a very low V60 of less than 0.07%, an intermediate-risk subgroup with a V60 of 0.07% to 16.99%, and a high-risk subgroup with a V60 of equal to or greater than 17% (Fig. 42.4).

Clinical Factors

In the meta-analysis of Auperin et al.,[94] which demonstrated the superiority of concurrent over sequential chemoradiation for NSCLC, the incidence of grade 3 or grade 4 esophagitis increased from 4% in the sequential group to 18% in patients randomized to concomitant chemotherapy. The type of chemotherapy may be important, as a strong association was found between maximum grade of neutropenia and severity of dysphagia by de Ruysscher et al.[95]

A systematic review of the literature was published comparing acute and late toxicities and to determine which concurrent

chemoradiation scheme should preferably be offered to patients with locally advanced nonmetastatic NSCLC.[82] In all 17 selected papers (phase II and phase III trials published between 1992 and 2010) on concurrent concurrent chemoradiation, acute toxicity consisting of esophagitis equal to or greater than grade 3 was reported. AET incidence varied from 1% up to 18% of the patients. In three studies the incidences of AET grades ≥3 were similar: 17% and 18% (Table 42.6). In most studies late toxicity was not reported, however. In the low-dose cisplatin studies, LET grade 3 to grade 4 was reported in 5% of the patients. The conclusion of Koning's systematic review was that concurrent RCT with monochemotherapy consisting of daily cisplatin resulted in favorable acute and late toxicity compared with concurrent chemoradiation with single high-dose chemotherapy, doublets or triplets.[82]

Modified fractionation is also associated with a greater risk of esophagitis as demonstrated in the meta-analysis by Mauguen et al.[96] The risk of grade 3 or 4 esophagitis was 9% for conventional treatment and 19% with modified fractionation, with very accelerated fractionation being the most toxic.

Combined Dosimetric and Clinical Factors

Several groups analyzed the relation of clinical parameters and radiation esophagitis. No evidence, however, for increased acute toxicity in older patients treated with concurrent chemoradiation using IMRT or in patients with severe comorbidity was found in the analysis by Uyterlinde et al.[97] In a total of 35% of the patients acute toxicity grade greater than or equal to 3 was reported. Grade 5 toxicity was scored in 1% of the patients. Similar toxicity was observed between older patients (equal to or greater than 70 years) and younger patients (less than 70 years, $p = 0.26$). No significant association was found among prior weight loss, high Charlson Comorbidity Index of ≥5, and acute severe toxicity ($p = 0.36$). V50 esophagus (odds ratio [OR], 1.33 per 10% increase; $p = 0.01$) and patients with PS ≥2 (OR, 3.45; $p = 0.07$) were at risk to develop acute toxicity grade 3.

Esophageal FDG uptake using 18FDG-PET postconcurrent chemoradiation was investigated and correlated with AET grade.[98] A total of 82 patients treated with 66 Gy in 24 fractions were selected on the presence of a post-RT positron emission tomography (PET) scan acquired within 3 months after concurrent RCT. The value of PET(post) in relation to AET was evaluated by comparing the mean esophageal standard uptake value of the highest 50% between grade less than 2 and grade greater than or equal to 2 AET. The local dose on the esophagus wall was correlated to the standard uptake value and modeled using a power-law fit. The Lyman-Kutcher-Burman model was used to predict grade ≥2AET. The local dose–response relation was used in the Lyman-Kutcher-Burman model to calculate the EUD. Resulting prediction accuracy was compared to D(mean), V(35), V(55), and V(60). The LKB parameters (95% CI) were $n = 0.130$ (0.120 to 0.141), $m = 0.25$ (0.13 to 0.85), and TD(50) = 50.4 Gy (37.5–55.4), which resulted in improved predictability of AET compared with other predictors.[98]

Prevention and Management

Elective nodal irradiation has been associated with increased esophageal dose, resulting in a two-fold increase in the esophageal V50 compared with treatment plans treating involved lymph nodes only.[99] Due to the steep dose fall-off of IMRT compared with 3DCRT and the ability to shape the dose around organs at risk, it is possible to reduce the volume of the esophagus irradiated, so a lower incidence of AET is expected. One planning study in node-positive patients achieved a decrease in esophageal V50 from 26% to 28% with 3DCRT to 19% using IMRT while maintaining the same tumor control probability.[99] In order to investigate the differences between AET and the use of 3DCRT or IMRT, the AET incidences for patients treated with the same concurrent RCT regimen were compared.[81] The AET incidences were not significantly different between 3DCRT-based and IMRT-based concurrent RCT patients. In order to illustrate the differences between 3DCRT and IMRT, the Vx (α/β-ratio = 10) in steps of 5 Gy derived for 36 patients treated with concurrent RCT (EORTC 08972-22973 trial) and the AET study by Kwint et al.[81] are depicted in Fig. 42.5. From this figure it can be appreciated that with IMRT the volume of esophagus receiving a dose from 5 Gy to 40 Gy was significantly smaller, while at 70 Gy it was increased. Moreover, the LKB model based on the V50 was not significantly different between IMRT and 3DCRT. In clinical practice, high-dose volumes to the esophagus (V50 to V60) and the use of concurrent chemotherapy are the most important predictors for AET and LET.[13,68,81] The NTD-corrected esophagus EUD less than 70 Gy could be a dose constraint to minimize
Fig. 42.5. Average esophageal dose–volume histogram for the historical NSCLC patients planned with concurrent chemotherapy and 3DCRT, and the IMRT dataset. severe LET.[99] Another way to prevent esophagus toxicity was reported by Uyterlinde et al.:[97] daily prehydration was associated with a reduced rate of both renal and acute esophageal toxicity and an increased chemotherapy adherence in patients receiving a daily dose of cisplatin and concurrent radiotherapy for locally advanced NSCLC.

Management

Acute esophagitis is treated with dietary changes, proton pump inhibitors, analgesics (including opiates), local anesthetics (lignocaine viscous), promotility agents, intravenous fluids, and/or nasogastric tube or gastrostomy tube insertion. Dietary changes are focused on keeping the patient comfortable and maintaining nutrition, body weight, and fluid intake. High-calorie food and liquids are good choices. Softening the patient's diet, avoiding extremely hot or cold foods, and refraining from alcohol and spicy food are important in alleviating the discomfort of esophagitis. Patients with complaints of esophagus stenosis are generally treated by (repeated) dilatation procedures. Some patients will develop a perforation or fistula, which can be treated with intraluminal stenting.

HEART

Much of what is known about radiation injury to the heart, especially effects on mortality, has been derived from studies in patients with breast cancer, in whom the heart is irradiated incidentally, and the majority of whom are long-term survivors after treatment.

Pathophysiology

Evidence from rodent models suggests that radiation can cause both microvascular and macrovascular cardiac pathology.[100] The microvascular pathology is characterized by a decrease in capillary density, causing chronic myocardial ischemia and fibrosis. Macrovascular disease occurs through an accelerated development of age-related atherosclerosis.[100]

Based on these experimental findings, Darby et al.[100] suggested two hypotheses for the biologic mechanisms that lead to increased morbidity and mortality from coronary artery disease after radiation exposure in humans. The first hypothesis is that radiation increases the frequency of MI by accelerated atherosclerosis of "large vessels." The macrovascular injury is often manifest only many years/decades post-RT. The second hypothesis is that radiation causes microvascular injury that is largely subclinical (this is consistent with the imaging changes observed in clinical studies). If and when the patient experiences some macrovascular injury, the latent subclinical microvascular injury may synergistically increase the risk/clinical severity by reducing the heart's reserve[100] (Fig. 42.6).

Heart Imaging Data From Irradiated Patients

In order to study heart injury in a prospective manner, surrogate markers such as imaging have been used to assess cardiac injury.[101–105] In a large prospective study conducted at Duke University, tangential RT to the left breast/chest wall was found to be associated with reductions in regional perfusion as assessed by SPECT scans.[101] A representative pre-RT and post-RT image from one patient is shown in Fig. 42.7.[101] The perfusion defects were typically seen on the anterior heart, that is, limited to and within the RT field. The frequency of observing new perfusion defects was related to the volume of the left ventricle within the RT beam (Fig. 42.8).

The functional consequence of these perfusion defects is unknown. There were higher rates of wall motion abnormalities in patients with (versus without) perfusion defects in this study, i.e., 12% to 40% versus 0% to 9%, respectively, depending on the post-RT interval ($p = 0.007–0.16$).[101]

Similarly, Gyenes et al.[106] noted myocardial perfusion defects at about 1 year post-RT. Several other authors also reported myocardial perfusion imaging abnormalities post-RT, but the majority of these studies considered patients treated many years post-RT.[107]

Gayed et al.[108] assessed myocardial perfusion imaging results before and after chemoradiotherapy in 16 patients with esophageal cancer and 25 patients with lung cancer.[108] Seven of the 25 (29%) patients with lung cancer developed myocardial ischemia in the radiation field at a mean of 8.4 months after radiotherapy. Considering the combined group, myocardial perfusion imaging result was not a statistically significant predictor of future cardiac complications after chemoradiotherapy. A history of congestive heart failure or arrhythmia was a significant predictor of cardiac morbidity.[108]

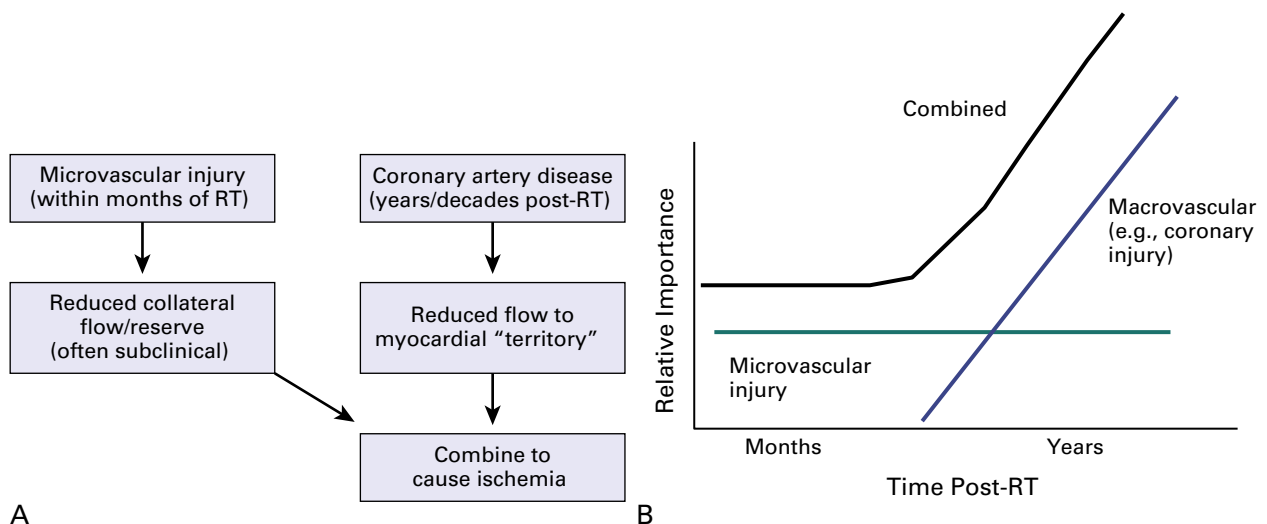
Umezawa et al.[109] evaluated subclinical radiation-induced myocardial changes using scintigraphy with a new agent, iodine-123 β-methyl-iodophenyl pentadecanoic acid (I-123


Fig. 42.6. (A) Interaction of two mechanisms to produce clinical heart disease; and (B) hypothesis of the combined effect of these two mechanisms over time.

BMIPP), in 34 patients who maintained complete response to curative radiation therapy for esophageal cancer. I-123 BMIPP evaluates myocardial fatty acid metabolism. Reduced uptake was detected in 13%, 43%, and 68% of the myocardial segments that received 0 Gy, 40 Gy, and 60 Gy, respectively. These investigators suggested that I-123 BMIPP myocardial scintigraphy may be useful to identify RT-induced myocardial damage.[109]

In conclusion, these imaging data demonstrate that there are acute physiologic changes in the heart post-RT (i.e., within a few years of RT) and that these changes are correlated with dose and might reflect subclinical injury.

Grading of Heart Toxicity

Types of Cardiovascular Toxicity

Radiation-associated heart disease includes a wide spectrum of cardiac diseases, which are listed in Table 42.7. Early effects include pericarditis and pericardial effusion (months to a few years postradiation). Late effects include disease of the coronary arteries, the heart valves, the myocardium, and the conductive system (10 to 15 years after radiation). Both chemotherapy and radiotherapy may cause cardiovascular toxicity. This has been clearly demonstrated in patients irradiated for Hodgkin disease, breast cancer, esophageal cancer, and medulloblastoma.

Scoring of Cardiac Toxicity

Cardiac toxicity is scored using the CTCAE (version 4.0) including all types of adverse events related to pericardium, myocardium, valves, coronary arteries, and cardioelectrical activity. The CTC scoring system, however, does not differentiate between early and late symptoms. The RTOG/EORTC scoring system differentiates between acute and late cardiac toxicity (Table 42.8).

TABLE 42.7 Radiation Effects on the Heart[a]

	Acute	Late
Pericarditis	Acute exudative pericarditis is rare and often occurs during radiotherapy as a reaction to necrosis/inflammation of a tumor located next to the heart. Delayed acute pericarditis occurs within weeks after radiotherapy and can be revealed by either an asymptomatic pericardial effusion or a symptomatic pericarditis. Cardiac tamponade is rare. Spontaneous clearance of this effusion may take up to 2 years.	Delayed chronic pericarditis appears several weeks to years after radiotherapy. In this type, extensive fibrous thickening, adhesions, chronic constriction, and chronic pericardial effusion can be observed. It is observed in up to 20% of patients within 2 years following irradiation. Constrictive pericarditis can be observed in 4–20% of patients and appears to be dose–dependent and related to the presence of pericardial effusion in the delayed acute phase.
Cardiomyopathy	Acute myocarditis related to radiation induced inflammation with transient repolarization abnormalities and mild myocardial dysfunction.	Diffuse myocardial fibrosis (often after a >30-Gy radiation dose) with relevant systolic and diastolic dysfunction, conduction disturbance, and autonomic dysfunction. Restrictive cardiomyopathy represents an advanced stage of myocardial damage due to fibrosis with severe diastolic dysfunction and signs and symptoms of heart failure.
Valve disease	No immediate apparent effects.	Valve apparatus and leaflet thickening, fibrosis, shortening, and calcification predominant on left-sided valves (related to pressure difference between the left and right side of the heart). Valve regurgitation more commonly encountered than stenosis. Stenotic lesions more commonly involving the aortic valve. Reported incidence of clinically significant valve disease: 1% at 10 years; 5% at 15 years; 6% at 20 years after radiation exposure. Valve disease incidence increases significantly after >20 years following irradiation: mild AR up to 45%, > moderate AR up to 15%, AS up to 16%, mild MR up to 48%, mild PR up to 12%.
CAD	No immediate apparent effects. (Perfusion defects can be seen in 47% of patients 6 months after radiotherapy and may be accompanied by wall-motion abnormalities and chest pain. Their long-term prognosis and significance are unknown.)	Accelerated CAD appearing at a young age. Concomitant atherosclerotic risk factors further enhance the development of CAD. Latent until at least 10 years after exposure. (Patients younger than 50 years of age tend to develop CAD in the first decade after treatment, while older patients have longer latency periods.) Coronary ostia and proximal segments are typically involved. CAD doubles the risk of death; relative risk of death from fatal myocardial infarction varies from 2.2 to 8.8.

[a]Adapted from Lancellotti P et al.[138]

AR, Aortic regurgitation; *AS*, aortic stenosis; *CAD*, coronary artery disease; *MR*, mitral regurgitation; *PR*, pulmonary regurgitation.

TABLE 42.8 Acute and Late Cardiac Toxicity Scoring According to RTOG/EORTC

A. ACUTE CARDIAC TOXICITY SCORING ACCORDING TO RTOG/EORTC

Grade 0	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
No change over baseline	Asymptomatic but objective evidence of EKG changes or pericardial abnormalities without evidence of other heart disease	Symptomatic with EKG changes and radiologic findings of congestive heart failure or pericardial disease/no specific treatment required	Congestive heart failure, angina pectoris, pericardial disease responding to therapy	Congestive heart failure, angina pectoris, pericardial disease, arrhythmias not responsive to nonsurgical measures	Death

B. LATE CARDIAC TOXICITY SCORING ACCORDING TO RTOG/EORTC

Grade 0	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
None	Asymptomatic or mild symptoms Transient T wave inversion & ST changes Sinus tachycardia >110 (at rest)	Moderate angina on effort Mild pericarditis Normal heart size Persistent abnormal T wave and ST changes Low QRS	Severe angina Pericardial effusion Constrictive pericarditis Moderate heart failure Cardiac enlargement EKG abnormalities	Tamponade/severe heart failure/severe constrictive pericarditis	Death

EKG, Electrocardiogram; *RTOG,* Radiation Therapy Oncology Group.

Data From Lung Cancer Patients

The data for patients with lung cancer are more sparse. Historically, radiotherapy-associated cardiac toxicity has generally not been considered a significant clinical issue in patients with lung cancer. This has been due, at least in part, to the fact that many patients with lung cancer have limited survival duration and that radiation-induced cardiotoxicity has been considered a "late effect." In the postoperative setting, there have been several studies noting decreased overall survival with the addition of postoperative RT in lung cancer patients.[110–112] In a meta-analysis of randomized trials, there was a 6% absolute reduction in overall survival at 2 years for NSCLC patients irradiated postoperatively.[113] The causes of death in these studies are not uniformly reported. In the Dautzenberg et al.[110] trial (which randomized 728 patients with NSCLC who had undergone complete surgical resection to receive either postoperative RT at a total dose of 60 Gy or observation only), the RT patients had a

rate of cardiac mortality that was approximately three times the rate seen in the control group (an estimated 5.1% versus 1.7%, or an absolute excess 3.4% rate).[110]

Data From Breast Cancer Patients

One of the earliest recognitions of radiation-associated cardiac injury was in patients radiated for breast cancer. In 1987 and 1989, Cuzick et al.[114,115] published a series of articles based on meta-analysis studies comparing treatment with surgery, with or without postmastectomy radiation therapy. This seminal analysis clearly demonstrated the potential negative cardiotoxic effects of radiation treatment. In a classic figure (Fig. 42.9), there is a detriment in overall survival for the irradiated patients that is clinically manifest between 10 to 15 years postrandomization. A similar finding is well illustrated in a review by Demirci et al.[116]

On the other hand, the recently published study from Darby et al.[117] notes excess radiation-associated cardiac events very soon post-RT. How do we reconcile this finding with the apparent delayed cardiac toxicity observed in the earlier studies, such as those from Cuzick et al.[114,115] This simply is an issue of competing risks. The observed impact of RT on overall survival reflects the competing improvements in breast cancer–specific mortality, and reductions in overall survival due to cardiac disease. If there are indeed early post-RT excess ≥ cardiac deaths, there must be counterbalancing reductions in breast cancer specific mortality

during the first approximate 0–10 years post-RT, accounting for the net "no change" in overall survival seen by Cuzick et al.[114,115] and others.[118,119] Therefore, there likely was an improvement in breast cancer–specific mortality in the short term that was negated by the toxic effects of the radiation (Fig. 42.10).

Data From Patients With Hodgkin Disease

A retrospective series from Stanford including 2332 patients with Hodgkin disease treated in 1960 to 1991 compared cardiac event rate with that of the general population.[120] In that series, the mean age was 29 years and treatment varied: 1183 received radiation therapy alone, and 1119 received radiation + chemotherapy. The mean follow-up was 9.5 years and there were 88 deaths attributed to heart disease. Relative risks of posttreatment death from acute myocardial infarction according to years after initial Hodgkin disease treatment are shown in Table 42.9. Note that the relative risk of cardiac events is increased within just a few years of RT.

Dosimetric Factors

The Darby study in breast cancer patients noted a 7.4% increased risk for ischemic heart disease per Gy (for mean heart dose).[117] In a series of patients with NSCLC that were treated postoperatively with external-beam radiation, the mean heart dose was 18
Fig. 42.9. The overall impact on overall survival is the summation of the effects on breast cancer–specific survival and for radiation-induced cardiac mortality, as shown. *XRT (Adapted from Cuzick J. Overview of adjuvant radiotherapy for breast cancer.* Recent Results Cancer Res. *1989;115:220–225.)*
Fig. 42.10. Relative risk of cardiac mortality in patients with breast cancer treated with radiotherapy as a function of both treatment era (x-axis) and follow-up duration (y-axis). *(Reprinted with permission from Demirci S, Nam J, Hubbs JL, Nguyen T, Marks LB. Radiation-induced cardiac toxicity after therapy for breast cancer: interaction between treatment era and follow-up duration.* Int J Radiat Oncol Biol Phys. *2009;73(4): 980–987.)*

Gy. As a gross estimation, the product of these two values would suggest a 133% increased risk of cardiac injury in these patients. That corresponds to a relative risk (RR) of 2.33, which is similar to the ≈3 RR reported in the study by Dautzenberg et al.[110]

In RTOG 0617, a randomized, two-by-two factorial phase 3 study, standard-dose (60 Gy) versus high-dose (74 Gy) conformal radiotherapy with concurrent and consolidation carboplatin plus paclitaxel with or without cetuximab for patients with stage IIIA or IIIB NSCLC was investigated.[137] The high-dose arm was associated with a lower overall survival rate due to (at least in part) more toxicity. Multivariate analysis revealed heart V5 as an independent prognostic factor affecting overall survival ($p = 0.0035$). While several heart dose–volume constraints have been suggested, additional work is needed to better understand the dose/volume/risk relationships.

Combined Modality Therapy

Hardy et al.[121] reported a SEER-based study of 34,209 patients with stages I–IV NSCLC treated from 1991 to 2002. Their data are summarized in Table 42.10 and perhaps suggest an increased risk of cardiac injury with RT and/or CT.[121]

TABLE 42.9 Relative Risks of Posttreatment Death From Acute Myocardial Infarction According to Years After Initial Hodgkin Disease Treatment[a]

Years After Initial HD Treatment	Relative Risk of Acute MI Death	95% Confidence Interval
0–4	2.0	1.1–3.3
5–9	3.6	2.2–4.5
10–14	3.0	1.6–5.2
15–19	5.0	2.6–8.7
>20	5.6	1.8–13.6

HD, Hodgkin disease; *MI*, myocardial infarction.

Pneumonitis Versus Cardiac Injury

Given the uncertainties in scoring radiation pneumonitis it has been suggested that some patients considered to have radiation pneumonitis might really have cardiac injury (or perhaps both).[122,123] Several authors have looked for a relationship between cardiac dosimetric parameters and radiation pneumonitis, with inconsistent findings.[124–126] Huang et al.[124] and van Luijk et al.[125] noted cardiac parameters to be associated, while Tucker et al.[126] did not. The most compelling dataset is from Washington University. In a study of 209 patients receiving definitive radiation therapy for NSCLC, the risk of radiation pneumonitis was most related to the heart D10 (minimum dose to the hottest 10% of the heart), lung D35, and maximum lung dose (Spearman Rs = 0.268, $p < 0.0001$).[124] Similarly, some studies,[127,128] but not all, have noted radiation pneumonitis to be more common in patients with tumors located in the inferior (versus superior) aspects of the lung.[129] Thus, the human data are unclear as to the role of cardiac irradiation in the genesis of radiation pneumonitis.

In an elegant study performed in rats using protons, the addition of cardiac irradiation to lung irradiation has been demonstrated to influence the post-RT respiratory rate.[125] While this can be interpreted to suggest that cardiac irradiation influences radiation pneumonitis, respiratory rate is a somewhat nonspecific end point.

Prevention and Management

In cases where the heart can be spared, it is recommended to limit the dose to the heart as much as possible. However, limiting the dose to the heart usually results in excess dose to other neighboring structures. In weighing the risks to the various organs, we typically follow the QUANTEC guidelines. Additional suggested dose–volume limits for the heart from other reports, listed in Table 42.11, should also be taken into consideration. Various techniques exist for achieving heart sparing in the RT of patients with lung cancer. When using 3-D conformal RT for lower lobe lung tumors, the dose to the heart can be reduced by using nonaxial beams.[130] IMRT can also be effectively used to reduce cardiac doses.[131,132] In general, in the curative setting, under-dosing the target to limit cardiac dose should be avoided since local failure is usually the greater problem.

TABLE 42.10 Cardiac Toxicity Related to Treatment for Nonsmall Cell Lung Cancer Patients 65 Years or Older[a]

	Relative Risk of Ischemic Heart Disease	Relative Risk of Cardiac Dysfunction	Relative Risk of Conduction Disorders	Relative Risk of Cardiomyopathy	Relative Risk of Heart Failure
No treatment	1	1	1	1	1
Chemotherapy only	1.2	1.6	1.02	0.82	1.3
Radiotherapy only	0.85	1.5	1.01	0.46	1.06
Chemoradiotherapy	1.1	2.4	1.4	0.49	1.2

[a]Adapted from Hardy D, Liu CC, Cormier JN, Xia R, Du XL. Cardiac toxicity in association with chemotherapy and radiation therapy in a large cohort of older patients with non-small-cell lung cancer. *Ann Oncol*. 2010;21(9):1825–1833.

TABLE 42.11 Suggested Dose–Volume Limits for the Heart

Author (Y)	Center	End Point	Suggestion for Limit
Schytte et al. (2010)[133]	Odense University Hospital, Denmark	Survival	Mean left ventricle dose <14.5 Gy
Konski et al. (2012)[134]	Fox Chase Cancer Center, USA	Symptomatic cardiac toxicity	Whole heart V20 <70% Whole heart V30 <65% Whole heart V40 <60%
Fukada et al. (2013)[135]	Keio University, Japan	Symptomatic pericardial effusion	Mean pericardial dose <36.5 Gy Pericardial V45 <58%
Wei et al. (2008)[136]	MD Anderson Cancer Center, USA	Pericarditis/Pericardial effusion	Mean pericardial dose <26 Gy Pericardial V30 <46%
Bradley et al. (2013)[137]	RTOG 1308 (tentative)		V30 ≤50%; V 45 ≤35% Max dose to 0.03 cc ≤70 Gy

RTOG, Radiation Therapy Oncology Group.

CONCLUSION

The toxicities of thoracic radiation described in this chapter can result in significant patient discomfort and reduced quality of life, especially with esophagitis. Occasionally these toxicities can result in death. The only existing and effective preventive strategy is to limit the dose–volume metrics of the organ at risk. Treatment of esophagitis and pneumonitis is essentially supportive as in most cases the toxicities are self-limiting. There is therefore a pressing need for the development of prophylactic treatments that can selectively protect normal tissues without impairing the anticancer effects of full-dose radiotherapy.

43 Neurotoxicity Related to Radiotherapy and Chemotherapy for Nonsmall Cell and Small Cell Lung Cancer

Thomas E. Stinchcombe and Elizabeth M. Gore

SUMMARY OF KEY POINTS

- Radiation-induced brachial plexopathy (RIBP) occurs with treatment of apical tumors and is frequently complicated by tumor-related brachial plexopathy (TRBP). Stereotactic ablative radiotherapy (SABR) of apical tumors, which employs a higher dose per fraction, can cause RIBP as well.

- RIBP symptoms include upper extremity paresthesias, motor weakness, muscle atrophy, and neuropathic pain. The peak incidence is 1–2 years, and the onset is often insidious over months to years.

- The most common side effect of radiation to the spinal cord is Lhermitte sign, which is caused by reversible demyelination of the ascending sensory neurons. Lhermitte sign is a shock-like sensation in the spine and extremities exacerbated by neck flexion, almost always symmetrical, and not associated with a dermatomal distribution. Radiation-induced Lhermitte sign begins 3 months and subsides within 6 months of the completion of radiotherapy.

- Radiation myelopathy can be devastating, and the clinical presentation depends on the level of the spinal cord affected. In general it begins with paresthesia and muscle weakness, and as the syndrome progresses gait disturbance and paraparesis appear. Radiation myelopathy is a diagnosis of exclusion, and patients must be evaluated for tumor progression and paraneoplastic syndromes with magnetic resonance imaging (MRI) of the cord.

- Assessment of the neurotoxic effects of radiation therapy can be confounded by the impact of brain metastases on neurologic function. Long-term outcome data are limited as a result of the short survival, and pretreatment and posttreatment neurologic testing has not been routine.

- Chemotherapy induced peripheral neuropathy (CIPN) is associated with taxanes (e.g., paclitaxel, docetaxel, nanoparticle albumin-bound paclitaxel), platinum agents (e.g., cisplatin and carboplatin), and vinca alkaloids (vinorelbine). Neuropathy associated with microtubule-targeting agents (vinca alkaloids and taxanes) is dependent on the length of the nerves, and patients frequently present with numbness and paresthesias of the feet and fingertips.

- The rate and severity of CIPN depends on the dose, duration and combination of chemotherapy agents used. Patients with a history of nerve damage from diabetes, alcohol use, and inherited neuropathy are at increased risk for the development of CIPN.

Chemotherapy and radiotherapy are routinely used for the treatment of nonsmall cell lung cancer (NSCLC) and small cell lung cancer (SCLC). Both types of treatment can cause acute and chronic neurotoxicities, which may affect the health-related quality of life of the patient and his or her ability to tolerate therapy. Management of the toxicities varies depending on the patient's prognosis. In the palliative setting, acute toxicities may result in dose reduction, treatment delay, or treatment discontinuation, thus offsetting the potential benefits of palliative treatment. In the potentially curative setting, chronic treatment-related toxicities may be more clinically relevant. Unfortunately, the assessment of acute neurotoxicities has been variable, and the prospective collection of data on chronic neurotoxicities has been limited. Selected neurotoxicities are addressed in the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) version 4.0 (Table 43.1);[1] however, many of these toxicities are based on physician assessment, and the determination of a grade 2 or grade 3 toxicity can be patient- and/or physician-dependent. When neurotoxicities do develop, management is often based on the patient's symptoms. Current research is investigating methods of identifying patients who are at increased risk for neurotoxicity, as well as prevention strategies and improved treatment options.

NEUROTOXICITY FROM RADIOTHERAPY

Neurotoxic effects of radiotherapy for lung cancer, predominantly to the brachial plexus, spinal cord, and brain, are important in the curative and palliative setting. Understanding the neurotoxic effects of radiotherapy is increasingly important, as patients with lung cancer are living longer and radiotherapy techniques are evolving. Intensity-modulated radiotherapy (IMRT) and image-guided radiotherapy (IGRT) allow for delivery of increasing total doses of radiation to the tumor while potentially resulting in a high total dose of radiation to small volumes of normal tissues and inhomogeneous doses across large volumes. SABR is a special consideration because it can potentially result in a very high dose per fraction to small volumes of the lung. As patients are living longer with more aggressive local treatment and more effective systemic therapy, the effects of late toxicity are more likely. It is imperative that current and future studies and clinical practice include long-term follow-up with appropriate documentation of dose, grading, and resulting toxicity.

Brachial Plexus

Data regarding RIBP in patients with lung cancer are limited because of the perceived lack of clinical significance. High-dose radiation to the brachial plexus is limited to cases of apical tumors and is frequently complicated by TRBP. However, RIBP may increase in incidence because of improved therapy for advanced lung cancer and treatment of earlier-stage lung cancer, with SABR resulting in longer survival. The risk of RIBP is associated with increased radiation dose and higher dose per fraction,

TABLE 43.1 National Cancer Institute Common Terminology Criteria for Adverse Events Version 4.0, Grades 1–4

Adverse Event	Grade 1	Grade 2	Grade 3	Grade 4
Brachial plexopathy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms, limiting instrumental ADL	Severe symptoms; limiting self-care ADL	NA
Cognitive disturbance	Mild cognitive disability; not interfering with work, school, life performance; specialized educational services, devices not indicated	Moderate cognitive disability; interfering with work, school, life performance but capable of independent living; specialized resources on part-time basis indicated	Severe cognitive disability; significant impairment of work, school, life performance	NA
Concentration impairment	Mild inattention or decreased level of concentration	Moderate impairment in attention or decreased level of concentration; limiting instrumental ADL	Severe impairment in attention or decreased level of concentration; limiting self-care ADL	NA
Memory impairment	Mild memory impairment	Moderate memory impairment; limiting instrumental ADL	Severe memory impairment; limiting self-care ADL	NA
Neuralgia	Mild pain	Moderate pain; limiting instrumental ADL	Severe pain; limiting self-care	NA
Paresthesia	Mild symptoms	Moderate symptoms; limiting instrumental ADL	Severe symptoms; limiting self-ADL	NA
Peripheral motor neuropathy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADL	Severe symptoms; limiting self-care ADL; assistive device indicated	Life-threatening consequences; urgent intervention indicated
Peripheral sensory neuropathy	Asymptomatic; loss of deep tendon reflexes or paresthesia	Asymptomatic; loss of deep tendon reflexes or paresthesia	Severe symptoms; limiting self-care ADL	Life-threatening consequences; urgent intervention indicated

ADL, activities of daily living; *NA*, not applicable.

as well as with the volume of the brachial plexus treated and the concomitant use of chemotherapy.[2] Appropriate radiation dose to the brachial plexus and acceptable risk of RIBP varies depending on the stage of disease and intent of therapy. In many cases, avoiding high radiation dose to the brachial plexus results in undertreating the tumor. When disease is potentially curable or long-term survival is anticipated, the high risk of RIBP may be unavoidable and an understanding of the risks is important for counseling patients.

The diagnosis of RIBP is often complicated by tumor involvement, surgery, and/or unrelated trauma or injury. Symptoms include upper extremity paresthesias, motor weakness, muscle atrophy, and neuropathic pain. The latency period for the onset of symptoms can be a few months to as many as 20 years; the peak incidence is around 1 to 2 years.[3–5] The onset of RIBP is often insidious, occurring over 6 months to as long as 5 years and progressing in intensity, eventually resulting in paralysis of the upper extremity.[3] RIBP is almost always chronic and progressive, although there are rare reports of early transient RIBP. Symptoms reported and attributed to early transient RIBP include pain, paresthesias, and weakness occurring in 2 to 14 months following therapy with regression and often complete resolution of symptoms.[6] MRI and/or computed tomography (CT) are important diagnostic tools to rule out progressive or metastatic disease. Electromyography can be used to support a diagnosis of RIBP.[7]

Most information regarding the effects of radiation on the brachial plexus is from the literature on breast cancer. The brachial plexus is at least partially treated in almost all cases of breast or chest wall radiotherapy and is frequently involved in regions of matching fields, leading to high doses as a result of unintended field overlap. In addition, patients who receive radiotherapy for breast cancer tend to have relatively long follow-up, increasing the likelihood that late reactions will manifest. Over the past 50 years, different radiation techniques have been used to treat breast cancer, resulting in varying incidences of RIBP. In the 1950s and 1960s, RIBP was diagnosed in more than 50% of patients treated with 50 Gy to 60 Gy at 5 Gy per fraction; currently, RIBP develops in less than 1% to 2% of patients treated with less than 55 Gy at 1.8 Gy to 2 Gy per fraction.[8]

RIBP in patients with head and neck cancer is an increasing area of interest because of the use of IMRT for treatment of the disease. In an attempt to restrict radiation dose to organs at risk while maximizing dose to treatment target volumes with the use of IMRT, there is a relatively inhomogeneous dose distribution, and the implications may not be completely understood. If organs at risk are not appropriately contoured, these hot spots could be inadvertently in a high-risk area. Proper anatomic definition of the brachial plexus is necessary for understanding potential side effects and complying with dose–volume constraints. The development of a brachial plexus contouring atlas by the Radiation Therapy Oncology Group (RTOG) has facilitated and encouraged the consistent and routine evaluation and reporting of radiation effects to the brachial plexus in the treatment of head and neck cancers. RTOG guidelines recommend a maximum dose of 60 Gy to 66 Gy or less to the brachial plexus. Truong et al.[9] retrospectively contoured and reviewed doses to the brachial plexus in 114 patients treated with IMRT for head and neck cancer with 69.3 Gy in 33 fractions. There were no reports of RIBP, despite a maximum dose of more than 66 Gy to the brachial plexus in 20% of patients, with a median follow-up of 16.2 months. Longer follow-up is needed to assess the true incidence of RIBP in patients with head and neck cancer. Chen et al.[10] prospectively evaluated the incidence of clinically significant peripheral neuropathies in patients undergoing radiotherapy for head and neck malignancies and reported an incidence of 12% for all patients and 22% for patients who were followed for more than 5 years. The investigators also suggested that RIBP symptoms in patients with head and neck cancer are underreported. Their data suggested a threshold dose of more than 70 Gy to the brachial plexus, although RIBP was also reported in some patients treated with doses less than 60 Gy, suggesting other contributing factors. Prior neck dissection and higher maximum dose of radiotherapy were associated with an increased risk of RIBP.[10]

Eblan et al.[2] evaluated RIBP in 80 patients treated to 50 Gy or more of conventionally fractionated radiotherapy for apical NSCLC; the median follow-up was 17.2 months. RIBP developed in five patients, which was more common among patients who had prior TRBP. The 3-year competing risk-adjusted rate of RIBP was 12%, whereas the 3-year estimated rate of TRBP as a

CHAPTER 43 Neurotoxicity Related to Radiotherapy and Chemotherapy for Nonsmall Cell and Small Cell Lung Cancer **411**

43

result of treatment failure was 13%. The median onset of TRBP was 4 months compared with 11 months for RIBP, and symptom severity was greater for patients in whom TRBP developed. RIBP did not develop in any of the patients who received less than a maximum dose of 78 Gy to the brachial plexus, and for patients in whom RIBP did develop, considerable volumes were irradiated to doses above 66 Gy.[2] Amini et al.[11] identified 90 patients treated with definitive radiotherapy and concurrent chemotherapy and more than 55 Gy to the brachial plexus. The median dose to the brachial plexus was 70 Gy and the median follow-up was only 14 months; grade 1 to grade 3 RIBP developed in 16% of patients. The median time to symptoms was 6.5 months. Independent predictors of RIBP were a median dose to the brachial plexus of more than 69 Gy, a maximum dose of more than 75 Gy to 2 cm,[3] and the presence of plexopathy before radiation.

The brachial plexus receives a considerably higher dose per fraction with SABR and therefore is susceptible to greater risk of late complications. Maximum dose of SABR, as well as dose–volume tolerance and clinical presentation with high dose per fraction, is uncertain. Forquer et al.[12] evaluated the risk of brachial plexopathy in 37 lesions treated with SABR for apical lung tumors; RIBP developed in 7 of 37 patients treated.[12] Five patients had neuropathic pain alone, one patient had pain and weakness, and one patient had pain, numbness, and paralysis of the hand and wrist. At a median follow-up of 7 months, the absolute risk of RIBP was 32% with a dose to the brachial plexus of more than 26 Gy and 6% with a maximum dose of 26 Gy or less in three to four fractions. The median time to development of RIBP was 13 months. In contrast to RIBP reported in other series, symptoms improved in six of seven patients over 3 to 10 months, including improvement of neuropathic pain. One patient who had received a maximum dose of 76 Gy to the brachial plexus had onset of pain and tingling at 9 months of follow-up, with progression to muscle wasting and weakness at 42 months.

Consistent contouring and dose–volume analyses in symptom reporting in the literature will continue to improve the clinical understanding of radiation tolerance of the brachial plexus. Currently, for apical lung tumors adjacent to or contiguous with the brachial plexus, restricting the dose to the brachial plexus may not be possible without compromising tumor control. A better understanding of dose–volume constraints and symptoms will assist in determining the risk of RIBP and proper patient counseling.

Spinal Cord

Radiation myelitis is a rare complication of radiotherapy for lung cancer because, in most cases, the spinal cord can be avoided without compromising disease coverage. This avoidance is particularly true for lung cancer in an era of smaller treatment fields directed at gross disease, three-dimensional conformal radiotherapy planning, IMRT, and IGRT. IMRT plans can shape the high-dose lines around the cord, and with IGRT, high doses adjacent to the spinal cord can be delivered with relative confidence that the set-up is reproducible and accurate.

The most common side effect of radiation to the spinal cord is Lhermitte sign, which is caused by reversible demyelination of the ascending sensory neurons as a result of inhibition of oligodendrocyte proliferation.[13] Lhermitte sign was first described in relation to injury to the cervical spinal cord; is associated with other demyelinating disorders, including multiple sclerosis; and can be induced by radiotherapy or chemotherapy.[14–16] Lhermitte sign is a shock-like sensation in the spine and extremities exacerbated by neck flexion; it is almost always symmetrical, is not associated with a finite dermatomal distribution, and is transient, subsiding with oligodendrocyte recovery and remyelination. Radiation-induced Lhermitte sign begins at about 3 months and subsides within 6 months of the completion of

radiotherapy. The incidence of Lhermitte sign is reported to be between 3.6% and 13% in large patient groups receiving radiotherapy for head and neck and thoracic malignancies. Risk factors associated with the development of Lhermitte sign are total radiation doses above 50 Gy to the cervical spinal cord and daily radiation fraction doses above 2 Gy.[14] Pak et al.[13] found a relatively high incidence of Lhermitte sign (21%) with IMRT for head and neck cancer and concurrent chemotherapy. The strongest predictors of Lhermitte sign were higher percentage and cord volumes receiving 40 Gy or more. The investigators suggested that the higher incidence of Lhermitte sign in their series might have been related to higher reporting in a prospective setting and the chemotherapeutic agents. Lhermitte sign appearing in the context of transient radiation myelopathy is not associated with chronic progressive myelitis; however, delayed radiation myelopathy, which is irreversible and results in paralysis, may be preceded by Lhermitte sign.[16] Lhermitte sign that predates delayed radiation myelopathy is found later in onset than the usual latency period of Lhermitte sign found in transient radiation myelopathy.

Because delayed radiation myelopathy can be a devastating side effect, radiation oncologists take every precaution to avoid it. Although glial cells and vascular endothelium are proposed to be the main targets for radiation and play a role in the pathogenesis of radiation myelopathy, experimental data support that radiation-induced vascular damage resulting in vascular hyperpermeability and venous exudation is a basic process.[17] The clinical presentation of radiation myelopathy depends on the area of the affected spinal cord and the extent of the lesion. Generally, paresthesia and muscle weakness, which begins in the legs, are the main early symptoms. As the lesion progresses, various symptoms present, such as gait disturbance and paraparesis.[17] Schultheiss and Stephens[18] emphasized that radiation myelopathy is a diagnosis of exclusion, and patients should be evaluated for tumor progression and paraneoplasia. In almost all cases of radiation myelopathy, the latency period is longer than 6 months, and MRI may show tumor swelling or atrophy, and the level of protein in cerebrospinal fluid may be slightly elevated, with lymphocytes present.[18] Radiation myelopathy is irreversible, although some interventions, including corticosteroids, heparin or warfarin, and hyperbaric oxygen, have been suggested to have benefit.[19]

The maximum dose considered safe for spinal cord tolerance and for the prevention of delayed radiation myelopathy is 45 Gy to 50 Gy delivered with conventional fractionation (1.8–2 Gy daily). Schultheiss[20] combined reported data from the literature to establish the parameters of the dose–response function for clinical radiation myelopathy. He used data from 18 reported series that included the number of patients treated with a consistent dose regimen, dose, number of fractions, number of myelopathy cases resulting from the dose regimen, and information about the survival experience of patients at risk. At a 45-Gy dose, the probability of myelopathy is 0.03%; at 50 Gy, the probability is 0.2%. The dose for a 5% myelopathy rate is 59.3 Gy. Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) analysis demonstrated that, when conventional fractionation of 1.8–2 Gy/fraction is delivered to the full-thickness cord, the estimated risk of myelopathy is less than 1% at 54 Gy and less than 10% at 61 Gy.[21]

Data are limited regarding the risk of radiation myelopathy and repeat radiation to the spinal cord. Data on repeat radiation in animals and humans suggest partial repair of radiotherapy-induced subclinical damage becoming evident about 6 months after radiotherapy and improving over the next 2 years. Follow-up data for spinal cord injury after repeat radiation for recurrent disease is limited and few cases of radiation myelopathy are reported. In general, attempts should be made to avoid the spinal cord if repeat treatment is indicated.

The understanding of spinal cord tolerance with SABR is evolving. The acceptable maximum dose is dependent on dose per fraction. Gibs et al.[22] reported six cases of radiation myelopathy among 1075 patients treated for benign and malignant spinal cord tumors. They recommended limiting the volume of spinal cord treated above an 8-Gy equivalent dose in one fraction. Delayed radiation myelopathy developed at a mean of 6.2 months (range, 2 to 9 months). Saghal et al.[23] evaluated five cases of radiation myelopathy following spine SABR and compared dosimetric data with those in a larger series of patients treated with spine SABR in which no radiation myelopathy occurred. The investigators concluded that the maximum point dose to the thecal sac should be respected for spine SABR. For single-fraction SABR, 10 Gy to a maximum point is safe, and up to five fractions and biologic estimated dose of 30 Gy to 35 Gy secondary to the thecal sac also poses a low risk of radiation myelopathy.[23] This finding was supported by data reported by Macbeth et al.,[24] showing no radiation myelopathy at 10 Gy in a single fraction. Based on extensive literature review, QUANTEC for spine radiosurgery demonstrated that a maximum cord dose of 13 Gy in a single fraction or 20 Gy in three fractions appeared to be associated with a less than 1% risk of injury.[21]

Brain

Neurotoxic effects of radiation to the brain are variably assessed in the setting of lung cancer. Data are available, primarily in the absence of controls, for patients with inoperable brain metastases treated palliatively with whole-brain radiation therapy (WBRT), local therapy with surgery or stereotactic radiosurgery for patients treated with and without WBRT, and with prophylactic cranial radiation for either SCLC or NSCLC. The neurotoxic effects of radiation therapy to the brain are difficult to assess because of several factors: most patients with lung cancer who are treated with WBRT have neurologic deficits from brain metastases, long-term follow-up is limited as a result of short survival, and neurologic testing has not been routine.

Series that evaluated neurotoxic effects of radiation for brain metastases have consistently shown that the risk of neurocognitive deficits as a result of WBRT is outweighed by the benefits of treatment. In 1989, De Angelis et al.[25] evaluated 12 patients with neurologic complications attributed to WBRT for brain metastases and reported an incidence of 1.9% to 5.1% for WBRT-induced dementia. All 12 patients, who were treated with total doses of 25 Gy to 39 Gy at 3 Gy to 6 Gy per fraction, had cortical atrophy and hypodense white matter on CT images. The authors concluded that more protracted schedules should be used for the safe and efficacious treatment of good-risk patients with brain metastases.

In RTOG 91-04, a phase III trial designed to assess overall survival of patients with unresectable brain metastases treated with 54.4 Gy/1.6 Gy twice daily or 30 Gy/3 Gy once daily, no difference in overall survival was found between radiation doses; the median survival in both arms was only 4.5 months.[26] A secondary analysis of this study was conducted to evaluate the importance of a Mini-Mental Status Exam (MMSE) before treatment on long-term survival and neurologic function of patients treated with 30 Gy/3 Gy once daily. Both pretreatment MMSE ($p = 0.0002$) and Karnofsky performance status ($p = 0.02$) were significant factors for survival. WBRT appeared to be associated with an improvement in MMSE score and a lack of decline to below 23 on the MMSE in long-term survivors.[27] Additional analysis of both arms of this trial showed that the use of 30 Gy/3 Gy once daily as compared with 54.4 Gy/1.6 Gy twice daily was not associated with a significant difference in neurocognitive function as measured by MMSE. Control of brain metastases had a noticeable effect on the MMSE score.[28]

Neurocognitive function with a neuropsychometric battery before and after WBRT (30 Gy/3 Gy once daily) was assessed prospectively in a phase III trial of WBRT with or without motexafin gadolinium.[29] Impairment was found in more than 90% of patients at baseline, and the results suggested that only tumor control correlated with neurocognitive function.[30] Li et al.[31] evaluated 135 of 208 patients in the control arm of the study who were available for evaluation at 2 months.[31] The authors found that WBRT-induced tumor shrinkage correlated with better survival and preservation of neurocognitive function. Neurocognitive function was stable or improved in long-term survivors, and tumor progression adversely affected neurocognitive function more than WBRT.

Studies in which patients treated with and without WBRT after local therapy for a limited number of brain metastases are evaluated have also routinely included assessment of neurotoxic effects. This setting provides an opportunity to review neurocognitive effects of radiotherapy in a patient population with a relatively good performance status and less extensive systemic disease. In general, these studies have shown that WBRT can be delivered safely without substantial changes in neurocognitive function and that it improves local control but not overall survival. Chang et al.[32] conducted a phase III trial comparing stereotactic radiosurgery with and without WBRT for patients with one to three brain metastases, with the primary end point being a change in neurocognitive function at 4 months as measured by the Hopkins Verbal Learning Test (HVLT). The investigators found that patients treated with stereotactic surgery plus WBRT had noticeable impairment in learning and memory function by HVLT compared with the patients who were treated with stereotactic radiosurgery alone. This study, however, has been controversial because of unexpected survival differences favoring the stereotactic radiosurgery arm and for the timing of the neurocognitive assessment to one time point.

The European Organisation for Research and Treatment of Cancer (EORTC) conducted a phase III trial assessing whether adjuvant WBRT (30 Gy/3 Gy once daily) increases the duration of functional independence after surgery or stereotactic radiosurgery for brain metastases.[33] Adjuvant WBRT reduced intracranial relapses (surgery: 59% to 27%, $p = 0.001$; stereotactic radiosurgery: 31% to 19%; $p = 0.040$) and neurologic deaths. WBRT did not affect the rate of decline in performance status. The median time to World Health Organization performance status higher than 2 was 10.0 months after observation and 9.5 months after WBRT ($p = 0.71$).

Aoyama et al.[34] prospectively evaluated WBRT after local therapy for brain metastases and did not find a difference in survival or in neurocognitive function. Intracranial relapse occurred considerably more frequently among patients who did not receive WBRT and, consequently, as demonstrated in other studies, salvage treatment was frequently needed when upfront WBRT was not used. Neurocognitive function was scored 0 to 4 based on the degree of functional impairment and level of assistance required. Neurocognitive function assessment using the MMSE was optional. MMSE data for at least one time point were available for 28 of 44 patients who lived 12 months or longer (16 patients in the WBRT plus stereotactic radiosurgery group and 12 in the stereotactic radiosurgery-alone group) at a median follow-up of 30.5 months (range, 13.7 to 58.7 months). The median MMSE scores before and after treatment were 28 and 27, respectively, in the WBRT plus stereotactic radiosurgery group and 27 and 28 in the stereotactic radiosurgery-alone group. The investigators also evaluated MRI for leukoencephalopathy, and radiographic findings consistent with leukoencephalopathy were found in seven patients in the WBRT plus stereotactic radiosurgery group and in two patients in the stereotactic radiosurgery-alone group ($p = 0.09$). Three of these

CHAPTER 43   Neurotoxicity Related to Radiotherapy and Chemotherapy for Nonsmall Cell and Small Cell Lung Cancer   **413**

43

nine patients also had symptomatic leukoencephalopathy; the other six patients were asymptomatic.

Prophylactic Cranial Radiation

Prophylactic cranial radiation is a superior setting to assess the effects of radiotherapy on the whole brain, although it comes with some challenges. Even with the use of prophylactic cranial radiation, survival is limited for patients with lung cancer, routine use of neuropsychologic testing in this patient population is limited, and frequently, patients have baseline neuropsychologic deficits before prophylactic cranial radiation, partially as a result of prior chemotherapy and possibly also because of paraneoplastic effects from the underlying malignant process.

Historically, high rates of toxicity with prophylactic cranial radiation were reported when it was given concurrently with chemotherapy or when it was given at high dose per fraction to patients with SCLC.[35] After low-dose concurrent chemotherapy and prophylactic cranial radiation, 44% of patients with SCLC had abnormal neuropsychologic tests at a median follow-up of 6.2 years.[35] Unexpected neurocognitive deficits have been detected in patients with SCLC after combination chemotherapy, with no noticeable change in those deficits after prophylactic cranial radiation.[36] The authors suggest that neuropsychologic abnormalities associated with SCLC may be secondary to the disease itself (paraneoplasia) and systemic therapy.

Le Péchoux et al.[37] published the results of an international phase III study (PCI99-01, EORTC 22003-08004, RTOG 0212, and IFCT 99-01) comparing 25-Gy and 36-Gy prophylactic cranial radiation for patients with limited-disease SCLC.[37] Over 3 years, the authors found no significant difference between the two groups in any of the 17 selected items assessing quality of life and neurologic and cognitive functions. However, in both groups, there was mild deterioration in communication, memory, intellectual capacity, and leg strength ($p < 0.005$ for all).

RTOG 0212 was a randomized phase II trial designed to evaluate the incidence of chronic neurotoxicity and changes in quality of life among patients who received prophylactic cranial radiation for limited-disease SCLC; some patients from this study were also involved in the international phase III prophylactic cranial radiation trial. Patients in RTOG 0212 were treated to 25 Gy/2.5 Gy once daily, 36 Gy/2 Gy once daily, or 36 Gy/1.2 Gy twice daily. There were no significant baseline differences among the treatment groups in terms of quality-of-life measures, and one of the neuropsychologic tests, namely the HVLT. However, at 12 months after prophylactic cranial radiation, there was a significant increase in the occurrence of chronic neurotoxity in the 36-Gy cohort ($p = 0.02$). According to logistic regression analysis, increasing age was found to be the most significant predictor of chronic neurotoxicity ($p = 0.005$).

RTOG 0214 evaluated the use of prophylactic cranial radiation for patients with locally advanced NSCLC. Prophylactic cranial radiation was shown to considerably decrease the risk of brain metastasis from 18% to 7.7% at 1 year. However, there was no significant difference in overall survival or disease-free survival.[38] A secondary end point of this study was to evaluate the neuropsychologic impact of prophylactic cranial radiation. There were no significant differences at 1 year between the two arms in any component of the EORTC Quality of Life Questionnaire (EORTC-QLQ) C30 or EORTC-QLQ BN20 studies, although a trend for greater decline in patient-reported cognitive functioning was noted with prophylactic cranial radiation. There were no significant differences in MMSE score or activities of daily living. However, for HVLT, there was a significantly greater decline in immediate recall ($p = 0.03$) and delayed recall ($p = 0.008$) in the prophylactic cranial radiation arm at 1 year.

Gondi et al.[39] reported a pooled secondary analysis of tested and self-reported cognitive functioning of patients treated with prophylactic cranial radiation in RTOG 0212 and RTOG 0214.[39] Among patients with lung cancer in whom brain relapse did not develop, prophylactic cranial radiation was associated with decline in HVLT-tested and self-reported cognitive functioning; however, decline in HVLT and self-reported cognitive functioning were not closely correlated, suggesting that they may represent distinct elements of the cognitive spectrum.

Radiographic Imaging Studies

WBRT is one of the most effective modalities for the treatment and prevention of brain metastases, although it can result in neurocognitive deficits. WBRT is associated with the development of delayed white matter abnormalities or leukoencephalopathy and has been correlated with cognitive dysfunction. The effects of WBRT have been studied in the setting of treatment for intracranial disease and prophylactic cranial irradiation. Prophylactic cranial irradiation is ideal for studying the effect of WBRT, as patients do not have baseline neurologic effects from metastatic or primary tumors in the brain.

Stuschke et al.[40] studied neuropsychologic function and MRI of the brain in patients with locally advanced NSCLC after prophylactic cranial radiation. T2-weighted MR images demonstrated white matter abnormalities of higher grade in patients who received prophylactic cranial radiation than in those patients who did not. Two of nine patients treated with prophylactic cranial radiation and none of four patients not treated with prophylactic cranial radiation had grade 4 white matter abnormalities. A trend toward impaired neuropsychologic functioning was also found in patients with white matter abnormalities of higher degree. Impairments in attention and visual memory in long-term survivors were found among patients in both prophylactic cranial radiation and nonprophylactic cranial radiation groups.

In prophylactic cranial radiation studies, MR images have not been prospectively evaluated before and after therapy for radiation effects and correlation with clinical toxicity. Johnson et al.[35] evaluated CT and MR images of patients 6 to 13 years after receiving prophylactic cranial radiation for SCLC. Findings on CT were abnormal (i.e., demonstrated ventricular dilation, cerebral atrophy, and/or cerebral calcification) in 12 of 15 patients, and white matter abnormalities were present on MR images for seven of 15 patients. Anatomic abnormalities documented by CT and MRI were more frequent among patients with abnormal neuropsychologic function.

Little is known about the factors that predispose patients to white matter changes that occur with WBRT. Sabsevitz et al.[41] used MRI volumetrics to prospectively evaluate the effect of white matter health before treatment on the development of white matter changes after WBRT. Age at the time of treatment and volume of abnormal fluid-attenuated inversion recovery before treatment were significantly associated with white matter changes following WBRT; however, pretreatment fluid-attenuated inversion recovery volume was the strongest predictor of white matter changes after treatment. No significant relationships were found between dose of WBRT, total glucose, blood pressure, or body mass index and development of white matter changes. Szerlip et al.[42] retrospectively reviewed serial MR images and measured volumetric white matter changes over time for patients treated with WBRT and who survived more than 1 year. Following WBRT, white matter changes accumulated at an average rate of 0.07% of total brain volume per month. On multivariate analysis, greater rates of accumulation were associated with older age, poor levels of glycemic control, and the diagnosis of hypertension.

Routine use of MRI before and after therapy and correlation with neuropsychologic assessment are necessary to better understand the neurotoxic effects of brain radiation. Additionally, factors predicting neurologic change or faster rate of neurologic change are important to understand. Paying careful attention

to mitigating risk, such as through control of hyperglycemia or hypertension or possibly avoiding or delaying WBRT for patients at high risk of complications, is vital for individualizing care.

PREVENTION OF NEUROCOGNITIVE COMPLICATIONS

Recent clinical efforts to minimize toxicity of radiotherapy have focused on modifying radiotherapy techniques and using neuroprotectants. Memantine is a clinically useful drug for many neurologic disorders, including Alzheimer disease. The principal mechanism of action of memantine is believed to be the blockade of current flow through channels of *N*-methyl-D-aspartate receptors. Memantine has been associated with a moderate decrease in clinical deterioration of cognition, mood, behavior, and the ability to perform daily activities in patients with Alzheimer disease. In RTOG 0614, a trial that studied the neuroprotective effects of memantine in patients treated with palliative WBRT,[43] memantine was found to be well tolerated, with a toxicity profile very similar to placebo. Overall, patients treated with memantine had better cognitive function over time; specifically, memantine delayed time to cognitive decline and reduced the rate of decline in memory, executive function, and processing speed of patients who received WBRT. The primary end point was delayed recall at 24 weeks; although less decline of delayed recall was found with the use of memantine, this decline lacked significance, possibly due to substantial patient loss. Follow up in this patient population is challenging secondary to death and noncompliance related to disease progression.

According to emerging evidence, the pathogenesis of radiation-induced neurocognitive function deficit may involve radiation-induced injury to proliferating neuronal progenitor cells in the subgranular zone of the hippocampi.[44] IMRT allows for sparing of the hippocampus while otherwise treating the whole brain with radiation therapy. In RTOG 0933, a single-arm phase II study, hippocampal avoidance WBRT for brain metastases with a primary cognitive end point was evaluated in comparison to a historic control of WBRT without hippocampal avoidance (RTOG 9801).[45] Conformal avoidance of the hippocampus during WBRT was associated with memory preservation at 4 and 6 months of follow-up. These phase II results compared favorably with those in historic series.[39]

Chemotherapy-Induced Peripheral Neuropathy

Agents commonly used in the treatment of NSCLC and SCLC that are associated with CIPN include the taxanes, (e.g., paclitaxel, docetaxel, nanoparticle albumin-bound paclitaxel [nab-paclitaxel]), platinum agents (e.g., cisplatin and carboplatin), and vinca alkaloids (e.g., vincristine, vinorelbine, vinblastine). The mechanism, incidence, and symptoms of CIPN vary with the class of agent. Neuropathy induced by microtubule-targeting agents (e.g., vinca alkaloids and taxanes) is dependent on the length of the nerves, and patients frequently present with symptoms in their fingertips and feet. The vinca alkaloids can cause autonomic neuropathy as well as peripheral neuropathy, symptoms of which can present as abdominal cramping, ileus and constipation, and, rarely, cranial nerve neuropathies.[46] Cisplatin-related sensory neuropathy usually becomes clinically detectable after a cumulative dose of 300 mg/m²; carboplatin has a lower rate of neurotoxicity than does cisplatin.[47] Oxaliplatin is associated with cold dysesthesias, paresthesias, and CIPN, but is not a standard agent used in the treatment of NSCLC or SCLC.

The rate and severity of CIPN depends on the dose, duration, and combination of agents used. Patients with a history of nerve damage from diabetes, alcohol-use, or an inherited neuropathy are at increased risk for the development of CIPN, and symptomatic neuropathy may develop with lower doses or earlier in treatment.[46] Initial symptoms of CIPN are often symmetric sensory and motor

impairment of the extremities causing tingling (paresthesias) or numbness (hypoesthesia) of the fingertips or feet. The loss of proprioception may cause unsteady gait, ataxia, or a tendency to fall. Other common symptoms are pain or motor neuropathy resulting in muscle weakness. In general, NCI-CTCAE grade 2 or grade 3 sensory neuropathy is thought to be clinically significant and requires an intervention such as dose delay and/or reduction or, potentially, discontinuation of the offending agent. Physicians often underestimate the frequency and severity of symptoms, and so patient-reported outcomes may be a more accurate assessment of the frequency and severity of this toxicity.[48,49]

Chemotherapy Treatments Associated With CIPN

The selection of chemotherapy combinations is frequently influenced by patients' preexisting conditions and their risk for the development of CIPN. Patients with a preexisting neuropathy or with conditions that predispose them to CIPN often will receive a chemotherapy combination that is associated with a lower rate of CIPN (e.g., a platinum agent and pemetrexed or a platinum agent and gemcitabine). Cisplatin or carboplatin and paclitaxel, docetaxel, vinorelbine, and nab-paclitaxel are used in the treatment of NSCLC, and all are associated with CIPN. The combination of cisplatin and vincristine is a standard combination for adjuvant therapy and for metastatic disease. Two different schedules of cisplatin and vinorelbine have been investigated in phase III trials of adjuvant therapy, and the rate of CIPN was evaluated with the use of these agents (Table 43.2).[50,51] The rate of all-grade constipation and grade 3 constipation—a symptom of autonomic neuropathy—found in these trials was approximately 45% and 5%, respectively. Given the significant improvement in overall survival and long-term survival in the adjuvant setting, the rate of neurotoxicities is acceptable, but diligent surveillance and symptom management are required. In a three-arm phase III trial, docetaxel plus cisplatin and docetaxel plus carboplatin were compared with vinorelbine plus cisplatin for advanced-stage NSCLC,[52] and patients could receive a maximum of six cycles. The rate of grade 3 or grade 4 sensory neuropathy was numerically lower in the docetaxel plus carboplatin arm (Table 43.2). These trials provide an estimate of the rate of CIPN with commonly used chemotherapy combinations.

The relationship between CIPN and single-agent paclitaxel and the combination of carboplatin and paclitaxel has been extensively studied in clinical trials. In a prospective study of patients receiving weekly paclitaxel (70–90 mg/m²) who completed the EORTC-CIPN instrument, 20% of patients had a clinically significant pain score with the first dose of paclitaxel.[53] The rate of chronic neuropathy was higher among patients with higher paclitaxel-acute pain syndrome pain scores with the first dose of paclitaxel.[53] Common symptoms of paclitaxel-acute pain syndrome include a diffuse aching of the legs, hips, and lower back 1 to 3 days after the paclitaxel administration. Numbness and tingling were more prominent chronic neuropathic symptoms than shooting or burning pain. Longer duration of treatment with carboplatin and paclitaxel has been associated with a higher rate of CIPN. A phase III trial of carboplatin and paclitaxel every 3 weeks for four cycles compared with carboplatin and paclitaxel until disease progression or unacceptable toxicity revealed similar efficacy.[54] However, the rate of grade 2 to grade 4 sensory neuropathy increased from 19.9% (95% CI, 13.6–26.2%) at cycle 4 to 43% (95% CI, 28.6–57.4%) at cycle 8. An association between cumulative paclitaxel dose and development of sensory neuropathy has been demonstrated in other studies as well.[55] In a phase III trial that compared cisplatin and paclitaxel every 3 weeks to carboplatin and paclitaxel every 3 weeks, patients continued therapy until disease progression or a maximum of 10 cycles.[56] Rates for all-grade and grade 3 peripheral neuropathy were similar for the two combinations.

TABLE 43.2 Rate of Chemotherapy-Induced Neuropathy Reported in Phase III Trials of Platinum Agent Doublets

Author	Chemotherapy	No. of Patients	Rate of Sensory Neuropathy (all grades) (%)	Rate of Grade 3 or 4 Sensory Neuropathy (%)
Winton et al.[50]	Cisplatin 50 mg/m² days 1 and 8 every 28 days Vinorelbine 25 mg/m² weekly for 16 weeks	242[b]	48	2[a]
Douillard et al.[51]	Cisplatin 100 mg/m² day 1 Vinorelbine 30 mg/m² days 1, 8, & 15 (cycle: every 28 days)	367[b]	28	3
Fossella et al.[52]	Cisplatin 75 mg/m² & docetaxel 75 mg/m² every 21 days	1218	NR	3.8
	Carboplatin AUC of 6 & docetaxel 75 mg/m² every 21 days		NR	3.9
	Cisplatin 100 mg/m² day 1 every 28 days & vinorelbine 25 mg/m² weekly		NR	0.7
Rosell et al.[56]	Cisplatin 80 mg/m² & paclitaxel 200 mg/m² every 21 days	618	58	9
	Carboplatin AUC of 6 & paclitaxel 200 mg/m² every 21 days		59	8
Bonomi et al.[58c]	Cisplatin 75 mg/m² & paclitaxel 135 mg/m² every 21 days	399	NR	23
	Cisplatin 75 mg/m² & paclitaxel 250 mg/m² every 21 days		NR	40
Belani et al.[59]	Carboplatin AUC of 6 & paclitaxel 225 mg/m² every 3 days	440	NR	18[d]
	Carboplatin AUC of 6 on day 1 & paclitaxel 100 mg/m² on days 1, 8, & 15 every 28 days		NR	12
Socinski et al.[60]	Carboplatin AUC of 6 on day 1 & nab-paclitaxel 100 mg/m² on days 1, 8, & 15 every 21 days	1052	46	3
	Carboplatin AUC of 6 & paclitaxel 200 mg/m² every 21 days		62[d]	11[e]

[a]The rate of all-grade and grade 3 motor neuropathy observed was 15% and 3%, respectively.
[b]Numbers represent patients receiving cisplatin and vinorelbine.
[c]This trial included three arms, and the two arms containing paclitaxel are included in the table. The results are reported as grade 3 neurologic toxicity.
[d]The results represent the rate of grade 2 or grade 3 neuropathy, and the difference is significant ($p = 0.05$).
[e]Significant differences in the rates of all grades of sensory neuropathy ($p < 0.001$) and grade 3 or grade 4 sensory neuropathy ($p < 0.05$) were noted.
AUC, area under the curve; *NR*, not reported.

A lower-dose weekly schedule compared with every-3-week paclitaxel has been investigated in several trials to improve efficacy or reduce toxicity, and higher and lower doses of paclitaxel have been researched as well. Paclitaxel sensory neuropathy is also dose-related, and it rarely occurs below doses of 170 mg/m².[55,57] In a phase III trial of cisplatin and low-dose paclitaxel (135 mg/m²) every 3 weeks or high-dose paclitaxel (250 mg/m²) every 3 weeks, a significantly higher rate of grade 3 neurologic toxicity was found in the high-dose paclitaxel arm (40% vs. 23%);[58] however, the low and high doses of paclitaxel investigated in this trial are not currently used in the treatment of NSCLC. In another phase III trial, carboplatin and paclitaxel every 3 weeks was compared with carboplatin on day 1 and paclitaxel on days 1, 8, and 15 every 4 weeks for four cycles; treatment was given for up to four cycles.[59] The rate of grade 2 and grade 3 neuropathy was significantly lower in the weekly arm compared with the every-3-week arm (12% vs. 18%; $p = 0.05$). In a smaller phase II trial, carboplatin every 3 weeks was compared with either paclitaxel 225 mg/m² every 3 weeks or 75 mg/m² weekly for 12 weeks;[60] the rate of sensory neuropathy was not significant between the two arms ($p = 0.27$). These data are suggestive of a lower rate of CIPN with a lower dose of paclitaxel used on a weekly schedule.

Standard formulation paclitaxel uses a Cremophor-base, and nab-paclitaxel formulation does not. In a phase III trial, carboplatin and nab-paclitaxel 100 mg/m² on days 1, 8, and 15 every 3 weeks was compared with carboplatin and standard formulation paclitaxel 200 mg/m² every 3 weeks.[61] Treatment was continued for at least six cycles and was allowed to continue in the absence of disease progression or unacceptable toxicity. The median cumulative dose of paclitaxel in the nab-paclitaxel and standard paclitaxel formulation arms was 1325 mg/m² and 1125 mg/m², respectively.

The rate of all-grade sensory neuropathy in the nab-paclitaxel and standard paclitaxel formulation arms was 46% and 62% ($p < 0.001$) respectively, the rate of grade 3 or grade 4 sensory neuropathy was 3% and 11% ($p < 0.05$), respectively, and the median improvement of grade 3 or higher sensory neuropathy to grade 1 in the nab-paclitaxel and paclitaxel arms was 38 and 104 days, respectively. It is important to note that the dose, schedule, and formulation of paclitaxel were different between the two arms, and it is unclear if one or a combination of these factors contributed to the difference in CIPN found in this trial. Infusion of nab-paclitaxel over 2 hours instead of the standard 30 minutes was compared with nab-paclitaxel 125 mg/m² on days 1, 8, and 15 every 4 weeks in a single-arm phase II trial.[62] A significant decrease was found in the grade of the average peripheral neuropathy, as well as in the rate of grade 2 or higher peripheral neuropathy compared with historic controls, which suggests that a longer infusion time with nab-paclitaxel may reduce the rate of clinically significant CIPN.

In summary, the rate of clinically relevant grade 2 or grade 3 sensory neuropathy found with platinum and taxane or vinorelbine combination therapy for the treatment of NSCLC is approximately 10% to 20%, and the rate of severe grade 3 sensory neuropathy is approximately 5%. Limiting the duration of carboplatin and paclitaxel to four cycles reduces the risk of clinically significant neuropathy, and the lower dose weekly schedule of paclitaxel may be associated with a lower rate of CIPN.

Prevention of CIPN

A number of agents have been investigated for the prevention of CIPN. Amifostine, an organic thiophosphate that acts as a scavenger of free radicals, was investigated as a cytoprotective agent for

chemotherapy-induced and radiotherapy-induced toxicities. This agent was investigated in several small trials of various chemotherapy regimens, and a definitive improvement in clinical symptoms of CIPN was not found.[47] Glutathione is thought to prevent the accumulation of platinum adducts in the dorsal root ganglia, and to date, the trials in which glutathione is being researched for prevention of CIPN have been inconclusive.[47] In a phase III placebo-controlled, double-blinded clinical trial glutathione was investigated for the prevention of CIPN in patients with ovarian cancer treated with carboplatin and paclitaxel (ClinicalTrials.gov identifier: NCT02311907). Acetyl-L-carnitine (ALC) is a natural compound involved in the acetylation of tubulin, a process that provides neuronal protection.[63,64] ALC was investigated in a randomized, double-blind, placebo-controlled trial of 409 women treated with paclitaxel for breast cancer.[65] CIPN was assessed using the Functional Assessment of Cancer Therapy-Taxane scale at 12 and 24 weeks (a lower score indicates worse CIPN); patients who were assigned to ALC compared with placebo had a 0.9-point lower score at 12 weeks than patients who received placebo (95% CI, –2.2 to 0.4; $p = 0.17$) and a 1.8-point lower score at 24 weeks (95% CI, –3.2 to –0.04; $p = 0.01$). Grade 3 or grade 4 neurotoxicity was more frequent in the ALC arm than in the placebo arm (8 vs. 1). The worsening of CIPN with this nutritional supplement is discouraging and illustrates the need to perform randomized controlled trials of nutritional supplements. Alpha-lipoic acid (ALA) may improve nerve blood flow by antioxidant action and has been investigated as a treatment of diabetic peripheral neuropathy.[66,67] Accrual has been completed for a placebo-controlled phase III trial to evaluate alpha-lipoic acid (given for at least 24 weeks) for the prevention of CIPN in patients receiving cisplatin or oxaliplatin (ClinicalTrials.gov identifier: NCT00112996).

Pharmacologic Therapy for CIPN

When clinically significant CIPN develops, often defined as grade 2 or higher, treatment options are limited. The most problematic symptom for many patients is pain associated with the paresthesias, and a number of therapies have been investigated with variable success (Table 43.3). The primary end point for these trials is generally assessment of the grade of toxicity and patient-reported outcomes. In 2013, duloxetine was investigated in a randomized, double-blind, placebo-controlled, cross-over trial with the primary end point of reduction in average pain score.[68] Patients were required to have at least grade 1 sensory pain based on the NCI-CTCAE version 3.0 (reported as 4 or higher on a 10-point pain scale) and have neuropathic pain for 3

months or longer after completing chemotherapy. To be considered eligible for the trial, patients could have received treatment with paclitaxel, oxaliplatin, single-agent docetaxel, nab-paclitaxel, or cisplatin; however, none of the patients enrolled had received cisplatin. The majority of the patients enrolled had breast cancer (38%) or gastrointestinal cancer (56%). Eligible patients were randomly assigned to receive either duloxetine daily during the initial treatment period and placebo at cross-over period, or to receive placebo as initial treatment and duloxetine as cross-over treatment. The initial treatment period was week 1 to week 5, followed by a 2-week washout period, and cross-over (weeks 8 to 12); treatment consisted of either placebo or duloxetine 30 mg daily for the first week, and placebo or duloxetine 60 mg daily for 4 weeks. Patients reported the pain severity and functional interference weekly using the Brief Pain Inventory Short Form, in which 0 indicates no pain and 10 indicates pain "as bad as you can imagine." The minimal clinically important difference in pain severity was determined to be a 0.98 difference in average pain score. CIPN was also assessed using the NCI-CTCAE version 3.0 on a weekly basis. Patients assigned to duloxetine as their initial 5-week treatment reported a decrease in average pain of 1.06 (95% CI, 0.72–1.40), and patients assigned to placebo reported a decrease in average pain of 0.34 (95% CI, 0.01–0.66; $p = 0.003$). The effect size was moderately large at 0.513, and the percentage of patients reporting a decrease in pain with duloxetine and placebo first was 59% and 38%, respectively. Patients treated with duloxetine reported a greater decrease in the amount of pain that interfered with daily function ($p = 0.01$) and greater improvement in pain related to quality of life using the Functional Assessment of Cancer treatment, Gynecological Oncology Group Neurotoxicity subscale ($p = 0.03$). The most common adverse events were fatigue (7%), insomnia (5%), and nausea (5%). In an exploratory analysis, patients who received oxaliplatin experienced more benefit from duloxetine than patients who received taxanes ($p = 0.13$).

Other agents that have been investigated in double-blind, placebo-controlled trials for the treatment of CIPN include gabapentin and venlafaxine (Table 43.3).[69,70] In a phase III trial of gabapentin (target dose of 2700 mg daily) compared with placebo, patients with either a numeric score of 4 or higher on the numeric rating scale or 1 or higher on the Eastern Cooperative Oncology Group neuropathy scale had a 2-week washout and then crossed over to the other therapy. Changes in symptom severity were similar between the two groups, and this study did not suggest any benefit for gabapentin for the treatment of CIPN. In a smaller study, venlafaxine 50 mg 1 hour before the oxaliplatin infusion and venlafaxine 37.5 mg twice a day from day 2 to

TABLE 43.3 Select Phase III Trials of Therapies for Treatment of Chemotherapy-Induced Peripheral Neuropathy

Author	Agent	No. of Patients	Trial Design	Primary End Point	Outcome[a]
Smith et al.[68]	Duloxetine	231	Randomized, double-blind, placebo-controlled, cross-over	Average pain assessed using BPI-SF	Significant improvement ($p = 0.003$)
Rao et al.[69]	Gabapentin	115	Randomized, double-blind, placebo-controlled, cross-over	Average pain assessed using NRS & ENS	No significant difference
Durand et al.[70]	Venlafaxine	48	Double-blind, placebo-controlled	NRS, NPSI, & oxaliplatin-specific neurotoxicity	Full relief according to NRS significantly more common in venlafaxine arm (31.3% vs. 5.3%, $p = 0.03$)
Barton et al.[71]	Topical BAK-PLO	208	Double-blind, placebo-controlled	EORTC QLQ-CIPN20 at 4 weeks	Sensory neuropathy ($p = 0.053$); motor neuropathy ($p = 0.021$)

[a]A trend toward improvement in sensory neuropathy and a significant improvement in motor neuropathy was observed with BAK-PLO compared to placebo.

BAK-PLO, baclofen 10 mg, amitriptyline 40 mg, ketamine 20 mg in a pluronic lecithin organogel; *BPI-SF*, Brief Pain Inventory-Short Form; *ENS*, Eastern Cooperative Oncology Group neuropathy scale; *EORTC QLQ-CIPN20*, European Organisation for Research and Treatment of Cancer 20-item quality-of-life chemotherapy-induced peripheral neuropathy questionnaire; *NRS*, numerical rating scale; *NPSI*, neuropathic pain symptom inventory.

CHAPTER 43 Neurotoxicity Related to Radiotherapy and Chemotherapy for Nonsmall Cell and Small Cell Lung Cancer **417**

43

day 11 or placebo was investigated. The primary end point was the percentage of patients reporting 100% relief while receiving treatment as assessed by a numeric rating scale; in the venlafaxine and placebo arms, this end point was reached in 31.3% and 5.3%, respectively ($p = 0.03$).

In a double-blind, placebo-controlled trial a compounded gel containing 10 mg of baclofen, 40 mg of amitriptyline, and 20 mg of ketamine (BAK-PLO) was investigated compared with an identical-appearing placebo gel.[71] The primary end point was change in sensory neuropathy subscale as measured by the EORTC QLQ-CIPN20 instrument, which includes sensory, motor, and autonomic subscales from baseline to 20 weeks. A trend toward improvement was found in the sensory subscale ($p = 0.053$) as well as in the motor subscale ($p = 0.021$). The improved symptoms included tingling and shooting or burning pain in the fingers and hands and the ability to a hold a pen. A significant difference between the two treatment arms in the Brief Pain Inventory score and the CTCAE grade was not found.

CONCLUSION

Historically the acute and chronic toxicities of radiotherapy and chemotherapy for patients with NSCLC and SCLC were not considered to be clinically relevant. Consequently the majority of the data on the frequency and severity of neurotoxicity was retrospective. However, with improved survival and an increased number of treatment options for lung cancer patients the impact of these toxicities has become more apparent and relevant. This has led to the development of clinical trials that prospectively assess neurologic toxicity. Many chemotherapy and radiotherapy trials are investigating treatment agents or radiotherapy techniques that may reduce the risk of neurologic toxicity. Several prospective studies have investigated preventive agents and assessed the efficacy of symptomatic treatments for neurologic toxicity.

Frontline Systemic Therapy Options in Nonsmall Cell Lung Cancer

Suresh S. Ramalingam, Rathi N. Pillai, Niels Reinmuth, and Martin Reck

SUMMARY OF KEY POINTS

- The determination of tumor histology in nonsmall cell lung cancer (NSCLC) has become essential in treatment decision-making due to differential efficacy and toxicities seen with newer therapies.
- International Association for the Study of Lung Cancer (IASLC) guidelines recommend testing all patients with lung adenocarcinoma for both *EGFR* mutations and *ALK* rearrangements.
- Further molecular profiling of both adenocarcinoma and squamous cell lung cancers has identified novel driver mutations that are being investigated as potential targets of new therapies.
- Platinum doublet chemotherapy is the established standard first-line therapy in patients with advanced or metastatic NSCLC.
- The duration of platinum-based first-line therapy should be four to six cycles.
- Triple drug chemotherapy in NSCLC does not improve survival and often results in increased toxicity.
- *ERCC1* and *RRM1* have not been useful as predictive biomarkers for selection of chemotherapy based on prospective randomized clinical trials.
- Bevacizumab has been approved in combination with chemotherapy for the first-line therapy of patients with advanced NSCLC with nonsquamous histologies. Other antiangiogenic therapies in NSCLC have been disappointing.
- Patients with activating mutations in *EGFR* benefit from upfront therapy with EGFR tyrosine kinase inhibitors.
- Patients with *ALK* rearrangements can be successfully treated with ALK inhibitors, such as crizotinib.
- For patients with tumor PDL-1 expression >50%, pembrolizumab, an immune checkpoint inhibitor, is superior to platinum-based chemotherapy.
- Elderly patients with advanced NSCLC benefit from combination chemotherapy; selection of appropriate patients is vital.
- Patients with borderline performance status can also benefit from combination chemotherapy; patient selection requires careful consideration of comorbidities.

Lung cancer presents at an advanced stage at the time of diagnosis in the majority of patients. The overall goals of treatment for advanced stage disease are palliation and improvement in survival. Local treatment modalities such as radiotherapy and surgery play a limited role and are implemented primarily for symptom control. Systemic therapy remains the principal

therapeutic modality for advanced stage nonsmall cell lung cancer (NSCLC). Until the late 1990s, treatment of advanced lung cancer followed the straightforward algorithm of platinum-based combination therapy, irrespective of histologic subtype, without any option for further lines of treatment. With the introduction of so-called third-generation cytotoxic drugs, the treatment of NSCLC changed and overall survival improved to approximately 8 months for patients with a good performance status. In the past two decades, there has been a gradual shift in therapy from the use of systemic chemotherapy in all patients, to the current approach in which histology and molecular status play a key role in treatment selection (Fig. 44.1). This has been made possible by greater insights into lung cancer biology, the availability of novel therapeutic agents, and the increasing focus on identification of biomarkers to guide therapy.[1] As a result, while a cure from advanced NSCLC still remains elusive, a significant subset of patients has long-term survival and an improved quality of life.

PROGNOSTIC FACTORS IN NONSMALL CELL LUNG CANCER

The assessment of prognosis is an important factor affecting the selection of appropriate treatment for each individual patient. The variables that are associated with prognosis can be grouped into categories: tumor-related, such as primary site, histology, and extent of disease; patient-related, such as performance status, comorbidity, and sex; and environmental factors, such as nutrition and the choice and quality of treatment.

Clinical Factors

Performance status and comorbid conditions are amongst the most important prognostic factors. Moreover, these determinants are also of utmost importance for the selection of therapy, as outlined later. The systematic determination of comorbidities is an essential component to preselect appropriate chemotherapy regimens and to provide the best supportive care.

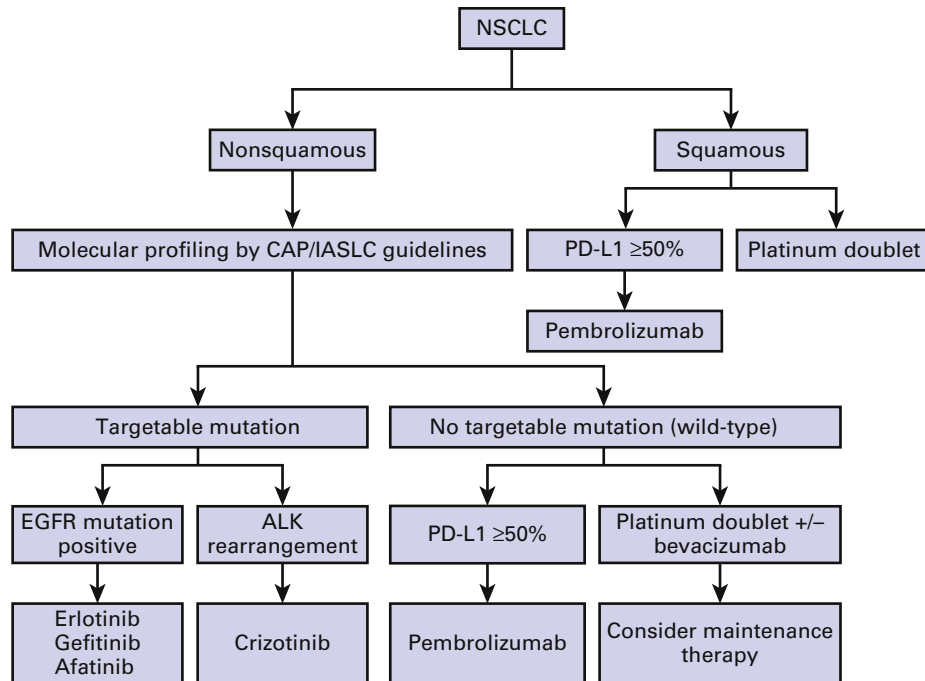
In addition to noncancer-related comorbidities, patients also suffer from symptoms related to the primary tumor, mediastinal spread, or paraneoplastic syndromes. Moreover, lung cancer commonly produces systemic effects such as anorexia, weight loss, weakness, and profound fatigue. In a study of 12,428 NSCLC patients in the international staging database of the International Association for the Study of Lung Cancer (IASLC), performance status, age, and gender appeared to be independent prognostic factors for survival in addition to clinical stage.[2] In advanced NSCLC, some routine laboratory tests (mainly white blood cells and hypercalcemia) were also found to be significant prognostic variables. Nowadays, the clear majority of lung cancer cases are diagnosed in patients aged >65 years.[3] Age at diagnosis is another important factor that needs to be considered for therapy decision making. Often, increasing age is accompanied by multiple comorbidities, which further limit therapeutic options and outcome of the patient.


Fig. 44.1. Treatment algorithm for treatment-naive NSCLC. *ALK,* anaplastic lymphoma kinase; *EGFR,* epidermal growth factor receptor; *IASLC,* International Association for the Study of Lung Cancer; *NSCLC,* nonsmall cell lung cancer.

Ethnicity

While lung cancer remains a leading cause of mortality for all races, recent research has focused on ethnic variations in this disease. One of the most striking disparities seen is the difference in lung cancer risk and survival for African and Asian ethnicities. For example, the epidermal growth factor receptor (*EGFR*) mutation rate differs considerably between various ethnicities. Epidemiologic research has focused on behavioral, cultural, and socioeconomic factors that may influence risk, although no clear link has been established.[4] Access to care is also variable among various ethnic groups and remains an important barrier to the delivery of optimal therapy.

Tumor Stage

The anatomic extent of the disease, as described by the TNM classification, is the most important prognostic factor in NSCLC. The seventh edition of the TNM classification that came into effect in 2010 derived from the analysis of the largest database ever generated for this purpose, with data from 46 sources in more than 19 countries around the world and with information about patients treated with all modalities of care.[5,6] An important change involved the recognition that patients with extrathoracic disease have a slightly less favorable outcome compared with patients with metastatic spread confined to the thorax, even within the stage IV category. This has resulted in the division of stage IV to M1a and M1b based on the presence or absence of extrathoracic metastasis. It has also been recognized that malignant pleural or pericardial effusions portend a particularly poor prognosis among those with stage IV disease. In recognition of the importance of this, malignant effusions were moved from stage IIIB to IV disease in the seventh edition.

With additional cases analyzed in this international database, there will be further changes to the TNM classification system forthcoming in the eighth edition.[7] The increased importance of T stage in prognosis has resulted in upstaging of tumors greater than 5 cm to T3 and those greater than 7 cm to T4. There will also be a new staging grouping, IIIC, created for patients with N3 nodal involvement and T3 or T4 primary tumors, to reflect the worse prognosis of these most locally advanced tumors. Finally, within metastatic disease, patients with a solitary metastasis in a single extrathoracic organ will be classified as M1b. Presence of oligometastases merits consideration of local therapies in addition to systemic therapy. These patients have similar survival to patients classified as M1a with lung, pleural or pericardial involvement and will share the stage IVA designation. The majority of metastatic patients who present with multiple metastatic lesions will be considered M1c disease and will be characterized as stage IVB.

Histology

The distinction between squamous and nonsquamous histology was the first step in the personalized treatment of patients with advanced NSCLC. Hence, accurate diagnosis of tumor histology has become essential in treatment decision-making and can impact considerations of both toxicity and potential efficacy of selected agents used in the management of this disease. For example, the use of the anti–vascular endothelial growth factor (VEGF) antibody bevacizumab is associated with a higher risk of pulmonary bleeding when used in patients with predominantly squamous cell histology. Also, the cytotoxic drug pemetrexed was found to be inactive in patients with squamous NSCLC. Therefore, the classification of NSCLC into the major categories of squamous cell carcinoma, adenocarcinoma, and large cell carcinoma is critical for treatment decisions. However, histologic subclassification of NSCLC remains a challenge for many reasons. The tumor is very heterogeneous in every aspect: pathology, presence of molecular alterations, radiographic appearance, clinical presentation, and response to systemic therapy. The initial diagnostic biopsies often have a limited amount of material that is inadequate to conduct necessary tests to identify histology and genotype. The availability of immunostains such as TTF-1, p63, and p40 has greatly improved the accuracy of histologic subclassification.

TABLE 44.1 Single-Agent Activity of Chemotherapy in Randomized Trials Comparing Monotherapy With Combination Chemotherapy

Cytotoxic Agent	Patients (n)	Response Rate (%)	Median Survival (months)	Reference (year)
Vinorelbine	206	14	7.2	Le Chevalier (1994)[11]
Irinotecan	129	21	10.6	Negoro (2003)[12]
Cisplatin	206	17	8.1	Gatzemeier (2000)[13]

Molecular Markers

NSCLC tumors often harbor mutations in a number of critical genes such as p53, K-RAS, and LKB-1. The prognostic relevance of these mutations continues to be defined for patients with advanced NSCLC. Certain markers have gained attention because they also harbor predictive value. For example, the presence of an activating *EGFR* mutation translates into both predictive and prognostic information. Patients with *EGFR* mutation have overall better outcomes compared with those with wild-type *EGFR*, and also derive robust benefits from specific therapeutic inhibitors of the EGFR pathway. Similarly, limited early evidence indicates that patients with abnormal anaplastic lymphoma kinase (*ALK*) gene rearrangement have higher risk of recurrence following surgery for early-stage disease and a higher clinical benefit with pemetrexed therapy. The prognostic role of *K-Ras* mutations in lung adenocarcinoma has been debated extensively. Earlier evidence suggested poor sensitivity to chemotherapy and overall prognosis with *K-Ras* mutation, but emerging recent data have failed to confirm this. *K-Ras* mutated patients appear to have a very low likelihood of objective response with *EGFR* inhibitors. The knowledge of the prognostic and predictive potential of various molecular markers is bound to increase significantly in the coming years as molecular testing is adopted to routine practice settings.

TREATMENT OF ADVANCED NONSMALL CELL LUNG CANCER

Systemic Chemotherapy

Systemic chemotherapy prolongs survival and leads to symptom palliation compared with best supportive care alone for patients with advanced NSCLC.[8] Similar to therapeutic developments for other solid tumors, the efficacy of a variety of cytotoxic agents has been tested in both preclinical and clinical studies in NSCLC in the last decades. Initial results on single-agent therapy, including cisplatin (CDDP), ifosfamide, vinblastine, vindesine, etoposide, and mitomycin-C, indicated limited activity leading to objective response rates of ≤15% and median response durations of 2 months to 3 months. However, complete responses after these treatments were rare, and their benefit on median survival, with the exception of cisplatin, was inconsistent.[9] The relatively modest efficacy and the considerable toxicity of these cytotoxic agents led to considerable nihilism regarding the use of chemotherapy for NSCLC for many years. Starting in the mid-1980s, several novel cytotoxic drugs were evaluated in NSCLC, such as vinorelbine, paclitaxel, docetaxel, irinotecan, gemcitabine, and oxaliplatin, which showed response rates of 20% to 25% (Table 44.1).[10]

Combinations of various agents have also been evaluated in patients with NSCLC. Two meta-analyses showed a clear significant survival advantage for a two-drug regimen versus monotherapy, but on the other hand also demonstrated a significant increase in hematologic and nonhematologic side effects.[22,23]

Among several combinations, platinum-based chemotherapy was shown to lead to higher response rates and prolonged survival in comparison with monotherapy, albeit with the cost of increased toxicity.[8] Given the limited availability of supportive care for chemotherapy-related toxicities in the early 1990s, the use of chemotherapy in patients with metastatic NSCLC was still under debate despite the consistent evidence for its modest activity.

Platinum Compounds

Platinum compounds form DNA adducts, which ultimately result in activation of p53-dependent and p53-independent apoptosis.[24] As monotherapy, cisplatin has anticancer activity comparable with that of other single agents, leading to response rates of approximately 15% and a median survival of 6 to 8 months.[21] In order to increase the efficacy of systemic treatment, several combination regimens have been extensively studied (Table 44.2). Several randomized trials as well as meta-analyses provided scientific evidence that platinum-based combination therapy prolonged the survival of patients with advanced NSCLC. In 1995, a meta-analysis using updated data on 1190 patients with advanced NSCLC from 11 randomized clinical trials was published. The results, updated in 2008, demonstrated a 27% reduction in the risk of death for patients treated with cisplatin-containing regimens compared with supportive care alone, which translated to an absolute improvement in survival of 10% (5% to 15%) at one year.[8]

Compared with older regimens such as cisplatin with vindesine or vinblastine, cisplatin and mitomycin-C with vinblastine or vindesine, or cisplatin with etoposide, combinations of cisplatin with newer drugs (referred to as third-generation drugs: gemcitabine, taxanes, vinorelbine, topoisomerase I inhibitors) seem to exert somewhat higher efficacy and improved tolerability. For example, compared with platinum–gemcitabine combinations, several studies indicated inferior response rates, time to progression, and median overall survival (OS) for cisplatin, ifosfamide and mitomycin,[30] cisplatin and vindesine,[31] or cisplatin and etoposide regimens.[32] Hematologic toxicity, especially thrombocytopenia, was pronounced in the gemcitabine-platinum groups whereas nonhematologic side effects appeared more frequently in the "classic" arms.[30–32] Moreover, Le Chevalier et al.[33] showed a significantly better response rate and survival for cisplatin–vinorelbine compared with cisplatin–vindesine.

The choice of the newer agent (gemcitabine, paclitaxel, or vinorelbine) that is combined with cisplatin does not seem to significantly affect the treatment efficacy (see Table 44.2). For instance, phase III studies (e.g., Southwest Oncology Group [SWOG] 9509) failed to demonstrate superiority of carboplatin–paclitaxel over cisplatin–vinorelbine in 408 patients.[25] Similarly, the Italian Lung Cancer Study Group failed to detect any significant difference in outcome for cisplatin–gemcitabine, carboplatin–paclitaxel, and cisplatin–vinorelbine in 612 patients with previously untreated advanced NSCLC.[26] However, both studies

demonstrated differences between these regimens regarding their toxicity profiles. In the largest study that included 1207 patients (Eastern Cooperative Oncology Group [ECOG] 1594), Schiller et al.[27] found no significant efficacy differences among the regimens cisplatin–paclitaxel, cisplatin–gemcitabine, cisplatin–docetaxel, and carboplatin–paclitaxel regarding response rates (17% to 22%) and median survival (7.4–8.1 months).[27] Differences were only noted in toxicity profiles, with cisplatin–gemcitabine causing more thrombocytopenia, cisplatin–docetaxel causing more neutropenia, and the carboplatin–paclitaxel arm experiencing the lowest rate of potentially life-threatening toxicities. Another phase III study (TAX 326) randomized 1218 patients to receive cisplatin–docetaxel, carboplatin–docetaxel, or the control arm of cisplatin–vinorelbine. Patients treated with cisplatin–docetaxel had a higher response rate (31.6% vs. 24.5%, $p = 0.029$) and median survival (11.3 vs. 10.1 months, $p = 0.044$).[28] Based on these observations, platinum-based chemotherapy remains the standard therapy in advanced or metastatic NSCLC. With the current combination partners, a plateau of efficacy has been reached.

Cisplatin Versus Carboplatin

Carboplatin is another platinum derivate with a tenfold longer half-life than cisplatin. Due to structural differences from cisplatin, it exhibits lower reactivity and slower DNA binding kinetics in vitro. In clinical studies, the nonhematologic tolerability of carboplatin is superior to that of cisplatin, making it a more convenient platinum analog for palliative chemotherapy.

Several studies have compared the efficacy of cisplatin with carboplatin in the management of advanced NSCLC. Rosell et al.[34] reported a significantly improved survival for cisplatin–paclitaxel compared with carboplatin–paclitaxel with a higher rate of nonhematologic side effects in the cisplatin arm and a higher rate of neutropenia and thrombocytopenia in the carboplatin arm.[34] In the TAX 326 trial, there was a nonsignificant trend toward improved survival for the combination of cisplatin–docetaxel over carboplatin–docetaxel.[28] In contrast, the ECOG 1594 trial noted similar survival duration between the cisplatin and carboplatin-based treatment arms. However, there was a lower incidence of nonhematologic events such as nausea, vomiting, nephrotoxicity, and neurotoxicity with carboplatin-based therapy.[27] This observation has also been made in other smaller trials[21] with carboplatin-based regimens.

A meta-analysis using data from eight trials demonstrated that cisplatin-based chemotherapy offered a significantly higher objective response rate compared with carboplatin-based chemotherapy (odds ratio [OR], 1.36; 95% confidence interval [CI], 1.15 to 1.61; $p = 0.001$) and a nonsignificant improvement in survival (hazard ratio [HR], 1.050; 95% CI, 0.907 to 1.216; $p = 0.515$).[35] In this meta-analysis, a subgroup analysis of the five trials that incorporated cisplatin or carboplatin with a new agent identified a significantly superior median survival for cisplatin-treated patients (HR, 1.106; 95% CI, 1.005–1.218; $p = 0.039$). These data were confirmed by another meta-analysis including 2968 patients from nine trials.[36] Cisplatin-treated patients experienced a significantly higher response rate (OR, 1.37; 95% CI, 1.16–1.61; $p < 0.001$). Moreover, cisplatin-based treatment was associated with an improved median OS relative to treatment with carboplatin (9.1 versus 8.4 months; HR, 1.07; 95% CI, 0.99–1.15; $p = 0.1$) that was significant in subgroup analyses for patients with nonsquamous tumors (HR, 1.12; 95% CI, 1.01–1.23) and those treated with third-generation chemotherapy (HR, 1.11; 95% CI, 1.01–1.21). However, cisplatin-based chemotherapy was associated with more severe nausea, vomiting, and nephrotoxicity while severe thrombocytopenia was more frequent during carboplatin-based chemotherapy.[36] Hence, the selection of the platinum compound should be made based on the regimen most likely to result in the best therapeutic index. In recent years, the availability of effective antiemetic agents has improved the therapeutic index of cisplatin-based regimens.

Triplets for Advanced NSCLC

To further increase the efficacy of systemic therapy in advanced NSCLC, a series of studies have evaluated the potential role for the use of three-drug regimens. These studies have consistently demonstrated that three-drug regimens are associated with higher toxicity, have at times higher objective response rates, but offer no statistically significant improvement in survival as compared with that offered by standard doublets (Table 44.3). For example, a phase III trial of 557 stage IIIB/IV NSCLC randomized patients to receive cisplatin–gemcitabine for six cycles, cisplatin–gemcitabine–vinorelbine for six cycles, or three cycles of gemcitabine–vinorelbine followed by three cycles of vinorelbine–ifosfamide.[37] Response rates were inferior for the nonplatinum sequential doublet while no differences in median survival or time to progression were observed. Predictably, toxicity was

TABLE 44.3 Two Drugs Compared With Three Drugs in NSCLC

Doublet Chemotherapy	Triplet Chemotherapy	Response Rate (%)	Grade 3–4 Neutropenia	Grade 3–4 Thrombocytopenia	Grade 3–4 Nausea/ Vomiting

Cisplatin/gemcitabine or gemcitabine/ vinorelbine[38]	Cisplatin/ifosfamide/ gemcitabine or gemcitabine/ifosfamide/ vinorelbine	29 vs. 28	36 vs. 44	16 vs. 20	8 vs. 7

NSCLC, Nonsmall cell lung cancer.

significantly higher for the triplet regimen. Similarly, a recent phase II study found no statistically significant difference between doublet (cisplatin–gemcitabine or gemcitabine–vinorelbine) and triplet (cisplatin–ifosfamide–gemcitabine, or gemcitabine–ifosfamide–vinorelbine) combinations; however, grade 3–4 leukopenia was significantly more common in triplets.[38]

In a systematic overview, third generation triplet therapy had a significantly higher response rate (OR, 1.33; 95% CI, 1.50–2.23; $p < 0.001$) compared with standard doublet therapy;[39] however, median survival (MR, 1.10; 95% CI, 0.91–1.35; $p = 0.059$) was not statistically different and the incidence of grades 3–4 hematologic toxicity, neuropathy, and diarrhea was significantly increased with triplet therapy. Based on these results, platinum-based doublet chemotherapy remains the standard first-line treatment for patients with metastatic NSCLC.

Platinum-Free Versus Platinum-Based Chemotherapy

In daily practice, several types of patients with advanced NSCLC are not optimal candidates to receive platinum-based chemotherapy due to the presence of certain comorbid conditions such as renal insufficiency, borderline performance status (PS), or preexisting sensory neuropathy. Hence, studies were conducted to evaluate whether the combination of two newer chemotherapeutic agents may be better suited for first-line therapy. In some earlier studies, a trend toward a higher survival was observed in patients treated with platinum-based combinations compared with those treated with platinum-free regimens.[21,40,41] In a recent phase II study, a total of 433 stage IIIB–IV NSCLC patients received cisplatin–gemcitabine, gemcitabine–vinorelbine, cisplatin–ifosfamide–gemcitabine, or gemcitabine–ifosfamide–vinorelbine.[38] Platinum-based regimens had a significantly longer overall survival (11.3 vs. 9.7; $p = 0.044$) compared with the other treatment arms but also resulted in higher incidence of grade 3–4 toxicity. In a meta-analysis based on abstracted data from randomized phase II and III studies, D'Addario et al.[42] observed a significantly higher 1-year survival rate for platinum-based combinations compared with the nonplatinum regimens (34% vs. 29%; OR, 1.21; 95% CI, 1.09–1.35; $p = 0.0003$). However, when single-agent trials were excluded and platinum-based therapies were compared with third-generation–based combination regimens only, no statistically significant difference could be found (1-year survival, 36% for platinum regimens vs. 35% for nonplatinum regimens). In a more recent systematic review of randomized controlled trials comprising 4920 patients, the use of cisplatin-based doublet regimens was associated with a higher 1-year-survival rate (Hazard Ratio (HR), 1.16, 95% CI, 1.06–1.27; $p = 0.001$) compared with nonplatinum regimens, but also with an increased risk of anemia, neutropenia, neurotoxicity, and nausea.[43] Conversely, carboplatin-based doublet regimens were associated with a similar 1-year survival rate (HR = 0.95, 95% CI, 0.85–1.07; $p = 0.43$) to that of nonplatinum doublets. Taken together, nonplatinum regimens do not have a clearly defined role in NSCLC and are only considered appropriate for patients that are not candidates for platinum agents.

Duration of Chemotherapy

The commonly used NSCLC chemotherapy regimens are administered in 3- or 4-week cycles. Imaging studies are recommended every two to three cycles to assess response to therapy. For patients that achieve an objective response or stable disease, the number of cycles of therapy has been a subject of several randomized studies. Socinski et al.[44] randomized advanced NSCLC patients to treatment with the combination of carboplatin and paclitaxel for either four cycles or to continuation of therapy until disease progression. Interestingly, the median number of treatment cycles administered in both arms was four. There was no statistically significant improvement in OS for the extended chemotherapy approach. Predictably, toxicity was more common with administration of chemotherapy beyond four cycles. Another study by Smith et al.[45] that compared three cycles of chemotherapy with six cycles also found no improvement in OS with the latter. In a systematic meta-analysis including 13 randomized control trials, 3027 patients receiving first-line (largely platinum-based) chemotherapy for three to four cycles were compared with patients with continuation of the same chemotherapy for six cycles or until disease progression.[46] While extending chemotherapy substantially improved progression-free survival (PFS; HR, 0.75; 95% CI, 0.69–0.81; $p < 0.00001$), there was a statistically significant, but clinically only modest reduction in the hazard for death as compared with standard duration of chemotherapy over three to four cycles (HR, 0.92; 95% CI, 0.85–0.99; $p = 0.03$). Moreover, extension of chemotherapy was associated with higher toxicity and impaired quality of life. These findings were confirmed in a recent systematic review and meta-analysis of randomized trials comparing six versus fewer cycles of only platinum-based chemotherapy that had individual patient data available for analysis.[47] While an improvement in PFS was observed in the four eligible studies with 1139 patients (HR 0.79; 95% CI, 0.68–0.90; $p = 0.0007$), there was no overall survival benefit to receipt of six cycles of platinum-based chemotherapy (median 9.54 months versus 8.68 months with fewer cycles; HR 0.94; 95% CI, 0.83–1.07; $p = 0.33$). This was independent of histology, sex, performance status, and age. Hence, most guidelines recommend limiting the duration of platinum-based first-line therapy to four to six cycles and prefer considering the induction of maintenance therapy.

Maintenance Therapy

After four to six cycles of first-line or induction chemotherapy, approximately two-thirds of patients have nonprogressive disease. Continuation of first-line platinum-based combination regimens beyond four to six cycles results in heightened toxicities and diminished quality of life without providing a major survival advantage.[44,46] Thus, the standard therapeutic approach has entailed stopping treatment at that point, close clinical and radiographic surveillance, and initiation of second-line treatment at the time of progression. This "wait and watch" approach is frequently chosen after achieving maximal response to initial therapy. However, a "drug holiday" is often associated with patient

anxiety about disease recurrence or progression coupled with concerns for clinical deterioration and the inability to receive subsequent therapy.

The availability of effective newer cytotoxic and molecularly targeted agents with overall good tolerability and low toxicity profile has led to the concept of maintenance therapy in order to maintain or improve the disease burden after completion of first-line therapy. Maintenance therapy involves either switching to a different compound (switch maintenance) or continuation of one drug partner of the induction regimen (continuation maintenance) in patients with a response or at least stabilization of disease.[48] The role of maintenance therapy is discussed extensively in Chapter 46.

IMPORTANCE OF HISTOLOGY IN THE TREATMENT OF NSCLC

NSCLC includes many histologic subtypes including adenocarcinoma, squamous cell carcinoma, and large cell carcinoma, all of which have diverse clinical behaviors. Until a few years ago, all histologic subtypes of NSCLC were treated with similar systemic therapy regimens. Though distinct differences in sites of metastasis, OS, and smoking behavior were recognized, there was no specific reason to use histology for selection of systemic therapy. The importance of distinguishing histology of NSCLC was realized with the development of new therapies that resulted in different toxicities and outcomes based on the histology. This effect was first realized in the phase II study of bevacizumab; the risk of pulmonary hemorrhage was predominantly seen in patients with squamous histology.[49] Bevacizumab was subsequently restricted to patients with predominant non-squamous histology. Several other antiangiogenic agents have also demonstrated a higher risk of bleeding with squamous histology, thus defining this as a class effect.

Pemetrexed was the first cytotoxic agent that has shown a clear correlation between histology and efficacy. Scagliotti et al.[1] conducted a phase III study to compare the efficacy of cisplatin and pemetrexed with that of cisplatin and gemcitabine for patients with advanced NSCLC. The OS and PFS were similar for the study population, which included approximately 1700 patients. A preplanned subset analysis was conducted to study the outcomes for patients with nonsquamous histology. This revealed a significant improvement in survival for nonsquamous patients with the cisplatin-pemetrexed regimen (11.8 months vs. 10.4 months). Conversely, the cisplatin–gemcitabine regimen was superior in patients with squamous cell histology. Based on this study, and similar observations from other studies with pemetrexed, this agent is not considered appropriate for the treatment of squamous cell lung cancer.

In contrast, nab-paclitaxel, an albumin-bound formulation of paclitaxel, benefits patients with squamous cell lung cancer preferentially over nonsquamous tumors. In a phase III study of weekly nab-paclitaxel with carboplatin compared with standard paclitaxel and carboplatin given every 3 weeks, comparable OS was noted for the two regimens.[50] The response rate was superior with nab-paclitaxel regimen for the overall patient population (32% vs. 25%). The response rate was higher with nab-paclitaxel in patients with squamous histology (response rate ratio 1.6890, 95% CI, 1.271–2.221, $p < 0.001$). There was no difference in overall response rate (ORR) in patients with nonsquamous histology between the two regimens (26% with nab-paclitaxel versus 25% with paclitaxel, $p = 0.808$). Nab-paclitaxel is a Food and Drug Administration approved therapy for advanced NSCLC in combination with carboplatin. It has the advantage of not requiring premedications needed with the standard formulation of paclitaxel. It is also associated with a lower incidence of grades 3–4 neuropathy compared with paclitaxel. The biologic reasons

behind the correlation between histology and efficacy of pemetrexed and nab-paclitaxel are not known, and some exploratory hypotheses are described in a subsequent section of this chapter.

MANAGEMENT OF ELDERLY PATIENTS

In the United States, patients aged more than 65 years represent two-thirds of the lung cancer cases, and the median age at diagnosis is >70 years. Furthermore, nearly 15% of patients are over the age of 80 years at diagnosis.[51] A number of physiologic functions, especially renal and hematopoietic functions, are altered with ageing that impact on chemotherapy tolerance and toxicity.[51] Furthermore, elderly patients have more comorbid conditions compared with younger ones and are more likely to take prescription medications for other ailments, which may interfere with the pharmacokinetic disposition of anticancer agents.[52–54] Comorbid conditions can be evaluated using the Charlson Comorbidity Index,[55] or by the more detailed Cumulative Illness Rating Scale-Geriatric.[56] In a Veterans Affairs Central Cancer Registry containing 20,511 NSCLC cancer patients from 2003 to 2008, the percentage of patients receiving guideline-recommended chemotherapy treatment decreased with increasing age.[57] In an analysis of the SEER-Medicare database in the United States, only about 25% of the older patients received systemic chemotherapy for advanced stage disease.[58] Furthermore, platinum-based regimens were given to less than 25% of the patients that received chemotherapy.

Until recently, the majority of the treatment recommendations for chemotherapy in elderly NSCLC patients were based on subset analyses of outcomes for elderly patients included in clinical trials for all patient age-groups. Elderly patients in these studies were likely to be highly selected based on functional status and might not be representative of the older patient population "at-large." Moreover, there is a wide variation between studies regarding the definition of older patients across clinical trials. In earlier studies, age >65 years was often used to define older patients. In recent trials, >70 years has become the threshold for elderly patient-specific trials. Another noteworthy aspect is that many studies in the general lung cancer population limit entry to patients <75 years of age. For all these reasons, treatment decisions for older patients should be made based on available data, patient preferences, comorbid illness, and molecular status.

The role of chemotherapy exclusively in older patients was established in a phase III study that demonstrated superiority for vinorelbine over best supportive care (ELVIS study).[59] The survival improvement was observed despite early closure of the study due to slow accrual and the fact that the necessary sample size had not been met. This was the first elderly patient–specific study in lung cancer to define the role for chemotherapy in advanced stage disease. Subsequently, a study that compared the combination of gemcitabine with vinorelbine versus both revealed no therapeutic advantage for the combination.[60] These studies led to the adoption of single-agent chemotherapy as the standard approach for older lung cancer patients.

The role of combination regimens in older patients was not defined until recently. Subset analysis from a number of randomized trials demonstrated that outcomes for older patients enrolled in clinical trials were similar to that of younger individuals.[61–63] In a study reported by Lilenbaum et al.,[20] treatment with carboplatin and paclitaxel was associated with an increase in response and survival compared with single-agent therapy with paclitaxel, but the differences did not reach statistical significance. A benefit of similar magnitude was observed for the combination compared with monotherapy in a subgroup analysis of patients >70 years, and there was no significant difference in survival between elderly patients and younger patients with carboplatin–paclitaxel. However, in a combined analysis of two SWOG trials, elderly patients (above 70 years) treated with platinum-based combinations had a

TABLE 44.4 Phase III Trials Including Elderly Patients With Advanced NSCLC

Author (year)	Number of Patients	Median Age (y)	Drugs	Response Rate (%)	Median Survival (Months)	1-Year Survival Rate (%)	p

shorter survival (7 months versus 9 months; (*p* = 0.04) and experienced more frequent grade 3–5 neutropenias compared with younger patients.[64]

Most studies addressing directly the benefit of chemotherapy to elderly patients demonstrated a survival benefit to some extent for patients treated with the more aggressive therapy arm (Table 44.4).[52] In a recent phase III study by Quoix et al.,[65] 451 patients aged 70–89 years with locally advanced or metastatic NSCLC and WHO performance status scores of 0–2 received either four cycles of carboplatin/paclitaxel or five cycles of vinorelbine or gemcitabine monotherapy.[65] Second-line treatment was defined to be erlotinib for both arms. The study population had a median age of 77 years. The median OS was significantly superior for doublet chemotherapy (10.3 versus 6.2 months; HR 0.64, 95% CI, 0.52–0.78; *p* < 0.0001). The combination regimen was also associated with more hematologic and nonhematologic toxicity including neutropenia (48.4% vs. 12.4%) and asthenia (10.3% vs. 5.8%). This is the first prospective trial for elderly patients that demonstrated a survival benefit for combination chemotherapy. It is noteworthy that the study utilized a weekly schedule of paclitaxel with administration of carboplatin every 4 weeks, which appears to have a slightly favorable tolerability over the standard 3-weekly schedule. It is evident from this cumulative evidence that elderly patients with a good performance status are appropriate candidates for platinum-based chemotherapy. Also, consideration for primary prophylaxis with granulocyte colony stimulating factor might be appropriate for certain combination regimens in elderly patients.[66] Given the potential detrimental effects of cisplatin on the kidneys and other end organs in older subjects, carboplatin-based regimens are preferred for the treatment of advanced NSCLC. For less fit patients, monotherapy might be suitable;[67] however, one needs to balance possible benefits and risk followed by discussion with the patients about the role of chemotherapy.

MANAGEMENT OF PATIENTS WITH A POOR PERFORMANCE STATUS

The performance status (PS) of the patient is an important prognostic factor in lung cancer. An ECOG PS of 2, alternatively termed "marginal PS" or "poor risk," is defined as being "ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours."[70] The designation of PS remains subjective, as evidenced by the discordance between physician assessments of performance status versus self-assessment by patients.[71] Physicians tend to overestimate the performance status of patients in general.

Subset analyses of trials for patients with advanced NSCLC with eligibility ranging from PS 0 to 2 have historically shown that PS 2 patients experience a much shorter survival.[65,72,73] Some studies have pooled PS 2 patients with the elderly, most commonly defined as being older than 70 years of age. Though decline in PS is often related to high disease burden related to lung cancer, it should be distinguished from poor PS related to comorbid illness. Until now, studies conducted in older patients have not adequately made this distinction, which makes it difficult to recommend aggressive therapies for those with poor PS. In recent years, several studies have been conducted exclusively for patients with a poor PS. The combination of carboplatin and paclitaxel was superior to single-agent paclitaxel (median survival of 4.7 vs. 2.4 months) in PS 2 patients in a prospectively specified subgroup analysis for patients with poor PS that were enrolled to the Cancer and Leukemia Group B (CALGB) trial.[20] In another study for patients with a poor PS, the combination of carboplatin and paclitaxel was superior to single-agent therapy with erlotinib (9.7 months compared with 6.5 months with erlotinib).[20,74] In a recent phase III trial for advanced NSCLC patients, patients with PS 2 were randomly assigned to a combination therapy of carboplatin–pemetrexed or pemetrexed alone.[75] PS was determined by the treating physician and verified by another physician at each participating site. There was a statistically and clinically significant improvement with the doublet in response rate (23.8% vs. 10.3%; *p* = 0.032), progression-free survival (median, 5.8 vs. 2.8 months; HR, 0.46; 95% CI, 0.35–0.63; *p* < 0.001), and OS (median, 9.3 vs. 5.3 months; HR, 0.62; 95% CI, 0.46–0.83; *p* = 0.001). However, toxicity was also higher in the combination arm, with more treatment-related deaths (3.9% vs. 0%). This was the first prospective study to demonstrate benefit from platinum-based therapy in patients with poor PS. Future trials should address the impact of comorbid conditions versus cancer burden as the reason behind decline in PS for patients and its correlation to outcome with combination therapies.

Taking the recent data into account, patients with heavy disease burden and poor PS may also be offered combination therapy. As with any clinical decision, therapy selection is utterly dependent on the patient preference and physician judgment throughout the process of selecting palliative chemotherapy in the setting of advanced NSCLC. Molecular testing is strongly recommended even in patients with a poor PS, since the use of appropriate targeted therapy in selected patients has been reported to result in robust responses and improved physical function.[76]

BIOMARKERS FOR SELECTION OF CHEMOTHERAPY

The use of biomarkers to select appropriate chemotherapy regimens has long been a focus of research. Lung cancer cells have a relative deficiency of DNA repair machinery compared with normal cells; this makes them more sensitive to the DNA

damaging effects of cytotoxic chemotherapy.[77] Somatic excision repair cross-complementing gene 1 (*ERCC1*) has been evaluated as a prognostic and predictive biomarker of response to treatment with platinum agents. Ribonucleotide reductase M1 (*RRM1*) is the catalytic subunit of ribonucleotide reductase, which converts ribonucleoside diphosphates into deoxyribonucleosides in DNA synthesis.[78] Since RRM1 is the primary target of gemcitabine, it has been studied as a predictive biomarker for efficacy of gemcitabine.

A randomized phase III study was conducted to utilize *ERCC1* expression to personalize therapy in NSCLC.[79] The hypothesis was to treat patients with *ERCC1*-overexpressing tumor with nonplatinum regimens and those with low *ERCC1* expression with platinum-containing regimens; 82.4% of patients randomized had adequate tissue for *ERCC1* mRNA expression analysis; 444 patients with stage IIIB or IV NSCLC were then randomized in a 2:1 ratio to the genotypic arm, where patients were treated according to their *ERCC1* status (*ERCC1* low patients with cisplatin and docetaxel and *ERCC1* high patients with gemcitabine and docetaxel) or to the control arm, where all patients received cisplatin and docetaxel irrespective of biomarker status. The study achieved its primary end point of improvement in response rate with 50.7% in the genotypic arm compared with 39.3% in the control arm ($p = 0.02$). However, since there was no significant improvement in survival in the genotype arm, this limited the utility of *ERCC1* as a predictive biomarker. In another recently published phase III study, treatment was assigned based on tumoral expression of ERCC1 and RRM1 for patients with chemotherapy-naive advanced NSCLC. ERCC1 and RRM1 expression were determined by an automated quantitative analysis (AQUA) based on immunohistochemistry.[80] Out of 275 eligible patients, 183 were randomized to the customized approach and 92 patients to control. There was no difference between the two groups in the primary end point of PFS, or the secondary outcomes of OS or response rate (11 months and 36.5% with customized therapy vs. 11.3 months and 38.8% in control arm, $p = 0.66$ for survival). In addition to these disappointing results, problems regarding the sensitivity of the antibodies used for detection of ERCC1 expression have recently been observed.[81]

Pemetrexed exerts anticancer effects by inhibiting thymidylate synthase (TS), dihydrofolate reductase, and glycinamide ribonucleotide formyl transferase.[82] TS is an enzyme that converts deoxyuridylate to deoxythymidylate that is necessary for DNA synthesis. Since TS is the main target of pemetrexed, low levels of TS have been hypothesized to predict increased response rate to pemetrexed therapy. In a study of 56 patients with NSCLC, TS mRNA and protein levels were higher in patients with squamous cell carcinoma.[83] TS levels may explain why patients with squamous cell histology are resistant to pemetrexed compared with adenocarcinoma histology, though this remains to be confirmed.

Taxanes bind to β-tubulin and lead to stabilization of microtubules, resulting in apoptosis. High levels of β-tubulin have been associated with resistance to treatment with docetaxel and paclitaxel in cell lines.[84] In 91 patients with advanced NSCLC who were treated with paclitaxel (47) or nontaxane regimens (44), those with low expression of class III β-tubulin by immunohistochemistry (IHC) had improved response rates, PFS, and OS when treated with paclitaxel.[85] In a meta-analysis of 552 patients in 10 studies examining either paclitaxel or vinorelbine containing regimens, decreased expression of class III β-tubulin was associated with improved OS (HR, 1.40; $p < 0.00001$).[86] These observations have not been confirmed in prospective studies and the role of β-tubulin as a predictive marker for taxanes still remains unproven.

COMBINATION OF TARGETED AGENTS WITH PLATINUM-BASED CHEMOTHERAPY

The development of molecularly targeted agents has led to the evaluation of several novel compounds in combination with platinum-based chemotherapy for first-line treatment of advanced NSCLC. These studies were usually supported by supra-additive or synergistic preclinical interactions between these agents. However, the vast majority of these studies failed to demonstrate an improvement in survival with the addition of a targeted agent to standard chemotherapy. These studies were typically conducted in unselected patient populations and did not include efforts to identify predictive biomarkers. More recently, studies with novel combinations are focused on identifying a subset of patients that might derive robust benefits. The first combination strategy to demonstrate survival benefit was the addition of bevacizumab, a monoclonal antibody against the VEGF, to standard chemotherapy.

ANTIANGIOGENIC THERAPY

It has been widely observed that for tumor development and growth to proceed beyond a defined volume, the development of a new blood supply is necessary.[87,88] Therefore, most solid tumors need the formation of new blood vessels for continued growth and metastasis, which may be achieved by the induction of endothelial cell sprouting from the preexisting vasculature (so-called angiogenesis).[87,89,90] The monoclonal anti-VEGF antibody bevacizumab, which blocks the binding of VEGF to its high-affinity receptors, was the first angiogenesis inhibitor to complete clinical development and is currently the only antiangiogenesis agent approved for the treatment of lung cancer.

In a phase II trial in 99 unselected NSCLC patients, a higher response rate (31.5% vs. 18.8%), longer median time to progression (7.4 vs. 4.2 months), and a modest increase in survival (17.7 vs. 14.9 months) was observed for treatment with carboplatin and paclitaxel plus bevacizumab (15 mg/kg) compared with the chemotherapy control arm.[49] However, 9% of the patients treated with bevacizumab experienced life-threatening pulmonary hemorrhage (PH), which was fatal in four patients. Since the majority of the patients with hemoptysis had squamous cell histology, tumor cavitation, and disease location close to major blood vessels, these clinical situations were excluded in subsequent studies.

Two large clinical trials demonstrated efficacy of bevacizumab in combination with a platinum containing chemotherapy in patients with advanced NSCLC of nonsquamous histology, resulting in the FDA approval for this setting (Table 44.5).[91,92] In the ECOG 4599 study, a substantial clinical benefit for NSCLC patients treated with 15 mg/kg bevacizumab plus carboplatin and paclitaxel versus chemotherapy alone was seen (HR, 0.66 for PFS with a median of 6.2 vs. 4.5 months; HR, 0.79 for OS with a median of 12.3 vs. 10.3 months).[91] These results were partly confirmed by another large phase III trial where NSCLC patients had an improved PFS with the addition of low-dose bevacizumab (7.5 mg/kg; HR, 0.75 (0.64–0.87); $p = 0.0003$) or high-dose bevacizumab (15 mg/kg; HR, 0.85 (0.73–1.00); $p = 0.0456$) to a standard chemotherapy of cisplatin and gemcitabine.[92] In the later study, however, the median net gain of PFS was relatively modest with bevacizumab, and, more importantly, there was no improvement in OS (HR, 0.93; 95% CI, 0.78–1.11; $p = 0.42$ and HR, 1.03; 95% CI, 0.86–1.23; $p = 0.761$ for the 7.5 and 15 mg/kg groups, respectively).[93] As a result of these phase III trials in chemotherapy-naive NSCLC patients, bevacizumab has been approved for the treatment of advanced NSCLC, excluding predominantly squamous cell histology, in combination with platinum containing chemotherapy.

Bevacizumab and other antiangiogenic agents are associated with a low, but significant risk of grade ≥3 or fatal (grade 5) pulmonary hemorrhage. Two meta-analyses have found that the use of bevacizumab in combination with chemotherapy for the treatment of various tumor types conferred a significantly increased risk of severe and fatal bleeding events and treatment-related mortality versus chemotherapy alone.[94,95] However, patients

TABLE 44.5 Comparison of Phase III Studies of Platinum Doublet Therapy With Bevacizumab

	ECOG 4599[79]	AVAiL[92,93]
Regimen	Carboplatin/paclitaxel/± bevacizumab	Carboplatin/gemcitabine/± bevacizumab
Bevacizumab Dose	15 mg/kg	Low dose: 7.5 mg/kg
		High dose: 15 mg/kg
Response Rate	35% vs. 15%	34% (low) vs. 30% (high) vs. 20%
Median Progression-Free Survival	6.2 months vs. 4.5 months	6.7 months (low) vs. 6.5 months (high) vs. 6.1 months
Median Overall Survival	12.3 months vs. 10.3 months	13.6 months (low) vs. 13.4 months (high) vs. 13.1 months
Hazard Ratio Death	0.79 (95% CI, 0.67–0.92), $p = 0.003$	0.93 (95% CI, 0.78–1.11), $p = 0.42$ (low)
		1.03 (95% CI, 0.86–1.23), $p = 0.76$ (high)

CI, Confidence interval.

with NSCLC are at an increased risk of pulmonary hemorrhage owing to the underlying disease process, with non–life-threatening bleeds occurring in 16% of 877 patients with lung cancer.[96] Nearly 3% of these were fatal. Massive pulmonary hemorrhage was significantly associated with squamous cell tumors, cavitation, and with bronchial (vs. peripheral) tumors.[96] Recently, an expert panel recommended that patients with squamous histology and/or a history of grade ≥2 hemoptysis (≥2.5 mL per event) should not receive bevacizumab.[97] However, no clinical or radiologic features (including cavitation and central tumor location) reliably predict severe pulmonary hemorrhage in bevacizumab-treated patients. Major blood vessel infiltration and bronchial vessel infiltration, encasement, and abutting may increase the risk of pulmonary hemorrhage; however, standardized radiologic criteria for defining infiltration have not been established. In all these studies, patients received maintenance therapy with bevacizumab after completion of chemotherapy; still, the benefit of this maintenance has not been prospectively addressed in large clinical trials for NSCLC, so far.

Other Antiangiogenic Agents

The therapeutic success achieved with bevacizumab in NSCLC has prompted the evaluation of several other antiangiogenic agents. Various small-molecule tyrosine kinase inhibitors (TKIs) have been tested in clinical studies in advanced NSCLC. As a common feature of these agents, the spectrum of inhibited receptors is not limited to VEGF receptor (VEGFR) but comprises various further growth factors and signaling pathways. While the broader activity was considered likely to improve the therapeutic benefit, the spectrum of side effects is also expanded, and it renders difficult conclusions regarding the relevance of targeting VEGFR. To date, no drug in this class has demonstrated survival improvement in randomized studies. Phase II studies addressing monotherapy with multi-TKIs have demonstrated modest activity with response rates ranging from 7% to 10% and median time to progression from 2.4 months to 5.8 months in pretreated NSCLC patients. Moreover, several phase III trials have recently been completed that have assessed multikinase antiangiogenic TKIs in a second-, third-, and/or fourth-line setting such as sunitinib (in combination with erlotinib),[98] vandetanib (in combination with docetaxel or pemetrexed),[99,100] and sorafenib monotherapy.[101] Unfortunately, the outcome of these trials was disappointing; despite an improvement in response rates and PFS in most trials, these antiangiogenic TKIs had no impact on OS. Some additional phase III trials are ongoing to assess novel newer agents that have shown promising activity in phase II trials such as pazopanib and apatinib.[102]

In a recent meta-analysis of 15 randomized controlled trials investigating multitargeted antiangiogenic TKIs (vandetanib, sunitinib, cediranib, sorafenib, motesanib) in combination with chemotherapy or as monotherapy in advanced NSCLC, treatment with multi-TKIs was associated with a significantly longer PFS (HR, 0.824; 95% CI, 0.759–0.895; $p < 0.001$) and superior response rate (OR, 1.27; 95% CI, 1.13–1.42; $p < 0.0001$) compared with the control arm.[103] However, OS was not significantly different (HR, 0.962; 95% CI, 0.912–1.015; $p = 0.157$). Other VEGFR inhibitors currently under development include pazopanib, apatinib, and nintedanib.

Two phase III trials (LUME-Lung 1 and 2) were presented investigating nintedanib, a TKI targeting VEGF-, PDGF-, and FGF-receptors. After failure of first-line chemotherapy, 1314 stage IIIB–IV NSCLC patients were randomized to treatment with docetaxel with or without nintedanib (LUME-1).[104,105] The primary end point, PFS, was significantly improved by the addition of nintedanib (3.4 vs. 2.7 months; HR, 0.79; 95% CI, 0.68–0.92; $p = 0.0019$) while OS was not significantly different (10.1 vs. 9.1 months; HR, 0.94; 95% CI, 0.83–1.05; $p = 0.2720$). However, in a prespecified subgroup analysis, patients with adenocarcinoma had both a significant and clinically meaningful improved PFS (4.0 vs. 2.8 months; HR, 0.77; 95% CI, 0.62–0.96; $p = 0.0193$) and OS (12.6 vs. 10.3 months; HR, 0.83; 95% CI, 0.70–0.99; $p = 0.0359$). Also, there was a significant improvement in disease control rate with the nintedanib plus docetaxel combination (adenocarcinoma 60.2% vs. 44%; OR, 1.93; $p < 0.0001$; squamous cell carcinoma 49.3% vs. 35.5%; OR, 1.78; $p < 0.0009$). These data were somewhat confirmed by another phase III trial investigating the second-line combination of pemetrexed with or without nintedanib in patients with advanced or recurrent, nonsquamous NSCLC after treatment with first-line chemotherapy (LUME-2).[106] Despite stopping the trial after recruitment of 713 of the 1300 intended patients, the primary end point was still met as PFS was significantly superior after treatment with nintedanib plus pemetrexed (4.4. vs. 3.6 months; HR, 0.83; 95% CI, 0.70–0.99; $p = 0.0435$). Collectively, the LUME-1 study is the first phase III study demonstrating a survival benefit of adding a multi-TKI to chemotherapy in a prespecified subgroup.

Ramucirumab is a monoclonal antibody that binds to VEGFR-2 and blocks ligand binding and activation. A phase III study (REVEL) investigated ramucirumab in combination with docetaxel as second-line therapy after failure of platinum-based therapy ($n = 1253$ patients including those with squamous histology).[107] The addition of ramucirumab to docetaxel resulted in a significant improvement in median OS (10.5 months vs. 9.1 months; HR, 0.86; 95% CI, 0.75–0.98; $p = 0.023$) and PFS (4.5 months vs. 3.0 months; HR, 0.76; 95% CI, 0.68–0.86; $p < 0.0001$). Notable toxicities with ramucirumab were neutropenia, febrile neutropenia, fatigue, leukopenia, and hypertension. The combination of docetaxel with ramucirumab has gained approval by the United States FDA for salvage therapy of advanced NSCLC. Aflibercept is an investigational recombinant protein composed of epitopes of the extracellular domains of human VEGFR fused to the constant region (Fc) of human immunoglobulin G1 (IgG1) functioning as a soluble decoy receptor. The addition of aflibercept to second-line docetaxel in NSCLC patients was associated with improved ORR, but there was no improvement in OS.[108] Vascular disrupting agents that cause destruction of existing tumor vasculature have also been studied in lung

TABLE 44.6 EGFR TKI Versus Platinum Doublet Chemotherapy in *EGFR*-Mutated NSCLC

Platinum Doublet	EGFR TKI	Response Rate	HR Progression (95% CI)	HR Death (95% CI)
Carboplatin/paclitaxel[118]	Gefitinib	31% vs. 74%	0.30 (0.22–0.41) $p < 0.001$	Not reported $p = 0.31$
Cisplatin/docetaxel[119]	Gefitinib	32% vs. 61%	0.489 (0.336–0.71) $p < 0.0001$	1.638 (0.749–3.582) $p = 0.211$
Carboplatin/gemcitabine[120]	Erlotinib	36% vs. 83%	0.16 (0.10–0.26) $p < 0.0001$	Not reported
Cisplatin/docetaxel or gemcitabine[121]	Erlotinib	18% vs. 64%	0.37 (0.25–0.54) $p < 0.0001$	1.04 (0.65–1.68) $p = 0.87$

cancer without much success.[109] There are no proven biomarkers to select patients for antiangiogenic agents in NSCLC. This has undoubtedly limited the utilization of these agents in the clinic.

EPIDERMAL GROWTH FACTOR BLOCKADE IN NSCLC

EGFR Tyrosine Kinase Inhibitors

EGFR is a member of the ErbB family of transmembrane tyrosine kinase receptors, which bind ligands such as epidermal growth factor. Upon ligand-binding, the receptor undergoes either homo- or hetero-dimerization with another member of the ErbB family, resulting in activation of downstream signaling cascades that lead to cell proliferation and survival.[110] The determination that many cancers, including NSCLC, have aberrant EGFR signaling led to the development of EGFR-blocking therapies. Gefitinib and erlotinib are small molecule EGFR TKIs that have activity in NSCLC, particularly in patients with activating mutations in EGFR.

EGFR TKIs were first studied in unselected NSCLC patients in the second- and third-line setting. Erlotinib was found to benefit patients with previously treated metastatic disease in the BR.21 study.[111] Initial phase II studies with gefitinib were also conducted in unselected patients and observed response rates of approximately 10% to 19%. With both of these agents, there was a greater likelihood for response in females, never-smokers, patients with Asian ethnicity, and those with adenocarcinoma histology. The biologic rationale for these observations came to light with the discovery of mutations in the EGFR in 2004.[100,101] Patients that derived robust responses to EGFR TKIs were likely to harbor an activating mutation in the tyrosine kinase-binding pocket of the *EGFR* gene. The mutations were primarily localized to two "hot" spots on exons 19 and 21. The prevalence of the activating mutations was more frequent in the clinical subset of patients that experienced a higher response rate with EGFR TKIs. Following this landmark discovery, a number of phase II studies were conducted exclusively for patients with EGFR mutation. Treatment with either gefitinib or erlotinib resulted in response rates of 50% to 80% with median PFS of 8 to 12 months.

Before the description of EGFR activating mutations, phase III studies were conducted to combine erlotinib and gefitinib with standard chemotherapy for the first-line therapy of advanced NSCLC. None of these studies demonstrated an improvement in OS.[112–115] Subsequent trials included clinical enrichment to identify patients that might benefit from EGFR TKI given alone or in combination with chemotherapy. The CALGB conducted a randomized phase II study in never-smokers with advanced NSCLC.[116] Patients received erlotinib alone or in combination with carboplatin and paclitaxel. Overall, there was no difference in efficacy for the entire patient population in the two treatment arms. However, in the 40% of patients with EGFR mutation, the response rate and OS were higher than in those with wild-type EGFR. There was no suggestion of improvement in efficacy

with the addition of chemotherapy to erlotinib in patients with an EGFR mutation. This study suggested that clinical selection is unlikely to help identify patients appropriate for EGFR TKI therapy.

This issue was definitively addressed by the Iressa Pan-Asia Study (IPASS) that enrolled Asian patients with adenocarcinoma of the lung and never or light cigarette smoking history. Patients were randomized to treatment with gefitinib or carboplatin and paclitaxel for frontline therapy of advanced stage disease.[117] There was a significant improvement in PFS with gefitinib compared with carboplatin/paclitaxel with a HR of 0.74 (95% CI, 0.65–0.85; $p < 0.001$). In 261 patients found to have *EGFR* mutations, treatment with gefitinib achieved an ORR of 71.2% compared with only 47.3% with chemotherapy, with an increase in PFS (HR, 0.48; 95% CI, 0.36–0.64; $p < 0.001$). The response rate in the 176 patients who tested negative for *EGFR* mutation with gefitinib was only 1.1% versus 23.5% with chemotherapy; in contrast, the mutation negative patients derived a PFS benefit with carboplatin and paclitaxel (HR, 2.85; 95% CI, 2.05–3.98; $p < 0.001$). These results demonstrated that EGFR TKIs only benefit patients with *EGFR* mutations in the frontline setting. Therefore, molecular selection, and not clinical selection, should be used to identify patients that will benefit from frontline use of EGFR TKIs.

Several studies have compared gefitinib or erlotinib with different chemotherapy regimens in *EGFR*-mutated patients treated in the first-line setting; all these studies have shown an ORR from 60% to 80% with PFS benefit (Table 44.6).[118–121] Maemondo et al.[118] published the results of the first study of EGFR TKI versus carboplatin and paclitaxel in the frontline setting in patients with activating EGFR mutations. Patients were selected by the presence of activating *EGFR* mutation; patients with the resistant T790M mutation were ineligible. This study randomized 230 patients to treatment with either gefitinib or carboplatin and paclitaxel. Patients who received EGFR TKI achieved an ORR of 73.7% compared with only 30.7% with chemotherapy ($p < 0.001$). Patients with *EGFR* mutations treated with gefitinib also achieved a longer PFS with median of 10.8 months versus 5.4 months with chemotherapy (HR, 0.30; 95% CI, 0.22–0.41; $p < 0.001$). This was consistent with the results seen in the subgroup analysis of EGFR-mutated patients in the IPASS study. Although there was a trend toward longer OS with TKI (30.5 months vs. 23.6 months), this was not statistically significant ($p = 0.31$). Similar to other EGFR TKI studies, almost all (94.6%) of the patients treated in the chemotherapy arm went on to receive EGFR TKI at the time of disease progression. In a subgroup analysis by *EGFR* mutation type, there was no difference in PFS or response rate between patients with exon 19 deletions compared with point mutations in L858R on exon 21. This study helped confirm that *EGFR* activating mutations are predictive of therapeutic benefit from treatment with EGFR TKIs.

The majority of studies demonstrating the success of EGFR TKI in EGFR-mutated patients have been conducted in predominantly Asian populations. The EURTAC study was a randomized

phase III study comparing the efficacy of erlotinib with chemotherapy (cisplatin and docetaxel or cisplatin and gemcitabine) in European patients with activating *EGFR* mutations. This study achieved its primary end point of PFS benefit at the first interim efficacy analysis with only 174 patients enrolled: patients treated with erlotinib achieved a median PFS of 9.7 months compared with 5.2 months in the chemotherapy arm (HR, 0.37; 95% CI, 0.25–0.54; $p < 0.0001$). Interestingly, patients with exon 19 deletions seemed to derive a greater PFS benefit than those with L858R mutations, which was also observed in the IPASS study. Again, similar to previous studies of EGFR TKI versus chemotherapy, ORR with erlotinib was 64% compared with only 18% with chemotherapy, and there was no survival benefit seen (HR, 1.04; 95% CI, 0.65–1.68; $p = 0.87$). This was the first study examining the efficacy of EGFR TKI therapy in a non-Asian population, and its findings were similar to the PFS advantages seen in Asian populations with *EGFR* mutations treated with EGFR TKI. These studies substantiate the evidence that patients should be tested for the presence of activating *EGFR* mutations at the time of diagnosis of lung cancer, as they derive robust therapeutic gains from EGFR TKI therapy.

Afatinib, an irreversible inhibitor of EGFR, HER2, and ErbB4 receptors, was first studied in advanced NSCLC patients who failed prior EGFR TKI therapy after previous chemotherapy in the LUX-Lung 1 study.[123] In EGFR-mutated patients who were EGFR TKI naive, afatinib was associated with a response rate of over 60%.[124] Patients were initially treated with the maximum tolerated dose of 50 mg of afatinib; however, the higher dose resulted in severe rash and diarrhea, and consequently 40 mg/day was used thereafter. A phase III study was conducted to compare the efficacy of afatinib with standard chemotherapy in patients with an *EGFR* mutation. In the frontline setting, *EGFR*-mutated patients treated with afatinib had a longer PFS (11.1 months) than those treated with cisplatin and pemetrexed (6.9 months) (HR, 0.58; 95% CI, 0.43–0.78; $p < 0.001$); those with exon 19 deletions and L858R mutations achieved an even greater benefit, with PFS of 13.6 months (HR, 0.47; 95% CI, 0.34–0.65; $p < 0.001$).[122] On the basis of these results, the FDA approved afatinib for the treatment of *EGFR*-mutated NSCLC. Afatinib is associated with a higher incidence of skin rash, diarrhea, and mucositis compared with the first-generation EGFR TKIs. Dacomitinib, another irreversible EGFR inhibitor, also demonstrated favorable efficacy in a randomized phase II study when compared with erlotinib.[125] Based on these observations, phase III studies are presently underway to compare irreversible inhibitors with first generation compounds in patients with advanced NSCLC. The LUX-Lung 7 study randomized 319 patients with EGFR activating mutations to afatinib 40 mg daily or gefitinib 250 mg daily.[126] The primary end points of PFS (11.0 months with afatinib vs. 10.9 months with gefitinib; HR, 0.73; 95% CI, 0.57–0.95; $p = 0.017$) and time to treatment failure were more favorable with afatinib (13.7 months vs. 11.5 months; HR, 0.73; 95% CI, 0.58–0.92; $p = 0.0073$), though there was no difference in survival. The toxicity profile was less favorable with afatinib, though discontinuation rate of treatment due to toxicity was similar in both groups.

Combining EGFR-blockade with angiogenesis inhibition may be a strategy to improve outcomes in patients with activating *EGFR* mutations. In a phase II study in Japan, 154 patients were randomized to erlotinib 150 mg daily or erlotinib plus bevacizumab 15 mg/kg IV every 3 weeks.[127] The study achieved the primary end point with improvement in median PFS of 9.7 months with erlotinib to 16 months with combination therapy (HR, 0.54; 95% CI, 0.36–0.79; $p = 0.0015$). The addition of bevacizumab resulted in a higher incidence of grade 3 or higher adverse events (AEs) with 91% of patients in the combination arm compared with only 53% in the erlotinib arm, with the most common AEs including rash, hypertension, and proteinuria. This

combination has recently been approved for use in Europe. Confirmatory trials are underway in the United States.

Monoclonal Antibody Against EGFR

Cetuximab is a chimeric monoclonal antibody that binds and inhibits the EGFR. Cetuximab has been tested in combination with chemotherapy in patients with metastatic NSCLC in phase III studies. The First-Line ErbituX in lung cancer (FLEX) study randomized 1125 patients with chemotherapy naive advanced NSCLC (stage IIIB/IV) with EGFR expression by IHC to chemotherapy consisting of cisplatin and vinorelbine given with or without cetuximab.[128] This study demonstrated a superior OS with the addition of cetuximab to chemotherapy (11.3 months vs. 10.1 months, HR 0.871 [0.762–0.996, $p = 0.044$]). However, the median PFS was similar for the two arms, at 4.8 months (HR, 0.943; $p = 0.39$). Cetuximab increased ORR from 29% with chemotherapy alone to 36% ($p = 0.01$). Another phase III study (BMS099) failed to detect a survival benefit with the addition of cetuximab to first-line chemotherapy in the metastatic setting.[129] This trial randomized 676 patients with metastatic NSCLC to treatment with chemotherapy consisting of carboplatin and a taxane (either paclitaxel or docetaxel) with or without cetuximab. Unlike the FLEX study, this study did not select patients based on EGFR expression status. There was an improvement in ORR (25.7% with cetuximab versus 17.2% without, $p = 0.007$) but this did not result in a difference in median PFS, which was the primary end point, with a HR of 0.902 (0.761–1.069; $p = 0.236$). The lack of benefit remained consistent in analysis of OS: median OS with cetuximab was 9.69 months versus 8.38 months with chemotherapy alone but was not statistically significant (HR, 0.89 [0.754–1.051; $p = 0.169$]). In an exploratory post-hoc analysis, the development of a rash prior to day 21 with cetuximab was correlated with an OS benefit: median OS with early rash was 10.4 months compared with only 8.9 months in those without early rash (HR, 0.76; 95% CI, 0.59–0.98).

The SWOG S0819 study randomized 1333 patients to carboplatin and paclitaxel (with bevacizumab if appropriate) with or without cetuximab.[130] The primary end points of the study were OS and PFS in patients who were EGFR positive by fluorescence in situ hybridization (FISH). The addition of cetuximab did not increase median OS (HR, 0.94; $p = 0.34$). However, in the EGFR positive patients (by FISH), median OS improved from 9.8 months in the control arm to 13.4 months in the cetuximab arm (HR, 0.83; $p = 0.10$). In the squamous patients who were EGFR positive by FISH, the median OS benefit with cetuximab was more dramatic: 11.8 months versus 6.4 months (HR, 0.56; $p = 0.06$). These results suggest that EGFR FISH testing may help select patients who are the most likely to benefit from adding cetuximab to combination chemotherapy in the frontline setting.

Other novel EGFR-targeted antibody therapies have also been studied in NSCLC. Matuzumab, a humanized IgG1 monoclonal antibody against EGFR, was tested in a phase II study in combination with pemetrexed in the second-line treatment of NSCLC.[131] This study failed to achieve its primary end point of increase in ORR (11% with matuzumab compared with 5% pemetrexed, $p = 0.332$) with a trend toward an increase in survival with the addition of matuzumab (7.9 months with pemetrexed, 5.9 months with matuzumab every 3 weeks, and 12.4 months with weekly matuzumab); 87% of tumors had EGFR expression by IHC; in a subgroup analysis, all but one of the responses was seen in EGFR positive tumors. Panitumumab, a fully human IgG2 monoclonal anti-EGFR antibody, was tested in combination with multiple different chemotherapy regimens in phase I and II trials in patients with metastatic NSCLC in first-line and beyond, with modest results.[132] Finally, necitumumab (IMC-11F8), a

recombinant human antibody with a similar structure to cetuximab, was studied in the SQUIRE trial in combination with cisplatin and gemcitabine in squamous cell lung cancer. The addition of necitumumab to chemotherapy resulted in a modest but statistically significant improvement in median OS from 9.9 months to 11.5 months (HR, 0.84; 95% CI, 0.74–0.96; *p* = 0.01).[133] These findings have led to regulatory approval of this regimen for the frontline therapy of patients with metastatic squamous cell carcinoma of the lung in both the United States and Europe.

Biomarkers for EGFR Blockade

Many different biomarkers have been assessed in patients treated with EGFR-targeted therapies. Biomarker analyses of early studies have demonstrated no consistent association with EGFR IHC, copy number by FISH, or Kirsten rat sarcoma (KRAS) mutations.[134–137] The cytosine-adenine (CA) dinucleotide repeat, a polymorphism present in intron 1 of EGFR that modulates its transcription, has also been studied as a potential biomarker for EGFR-targeted therapies. There have been conflicting data about the utility of short CA repeats as a biomarker, as this was correlated with response and PFS in a Korean study but not in a retrospective analysis of the BR.21 study.[138,139] Given the challenges of obtaining adequate tumor tissue for analysis of EGFR mutations, there has been interest in utilizing serum proteomics to develop a predictive algorithm with matrix-assisted laser desorption ionization mass spectrometry (MALDI MS).[140] Patients can be stratified into good and poor prognosis subgroups by MALDI MS, which has been commercially developed as the VeriStrat assay (Biodesix, Boulder, CO, USA). The utility of the VeriStrat assay has been evaluated in retrospective patient cohorts.[141,142] More recently, VeriStrat was tested prospectively in the phase III PROSE study, which randomized patients with metastatic NSCLC to treatment with erlotinib or chemotherapy with either pemetrexed or docetaxel.[143] VeriStrat was able to identify patients that benefited from erlotinib in the second-line setting. The utility of this test in the frontline therapy setting has not been studied.

In 2004, two groups independently described sensitizing mutations in EGFR in patients with NSCLC that achieved objective responses with gefitinib.[144,145] The predictive potential of EGFR mutations was confirmed in the IPASS study that demonstrated improved ORR and PFS benefit in patients treated with gefitinib.[117] In an updated analysis of the IPASS study, there was no OS benefit seen in patients treated with gefitinib versus carboplatin and paclitaxel, with a HR of 0.90 (95% CI, 9.79–1.02; *p* = 0.109), irrespective of EGFR mutation status.[146] These results suggest that the presence of an EGFR mutation is the strongest predictor of ORR and PFS in patients treated with EGFR TKIs. The lack of association of EGFR mutation with predicting OS benefit is likely due to the crossover design of the IPASS study and subsequent EGFR TKI studies in the frontline setting.[118–121] Multiple studies have proven the value of utilizing activating EGFR mutations as the selection criterion for first-line therapy with EGFR TKI.[118–121]

On the basis of these studies, new guidelines have been created to guide testing of NSCLC tissue for EGFR mutations in pathology labs.[147] These guidelines confirm that molecular testing should be performed to select patients with adenocarcinoma of the lung for EGFR TKI therapy. All patients with adenocarcinoma histology should be tested for EGFR mutations, irrespective of clinical characteristics or the presence of other histologies mixed with adenocarcinoma histology. Testing should be performed at the time of diagnosis for patients with metastatic disease and can be performed on resection specimens based on institutional preferences. Specimens that can be used for testing include fresh, frozen, or formalin-fixed, paraffin embedded tissue. There are multiple acceptable methodologies available for detection of EGFR mutations (Sanger sequencing, polymerase chain reaction [PCR]-based assays, single-base extension genotyping, high performance liquid chromatography assays). It is recommended that the assay used should be able to detect mutations in samples with at least 50% tumor content. Based on the studies discussed above, it is not recommended to routinely test for EGFR IHC, copy number by FISH, or Kirsten rat sarcoma (KRAS) mutations to select patients for EGFR TKI therapy.

Resistance to EGFR TKIs

The efficacy of EGFR TKIs in EGFR-mutated NSCLC is eventually overcome by the development of acquired resistance, with a median PFS ranging from approximately 10 to 14 months. The Jackman criteria were developed to clearly define patients with acquired resistance to help guide future studies for this patient population.[148] The Jackman criteria define acquired resistance as the development of disease progression while on EGFR TKI for at least 30 days with no other intervening systemic therapy in patients treated with single-agent EGFR TKI with either a known sensitizing EGFR mutation or documented disease stabilization or response by Response Evaluation Criteria in Solid Tumors (RECIST) criteria for at least 6 months while on EGFR TKI if mutation status is unknown.

Various strategies have been studied in the clinic to overcome resistance to EGFR inhibitors. One strategy has been to continue EGFR TKI beyond progression. The ASPIRATION study investigated the efficacy of this approach in an Asian population.[149] Patients received erlotinib 150 mg daily until disease progression and could be continued on therapy postprogression at the investigator's discretion. The median time to initial progression (PFS1) was 10.8 months; of these 176 patients, 93 continued on TKI postprogression. The PFS2 (time to discontinuation of erlotinib after initial progression) was 14.1 months with a median OS of 31 months. This prospective study shows that treatment beyond progression may help delay initiation of second-line therapy, although this should be limited to patients who do not have rapid disease progression or clinical deterioration.

The IMPRESS study examined the utility of continuing EGFR inhibition with the initiation of platinum doublet chemotherapy following the development of acquired resistance.[150] This international study randomized 265 patients to cisplatin and pemetrexed with gefitinib 250 mg daily or placebo for up to six cycles. There was no difference in the primary end point of PFS: median PFS was 5.4 months in both arms (HR, 0.86; 95% CI, 0.65–1.13; *p* = 0.27). These results confirm that there is no role for combining EGFR TKI with salvage platinum doublet chemotherapy in patients who develop acquired resistance to frontline EGFR inhibition.

Multiple mechanisms of resistance have been described by studying tumor tissue from patients who develop resistance on EGFR-targeted therapy. The most common is the development of the T790M mutation in nearly 50% of patients: T790M is a gatekeeper mutant, which hinders the binding of the TKI to the enzyme active site, similar to the T315I mutation in CML.[151,152] Surprisingly, T790M mutants have a slower rate of growth compared with the parent mutated EGFR. New TKIs that can overcome the steric hindrance of the T790M are being developed. The FDA recently approved a third-generation T790M inhibitor, osimertinib, dosed at 80 mg daily for the treatment of patients with T790M resistant EGFR-mutated NSCLC after progression on first-line TKI. The approval was on the basis of a phase I dose expansion study that showed an ORR of 61% (95% CI, 52–70) and median PFS of 9.6 months (95% CI, 8.3 to not reached [NR]) in patients with T790M mutation.[153] Those without T790M had a more modest ORR of 21% (95% CI, 12–34) with PFS of 2.8 months (95% CI, 2.1–4.3). The most common AEs with osimertinib were diarrhea, rash, and nausea;

the incidence of grade 3 or higher AEs was only 32%. Osimertinib is now being studied in the first-line setting for patients with EGFR mutation.

Combination strategies such as afatinib and cetuximab have shown some promise in the lab in overcoming EGFR resistance.[152,154] This combination can also overcome HER2 overexpression, which is another resistance pathway seen in close to 10% of patients with acquired resistance.[155] Another resistance mechanism is amplification of the hepatocyte growth factor receptor *(MET)* oncogene, which has been described in 5% to 20% of EGFR TKI resistant patients and can occur in the presence or absence of the T790M mutation.[156,157] Other mechanisms of resistance include phenotypic transformation to small cell lung cancer (14%), *PIK3CA* mutations (5%), and epithelial to mesenchymal transformation.[158] These varied resistance mechanisms highlight the importance of obtaining biopsies at the time of disease progression on EGFR TKI in order to guide subsequent therapies.

Although T790M is a common mechanism of acquired resistance to EGFR TKI, it has also been described as a de novo mutation in the absence of exposure to EGFR TKI. Inukai and colleagues[159] first described 9 patients with de novo T790M in a cohort of 280 patients when testing with a mutant enriched PCR assay; none of these patients responded to gefitinib, even the 4 patients with concurrent activating EGFR mutations. The IPASS study also had a low incidence of de novo T790M mutants (4.2% or 11 patients), seven of whom had either L858R mutation or exon 19 deletion as well; however, treatment responses for these patients were not reported.[117] In the iTARGET study, only one patient had a de novo T790M mutation and was resistant to treatment with gefitinib.[160] In a study of detection of EGFR mutations by sequencing of circulating tumor cells or plasma free DNA, low levels of T790M were detected in pretreatment samples in over a third of patients (10 of 26 patients); this resulted in a shorter PFS of 7.7 months compared with 16.5 months in EGFR-mutated patients treated with EGFR TKIs.[161] Recently a small series of patients with de novo T790M patients was reported.[162] The clinical features of these patients were similar to those of patients with activating EGFR mutations; however, the patients with de novo T790M had very low response rates to erlotinib with a much shorter median PFS and OS (1.5 months and 16 months, respectively) compared with patients with activating EGFR mutations (median OS 3 years). In this cohort, all patients had concurrent activating EGFR mutations (80% L858R and 20% exon 19 deletions). These studies suggest that de novo T790M mutations may exist subclinically in certain patients and are selected as a dominant clone with EGFR TKI therapy, leading to poor response rates and survival outcomes with TKI therapy. Interestingly, the presence of germline T790M mutations has been linked with familial lung adenocarcinoma cancer risk.[163,164] In an evaluation of 10 patients with de novo T790M mutations, 50% of the cases carried germline T790M alterations. There is an ongoing perspective trial (INHERIT-EGFR) to better characterize the lung cancer risk in carriers of germline T790M mutations.[165]

ALK-REARRANGED NSCLC

The *EML4-ALK* translocation in NSCLC was first described in 2007. This genetic abnormality induces the transformation of lung cancer cells by constitutive activation of ALK.[166] The *EML4-ALK* translocation is present in 1% to 5% of NSCLC cases and tends to occur more frequently in younger NSCLC patients who are never-smokers, with median age at diagnosis of 52 years.[167] Crizotinib is a dual inhibitor of ALK and MET, which was found to have activity in patients with *ALK* rearrangements, with an ORR of 57% in the initial phase I study.[168] In a recent update of the expanded phase I study, the ORR was reported at 60.8% with a median PFS of 9.7 months;[169] on the basis of these results, the

FDA approved crizotinib for the treatment of *ALK*-rearranged NSCLC. Patients treated with crizotinib in the second-line setting have an ORR of 65% and also derive a benefit of increased PFS of 7.7 months compared with 3 months with pemetrexed or docetaxel (HR, 0.49; 95% CI, 0.37–0.64; *p* < 0.001).[170] Crizotinib is generally well tolerated; the most frequently seen adverse events include gastrointestinal toxicities, vision changes that usually subside with continued therapy, and peripheral edema.

Unfortunately, similar to EGFR inhibition with EGFR TKIs, the benefits of crizotinib are frequently overcome by the development of resistance. A secondary mutation in the *EML4-ALK* gene, at C1196M, which is a gatekeeper mutant similar to T790M in EGFR, was observed in an initial report.[171] Amplification of the *ALK* gene also contributes to acquired resistance to crizotinib.[172] Evaluation of patients who developed crizotinib resistance has also shown other novel mutations in the ALK kinase, autophosphorylation of EGFR, *KRAS* mutation, and amplification of KIT as other mechanisms of resistance.[173,174]

Newer ALK inhibitors are in development to overcome some of these resistance mechanisms. Ceritinib is a potent ALK inhibitor that has shown impressive activity in a phase I study of 131 patients with *ALK*-rearranged NSCLC: the ORR was 58% (95% CI, 48–67) in patients who received at least 400 mg daily with median PFS of 7 months.[175] Clinical activity was seen in patients who had previously failed on crizotinib; the ORR was 56% in patients who were crizotinib failures. Ceritinib was mainly associated with gastrointestinal toxicities and fatigue.

Another novel ALK inhibitor, CH5424802, now known as alectinib, was tested in a phase I/II study in Japan for *ALK*-rearranged NSCLC patients: the maximum tolerated dose was defined as 300 mg twice a day though no dose limiting toxicities were observed.[176] The ORR was 93.5% with two complete responses, and the median PFS had not been reached at the time of the report. The most frequent grade 3 adverse events were neutropenia and elevated creatine phosphokinase (CPK). In a phase I/II study of alectinib in patients who progressed or were intolerant of crizotinib, dose limiting toxicities of grade 3 headache and elevated Gamma-Glutamyl Transpeptidase (GGT) were seen in two patients at a dose level of 900 mg twice daily.[177] The ORR was 55%, with a 52% response rate seen in central nervous system (CNS) metastases. This study determined the recommended phase II dose of alectinib to be 600 mg twice a day. Alectinib's activity in crizotinib resistant patients was confirmed in a phase II study of 87 patients who received alectinib 600 mg twice daily after disease progression on crizotinib.[178] The ORR was 48% (95% CI, 36–60) with median PFS of 8.1 months (95% CI, 6.2–12.6); 100% intracranial disease control was seen in the 16 patients with measurable CNS disease. The most common AEs were constipation, fatigue, myalgia, and peripheral edema. These results have led to approval of alectinib in patients who have progressed on or are intolerant of crizotinib.

Alectinib has also shown efficacy in treatment-naive *ALK*-positive NSCLC patients compared with the current standard crizotinib as reported in the J-ALEX study.[179] This study randomized 200 patients with centrally confirmed *ALK*-positive metastatic disease (by IHC, FISH, or reverse transcription-PCR) to alectinib 300 mg twice daily or crizotinib 250 mg twice daily in the frontline setting. The patients in the alectinib arm had an improved ORR of 91.6% (95% CI, 85.6–97.5%) compared with the crizotinib arm with only 78.9% (95% CI, 70.5–87.3%). More impressively, the primary end point of improved median PFS with alectinib was achieved with a HR of 0.34 (95% CI, 0.17–0.71; *p* < 0.0001). The improved efficacy of alectinib also came with reduced toxicity: the rate of grade 3–4 AEs was 26.2% compared with 51.9% in the crizotinib arm. Based on these impressive results, the FDA has designated breakthrough status for alectinib as first-line therapy in *ALK*-positive advanced disease. Finally, heat shock protein 90 inhibition with IPI-504[180]

and STA-9090[181] has shown promise in patients with *ALK*-rearranged NSCLC and may provide alternative approaches to overcome crizotinib resistance.

There are various diagnostic assays for the detection of ALK rearrangement, including FISH and IHC. A break-apart FISH assay was used to select patients for the initial phase I and II studies of crizotinib; the commercially available Vysis ALK Break Apart FISH probe kit (Abbott Molecular Probes, Abbott Park, Illinois, USA) was approved as a companion diagnostic for selection of ALK-rearranged patients to be treated with crizotinib by the FDA.[182] A positive result is the presence of at least 15% split red and green signals or isolated red signals.[183] IHC is a cheaper testing methodology and is more readily available in most pathology labs compared with the more technically challenging FISH test. The sensitivity and specificity of ALK detection of IHC has ranged between 90% to 100% and 95.8% to 99%, respectively, when correlated with ALK FISH in multiple studies.[184–186] Recent guidelines from the College of American Pathologists and IASLC recommend the use of ALK FISH for the diagnosis of ALK rearranged NSCLC to select patients for treatment with crizotinib; IHC may be used as an initial screening assay.[147]

MOLECULAR CHARACTERIZATION OF NSCLC

A number of genetic alterations beyond EGFR mutations and ALK rearrangements have been discovered in lung adenocarcinoma through the efforts of the Lung Cancer Mutation Consortium (LCMC).[187,188] More than 1000 adenocarcinomas were characterized for the presence of 10 driver mutations in LCMC-1 and more recently another 875 patient cases were analyzed for 14 driver mutations in LCMC-2.[189] Almost 60% of patients had at least one mutation: the most frequently found mutations were in *KRAS*, *EGFR*, *EML4-ALK*, and *MET* amplification (Table 44.7). Based on the testing, 28% of patients received a targeted therapy directed to the driver mutation, including several in ongoing clinical trials. Patients treated with targeted therapy in LCMC-1 achieved a longer median survival (3.5 years) compared with patients who did not receive targeted therapy or were identified as wild-type and had no targeted therapy options (2.4 years and 2.1 years, respectively, *p* < 0.0001). Similarly in LCMC-2, patients with driver mutations that received targeted therapy had prolonged survival (2.7 years) compared with those who did not receive targeted therapy (1.5 years) and wild-type patients (1.7 years). In *EGFR*-mutated patients who received targeted therapy, the presence of a secondary *TP53* mutation results in median survival of 2.9 years compared with NR in those without mutation, suggesting that p53 function may modulate response to targeted therapy. The results of both LCMC-1 and LCMC-2 demonstrate that expanded molecular profiling of lung adenocarcinomas and resultant targeted therapy improves survival in patients with advanced stages of disease.

Based on the efforts of the LCMC, there are multiple early phase studies of novel targeted therapies in lung adenocarcinoma patients. In fact, *BRAF*, which is a serine threonine kinase in the RAS-RAF-MEK pathway, is mutated in NSCLC in 2% to 5% of patients. Similar to melanoma and colon cancer, NSCLC can harbor activating mutations in *BRAF*, such as V600E, which accounts for at least half of *BRAF* mutations in NSCLC, and non-V600E mutations, which can be activating or inactivating.[190–192] Patients with *BRAF* mutations tend to have a smoking history in contrast to patients with *EGFR*-mutations and *ALK* rearrangements. As in *BRAF*-mutated melanoma, dual inhibition of the MAP kinase pathways with dabrafenib and trametinib has shown activity in *BRAF*-mutated NSCLC. In a single-arm phase II study of 57 patients with V600E *BRAF* mutations who have progressed on platinum doublet therapy, the ORR was 63.2% (95% CI, 49.3–75.6) with a median duration of response of 9.0 months

TABLE 44.7 Prevalence of Common Molecular Targets in Adenocarcinoma and Squamous Cell NSCLC

Molecular Target	Frequency (%)
ADENOCARCINOMAS (LCMC-2)	
KRAS	25
EGFR: sensitive to EGFR TKI (deletion 19, L858R, L861Q, G719X)	10
ALK rearrangement	4
MET amplification	3
V600E *BRAF*	2
EGFR: not sensitive to EGFR TKI (exon 20 insertions, T790M)	2
RET translocation	2
ROS1 translocation	2
HER2	1
PIK3CA	1
SQUAMOUS CELL (TCGA)	
TP53	81
MLL2	20
PIK3CA	16
CDKN2A	15
NFE2L2	15
KEAP1	12
NOTCH1	8
PTEN	8
RB1	7
HLA-A	3

ALK, anaplastic lymphoma kinase; *BRAF*, v-raf murine sarcoma viral oncogene homolog B; *CDKN2A*, cyclin dependent kinase inhibitor 2A; *EGFR*, epidermal growth factor receptor; *HER2*, human epidermal growth factor receptor 2; *HLA-A*, human leukocyte antigen-A; *KEAP1*, Kelch-like ECH-associated protein 1; *KRAS*, Kirsten rat sarcoma viral oncogene homolog; *LCMC-2*, lung cancer mutation consortium-2; *MET*, hepatocyte growth factor receptor; *MLL2*, myeloid/lymphoid or mixed lineage leukemia protein 2; *NFE2L2*, nuclear factor, erythroid 2 like 2; *NOTCH1*, Notch1; *NSCLC*, nonsmalll cell lung cancer; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3 kinase catalytic subunit alpha; *PTEN*, phosphatase and tensin homolog; *RB1*, retinoblastoma; *RET*, proto-oncogene tyrosine-protein kinase receptor; *ROS1*, ROS proto-oncogene 1, receptor tyrosine kinase; *TCGA*, The Cancer Genome Atlas; *TKI*, tyrosine kinase inhibitor; *TP53*, tumor protein 53.

(95% CI, 6.9–19.6).[193] *ROS1* fusions have been described in 1% to 2% of adenocarcinomas, which have been successfully targeted with crizotinib based on an expansion cohort of 50 patients from the phase I crizotinib study.[194] The use of crizotinib resulted in an ORR of 72% (95% CI, 58–84) with a median duration of response of 17.6 months (95% CI, 14.5–NR) and median PFS of 19.2 months (95% CI, 14.4–NR). These results have led to the approval of crizotinib for patients with *ROS1* translocations. *MET* exon 14 splicing variants result in MET amplification and are found in about 4% of lung adenocarcinomas and in a high number of sarcomatoid lung carcinomas; there are a growing number of reports of the success of using MET inhibitors like crizotinib and cabozantinib in patients with *MET* exon 14 mutations.[195–198] These studies emphasize the importance of routine genetic testing of lung adenocarcinomas to select patients who may benefit from new therapies.

In contrast, squamous cell lung cancers have lagged behind adenocarcinomas with targeted treatments, although a major breakthrough came as a result of the efforts of The Cancer Genome Atlas (TCGA).[199] The TCGA data have shown that squamous cell lung cancers, similar to other smoking-related cancers, have a high rate of somatic mutations. Multiple pathways are altered in these tumors (see Table 44.7), but up to 70% of squamous cell lung tumors have alterations in receptor tyrosine kinase pathways, which may be developed as targets for therapy.

IMMUNOTHERAPY IN NSCLC

Recent developments in the use of agents that modify immune checkpoints are finally realizing the promise of immune modulation in patients with NSCLC. Ipilumumab is a monoclonal antibody that blocks the binding of a T-cell inhibitory receptor CTLA-4 to its ligands and results in activation of T cells that can infiltrate and attack tumors. Another immune checkpoint that has been targeted with initial success in NSCLC is the programmed death-1 (PD-1) receptor, which is an inhibitory receptor on tumor infiltrating lymphocytes.[200] Its ligand, PD-L1, is overexpressed in many tumors, including NSCLC; blockade of this pathway with monoclonal antibodies against either PD-1 or PD-L1 has shown promising activity in NSCLC. The PD-1 inhibitors nivolumab and pembrolizumab have been shown to be superior to docetaxel in patients with squamous and nonsquamous histologies in the salvage setting.[201–203] PD-L1 expression by tumor proportion score has been highly correlated with efficacy of pembrolizumab;[204] regulatory approval of pembrolizumab in both the United States and Europe has been tied to high expression of PD-L1 by tumor proportion score, defined as 50% or higher expression.

Recent data with pembrolizumab have prompted a major shift in the treatment paradigm for first-line therapy of advanced NSCLC. The KEYNOTE-024 study screened 1934 treatment-naive advanced stage NSCLC patients who were *EGFR* and *ALK* negative to enroll 305 patients with at least 50% PD-L1 expression by tumor proportion score (30.2%).[205] These patients were randomized to pembrolizumab 200 mg every 3 weeks for up to 35 cycles or investigators' choice platinum doublet chemotherapy for up to 6 cycles. Patients with nonsquamous histology who received pemetrexed could receive continuation maintenance therapy. The primary end point of median PFS was superior with pembrolizumab (10.3 months vs. 6.0 months; HR, 0.50; 95% CI, 0.37–0.68; $p < 0.001$). The overall survival was also improved with a HR of 0.60 (95% CI, 0.41–0.89; $p = 0.005$). Compared with chemotherapy, pembrolizumab resulted in better ORR (44.8% vs. 27.8%) and duration of response (NR vs. 6.3 months), with less toxicity. The rate of overall treatment-related AEs and grade 3–5 AEs was 73.4% and 53.3% with pembrolizumab versus 90.0% and 26.6% with chemotherapy, respectively. These results show that PD-1 inhibition with pembrolizumab in patients with high PD-L1 staining is superior to the current standard of platinum doublet chemotherapy and will likely be reviewed favorably by regulatory agencies in the near future.

Combination immunotherapy strategies to overcome both CTLA4 and PD-1 inhibition have been successful in metastatic melanoma and are also being studied in NSCLC. The Checkmate 012 trial evaluated the safety of new dosing combinations of nivolumab and ipilimumab including nivolumab 1 mg/kg with ipilimumab 1 mg/kg every 3 weeks for four cycles followed by nivolumab maintenance 3 mg/kg every 2 weeks compared with various nivolumab dosing regimens (1 mg/kg and 3 mg/kg) every 2 weeks with longer interval ipilimumab dosing (every 12 weeks and every 6 weeks) until disease progression.[206] Interestingly, the longer interval ipilimumab dosing resulted in a numerically higher ORR (25% to 39% vs. 13%) with similar TRAE rates (69% to 73% vs. 77%). The rate of treatment adverse effects (TRAEs) (11% to 13%) leading to discontinuation in the longer ipilimumab interval arms was similar to nivolumab monotherapy. There was a trend toward higher response rate in patients with higher PD-L1 staining. On the basis of the promising results from this trial, the efficacy of nivolumab 3 mg/kg every 2 weeks plus ipilimumab 1 mg/kg every 6 weeks is being studied in multiple later stage trials.

CONCLUSION

The treatment of NSCLC has evolved dramatically from the early use of alkylating agents, to the use of cisplatin doublet therapy, to the development of newer more tolerable drugs that can be utilized beyond the frontline setting and in maintenance strategies, and more recently to targeted therapies against pathways activated in NSCLC such as VEGF, EGFR, and ALK. There are now novel immunotherapies that show promise in patients with advanced NSCLC. Future studies will better characterize patients likely to derive benefit from these targeted strategies by the identification of predictive biomarkers. Assessment of tumor tissue, both pretreatment and at the time of disease progression, will become more integral to the development of targeted therapies for specific genetic aberrations that drive metastasis and treatment resistance. The genomics revolution will ultimately lead to the realization of personalized therapy for NSCLC and improved outcomes for these patients.

45 Systemic Options for Second-Line Therapy and Beyond

Glenwood Goss and Tony Mok

SUMMARY OF KEY POINTS

- There are a growing proportion of patients who are candidates for second-line therapy and beyond.
- Treatment choices are dictated by tumor histology, molecular phenotype (e.g., *EGFR*, *ALK*, *ROS1*, etc.), and components of frontline chemotherapy including also the use of maintenance and bevacizumab.
- In patients with no actionable molecular targets, several options are available that include chemotherapy (docetaxel, pemetrexed), epidermal growth factor receptor (EGFR)-targeted therapies (erlotinib and afatinib for squamous cell carcinoma), and ramacirumab (an anti-vascular endothelial growth factor receptor [VEGFR] 2 monoclonal antibody) in combination with docetaxel and immune checkpoint inhibitors.
- Recent studies comparing EGFR tyrosine kinase inhibitors (TKIs) with single-agent chemotherapy for patients with known wild-type *EGFR* tumors have cast doubts on the clinical efficacy of second-line EGFR TKIs.
- Patients with actionable molecular targets such as *EGFR* sensitizing mutations, *ALK,* and *ROS1* translocation, who did not receive the appropriate targeted therapy in front line, must receive it in a second line strategies.
- Third-generation EGFR TKI such as osimertinib for patients with tumors positive for T790 resistant mutation and second-generation anaplastic lymphoma kinase (ALK) inhibitors (ceritinib, alectinib and brigatinib) showed relevant clinical activity when tested in the second-line setting.
- In the second-line setting immune checkpoint inhibitors (nivolumab, pembrolizumab, and atezolizumab) showed an overall response rate of 5% to 40% in patients with durable responses, but at the present time there are no reliable biomarkers predicting the subgroup of patients who would most benefit. Candidate biomarkers include PDL-1 expression, mutational load, and neoantigen expression.
- Although erlotinib is approved for third-line therapy, the strength of the evidence is limited and a new wave of clinical trials is needed.
- Studies comparing EGFR TKIs with single-agent chemotherapy for patients with known wild-type *EGFR* tumors have cast doubts on the clinical efficacy of second-line EGFR TKIs.

In order to discuss the systemic options for the management of patients in whom first-line chemotherapy has failed, it is necessary to revisit certain aspects of the disease that are covered elsewhere in this text in greater detail. Lung cancer is the most common cancer worldwide and it accounts for approximately 28% of all cancer deaths.[1] For therapeutic purposes, nonsmall cell lung cancer (NSCLC), which includes 85% of all lung cancers, is divided into squamous and nonsquamous histology, for which there are differing approaches to treatment.[2] Substantial advances in our understanding of the biology and molecular pathology of NSCLC have allowed us to identify oncogenic drivers and molecular biomarkers predictive of efficacy with targeted therapies, which further divides NSCLC into smaller therapeutic subgroups.[3] However, even in the case of the most intensively studied of these oncogenic drivers, the *EGFR* gene, there are still many unanswered questions. For example, at a histologic level, the mechanism of the evolution of NSCLC to small cell lung cancer is unknown and our knowledge of the genetic evolution of NSCLC between the first- and second-line settings is scanty.[4] Large studies evaluating the genetics of lung cancer in primary and metastatic sites sequentially across first, second, and subsequent lines of therapy have not been reported in the literature. In the setting of first-line treatment, controversy exists about treating patients with maintenance chemotherapy or waiting until disease progression. In the second-line setting, the appropriate treatment is unresolved and the number of patients eligible for second-line therapy following maintenance chemotherapy is uncertain, as there are conflicting data in the literature.[5,6] A study by Fidias et al.[5] comparing early maintenance chemotherapy with treatment at the time of progression demonstrated that only 37% of patients received second-line treatment at the time of progression compared with 95% who were treated with immediate maintenance.[5] Overall survival favored the maintenance arm (median overall survival, 12.3 vs. 9.7 months; $p = 0.853$), suggesting that immediate maintenance chemotherapy was the treatment of choice. However, the authors noted that the median overall survival for patients in the deferred-treatment arm who received second-line therapy (37%) was 12.5 months, equivalent to that for patients in the maintenance arm. In contrast, Bylicki et al.,[6] in a three-arm randomized study that enrolled 464 patients, found that with careful observation, 95% of patients in the observation arm were eligible for second-line chemotherapy at the time of disease progression (84% received study-defined second-line treatment) and that there was no difference in survival between the maintenance arm and the observation arm. The close observation required to establish eligibility for second-line treatment, however, may not be feasible outside of a clinical trial. In an older retrospective review by Murillo and Koeller[7], published in 2006, among patients with stage IIIb and IV NSCLC treated at 10 community centers in the United States, 84% received first-line, 56% received second-line, 26% received third-line, 10% received fourth-line, and 5% received fifth-line chemotherapy.[7] Further questions have recently been generated by the addition of the immune checkpoint inhibitors to our second-line armamentarium. These agents are by no means the universal panacea with overall only 5% to 40% of patients responding to treatment and our ability to identify the benefiting group mediocre at best.[8,9] With preliminary data suggesting intriguing signals of efficacy of immune checkpoint inhibitor monotherapy in certain treatment-naive subgroups and additional activity in combination with chemotherapy in

the upfront management of unselected patients with advanced NSCLC,[9–13] the role of immune checkpoint inhibitors as second-line agents is uncertain.

HISTORY

It was not until 1995 that a large meta-analysis of eight randomized studies comparing cisplatin-based combination chemotherapy with best supportive care for advanced NSCLC demonstrated with certainty that chemotherapy had a modest impact on survival, with a median survival improvement from 4 to 7 months and a 1-year survival rate of 5% to 15%.[14] The result of the meta-analysis was subsequently confirmed in a four-arm randomized phase III study evaluating response and survival rates between third-generation chemotherapies (e.g., paclitaxel, docetaxel, and gemcitabine) when combined with a platinum agent (either cisplatin or carboplatin). This study demonstrated a modest survival improvement, with a median survival of 7.9 months and a 1-year survival rate of 33%.[15] However, it should be noted that platinum-doublet chemotherapy control arms of recent trials have been associated with better median overall survival than chemotherapy arms in earlier trials, most likely because of better performance status of the study population and some stage migration.[16]

Until the two publications by Shepherd et al.[17] and Fossella et al.[18] in 2000, the role of second-line chemotherapy was uncertain. The literature consisted of phase I and phase II trials, most of which were small and consisted of fewer than 30 patients; in addition, details about prior treatment and patient performance status were frequently not included in the publication. Furthermore, although response rates were reported, very few studies provided median survival or 1-year survival rates. A review of the literature demonstrated disappointing results for clinical trials in a second-line setting, with most studies showing response rates of less than 10% and median survival times of 4 months or less.[19] The agents most frequently evaluated in phase II studies included the vinca alkaloids vindesine and vinorelbine, the taxanes (paclitaxel and docetaxel), and gemcitabine. Variable and conflicting results were reported with second-line vinorelbine and in two trials in which vinorelbine, 25 mg/m² or 20 mg/m², was administered weekly, no responses were seen.[20,21] However, in a small trial of vinorelbine 30 mg/m² that included only 10 patients a 20% response rate was reported by Sandora et al.[22] Several studies that tested paclitaxel also produced conflicting results, perhaps in part because of the variability in both the dose and administration time.[19] No responses were seen in a small study in which paclitaxel 140 mg/m² was administered over 96 hours.[23] In another trial, paclitaxel 200 to 250 mg/m² was administered over 24 hours and 2 (14%) confirmed partial responses were noted, with two additional responses that lasted less than 4 weeks.[24] In two trials in which varying doses of paclitaxel were given over 1 hour, 1 (2.5%) of 13 patients in the first study had a response,[25] whereas 26 responses (25%) occurred in the second study.[26] Gemcitabine was also investigated, and Gridelli et al.[27] noted partial responses in 6 (20%) of 30 patients treated with gemcitabine 1000 mg/m² weekly for 3 weeks of a 4-week cycle. However, the most extensively studied agent was docetaxel. In phase II trials, docetaxel was administered at 100 mg/m² every 3 weeks, with objective response rates ranging from 15% to 22%.[19] These promising results led to two randomized studies of second-line docetaxel for patients previously treated with cisplatin-based chemotherapy. (These studies will be discussed in more detail later in the chapter.)

SECOND-LINE CHEMOTHERAPY

Only one randomized phase III trial has compared chemotherapy plus best supportive care to best supportive care alone for patients with advanced NSCLC previously treated with platinum-based chemotherapy.[17] Patients with a performance status of 0 to 2, stage IIIb or IV disease with either measurable or evaluable tumor who had received one or more platinum-based chemotherapy regimens were randomly assigned to docetaxel 100 mg/m² or 75 mg/m² plus best supportive care every 3 weeks or best supportive care only. The primary outcome of the study was overall survival, and the secondary end points included objective tumor response, duration of response, and change in quality of life. All patients in the docetaxel arms were assessed every 3 weeks. Of the 204 patients randomized, 104 patients were assigned to the docetaxel arm, 84 had measurable lesions, and 6 (7.1%) of the 84 had a partial response. Time to progression was longer for patients treated with docetaxel than for patients who received best supportive care only (10.6 vs. 6.7 weeks; $p < 0.001$), as was the median survival (7.0 vs. 4.6 months; log-rank test, $p = 0.047$). The difference was more significant for the 75-mg/m² dose of docetaxel compared with the best supportive care arm (median survival, 7.5 vs. 4.6 months; log-rank test, $p = 0.010$; and 1-year survival rate, 37% vs.11%; $p = 0.003$). Adverse events included febrile neutropenia, which occurred in 11 patients treated with docetaxel at 100 mg/m², 3 of whom died, and in 1 patient treated with docetaxel, 75 mg/m². Grade 3 or grade 4 nonhematologic toxicity with the exception of diarrhea occurred at a similar rate in both the docetaxel and best supportive care arms. In this study, the 100-mg/m² dose was associated with five reported toxicity-related deaths. Three of the deaths were docetaxel-related, and an association with docetaxel treatment could not be ruled out for the other two deaths. At this dose, the median number of cycles delivered was only two and this, combined with a 10% early death rate, probably accounted for the lack of improved survival in the 100-mg/m² treatment arm. When the docetaxel dose was reduced to 75 mg/m² in the second half of the trial, dose delivery improved, with a median of four cycles, and the rate of febrile neutropenia decreased from 22% to 2%, with no toxicity-related deaths. This high rate of toxicity-related death had not been seen in other phase II studies involving a dose of 100 mg/m²,[18,19,28] but led the authors to conclude that only docetaxel at a dose of 75 mg/m² is associated with significant prolongation of survival. Of note, clinical benefit in this study could be demonstrated by end points other than response and survival. A significant positive effect of docetaxel was evident in the analysis of both the usage of narcotics and nonnarcotics for pain and in the need for radiotherapy. In summary, this was the first trial to document that in patients with advanced NSCLC and good performance status, second-line chemotherapy with docetaxel 75 mg/m² after platinum-based chemotherapy is justified, with a significant prolongation of survival and reduced pain.

The above findings were supported by a three-arm multicenter, open-label randomized phase III trial of patients with stage IIIb or IV NSCLC who progressed on platinum-based therapy.[18] The trial was designed to compare docetaxel 100 mg/m² every 3 weeks and docetaxel 75 mg/m² every 3 weeks to a control arm of vinorelbine 30 mg/m² administered intravenously on days 1, 8, and 15 of the 3-week cycle or ifosfamide 2 g/m² on days 1–3 of a 3-week cycle (with the choice of drug left to the investigator's discretion). Patients had to have either measurable or assessable lesions and an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 2. No restriction was based on the number of prior regimens or the amount of prior chemotherapy. A total of 373 patients were randomly assigned, and the three treatment groups were well-balanced for key patient characteristics. The overall response rates were 10.8%, 6.7%, and 0.8% for the docetaxel 100 mg/m², docetaxel 75 mg/m², and the vinorelbine or ifosfamide arms, respectively. Patients who received docetaxel had a longer time to disease progression ($p = 0.046$) and a greater progression-free

survival (PFS) at 26 weeks ($p = 0.05$). Although the overall survival was not significantly different between the three arms, the 1-year survival was significantly greater for the docetaxel 75 mg/m^2 arm when compared with the control arm (32% vs. 19%; $p = 0.025$). Prior exposure to paclitaxel did not decrease the likelihood of response to docetaxel nor did it impact survival. The authors concluded that clinical benefit as determined by objective response, PFS, and 1-year survival favored patients who received docetaxel. Grade 4 neutropenia and fever were higher in the two docetaxel arms than in the control arm; however, other treatment-related adverse events were similar across the three arms.

These two studies, supported by data from multiple phase II studies, resulted in docetaxel being registered with the US Food and Drug Administration (FDA) and the European Medicines Agency as an approved chemotherapy agent for second-line treatment for advanced NSCLC. However, despite the prolongation in 1-year survival by 10% to 20% and improved quality of life when compared with ifosfamide, vinorelbine, or best supportive care alone, these gains were modest, which led to the evaluation of pemetrexed, a novel multitargeted, antifolate in the second-line setting. This compound inhibits the enzyme thymidylate synthase, resulting in decreased thymidine necessary for pyrimidine synthesis.[29] As a drug that also inhibits dihydrofolate reductase and glycinamide ribonucleotide formyl transferase, vitamin supplementation with folate and vitamin B12 is required to limit hematologic and nonhematologic toxicity associated with pemetrexed, including neutropenic fever. Therefore, supplementation with folic acid at 0.35 mg to 1 mg orally daily and vitamin B12 at 1000 µg intramuscularly every 9 weeks is essential to control the toxicity of this drug and has been used in most trials investigating this agent.[30] Phase II studies of pemetrexed in previously untreated patients with NSCLC demonstrated single-agent response rates of 17% to 23%.[31,32] In a phase II study of pemetrexed for patients with advanced NSCLC who had disease progression within 3 months after completing first-line chemotherapy, the response rate was 8.9% and the median survival was 5.7 months.[33] Based on the similar overall survival found for pemetrexed and docetaxel and the expected lower toxicity with pemetrexed, a multinational phase III study comparing these two agents in the second-line treatment of NSCLC was undertaken. The primary objective of this noninferiority study was to compare overall survival between the two treatment groups on an intent-to-treat basis. Secondary objectives were to compare toxicities, response rate, PFS, time to progression, time to treatment failure, time to response, duration of response, and quality of life between the two treatment groups. Eligible patients had to have a performance status of 0 to 2 and have received previous treatment with one chemotherapy regimen for advanced NSCLC. The study included 571 patients who were randomly assigned to receive pemetrexed 500 mg/m^2 intravenously on day 1 plus vitamin B12, folic acid, and dexamethasone every 21 days or to receive docetaxel 75 mg/m^2 intravenously on day 1 plus dexamethasone every 21 days.[34] The overall response rate was 9.1% and 8.8% for pemetrexed and docetaxel, respectively ($p = 0.105$). The PFS was 2.9 months in both arms, and the median survival was 8.3 months and 7.9 months, respectively. The 1-year survival rate in each arm was 29.7%. Patients receiving docetaxel were more likely to have grade 3 or 4 neutropenia ($p < 0.001$), febrile neutropenia ($p < 0.001$), and neutropenia with infection ($p = 0.004$); hospitalization for neutropenic fever was more frequent in the docetaxel arm (13.4% vs. 1.5%; $p < 0.001$). Use of granulocyte colony-stimulating factor support was also greater in the docetaxel arm (19.2% vs. 2.6%; $p = 0.001$) than pemetrexed. The authors concluded that, in patients with advanced NSCLC in whom one line of previous chemotherapy had failed, pemetrexed was equivalent to docetaxel in terms of clinical efficacy but with fewer side effects and should therefore

be considered a standard treatment option in the second-line NSCLC setting.

Despite good overall clinical efficacy in these trials, not all patients benefit from pemetrexed. In a retrospective analysis of phase III pemetrexed studies Scagliotti et al.[35,36] found significant treatment-by-histology interaction for overall survival and PFS. Specifically, patients with nonsquamous tumors treated with pemetrexed had a significantly longer overall survival (hazard ratio [HR]: 0.78; 95% confidence interval [CI], 0.61–1.00; $p = 0.48$) and PFS (HR: 0.82; 95% CI, 0.66–1.02; $p = 0.076$) than patients treated with docetaxel. Conversely, patients with squamous tumors treated with pemetrexed appeared to have a worse overall survival and PFS (overall survival: HR: 1.56; 95% CI, 1.08–2.26; $p = 0.018$ and PFS: HR: 1.40; 95% CI, 1.01–1.96; $p = 0.004$) compared with docetaxel. The treatment-by-histology interaction test for overall survival and PFS was $p = 0.001$ and $p = 0.004$, respectively. This finding, confirming the benefit of pemetrexed for nonsquamous histology, has been supported by the findings of studies with pemetrexed in the first-line and maintenance settings.[16,37]

While a number of questions have been answered in trials, reviews, or meta-analyses of the literature,[38–42] a number of questions remain. Is a combination of two or more drugs superior to single-agent chemotherapy, and is a weekly schedule better than an every 3-week schedule?

CHOICE OF CHEMOTHERAPY AGENT

A review of multiple randomized phase II trials comparing docetaxel to single-agent paclitaxel, gemcitabine, ifosfamide, vinorelbine, and pemetrexed demonstrated that none of these agents was superior to docetaxel in the second-line setting.[40] In this review, two-drug combinations, both platinum and nonplatinum, were also compared with docetaxel in multiple phase II randomized studies. Among platinum-based doublets, none was found to be superior to docetaxel in the second-line setting. Four randomized studies compared a single-agent with a two-drug nonplatinum-based regimen, and three trials compared docetaxel to a combination of docetaxel plus gemcitabine or docetaxel plus irinotecan. Of note, in all trials reviewed, none of the two-drug regimens was shown to improve survival. Furthermore, toxicities were more common among combination regimens, sometimes leading to toxicity-related deaths or negative outcomes related to symptom relief, prolongation of survival, and improved quality of life for patients with incurable disease, which are the primary aims of second-line treatment.[43] Similarly, doublet therapy that includes pemetrexed does not appear to improve survival compared with single-agent pemetrexed in the second-line setting, based on the findings of a meta-analysis.[41] The comparable efficacy of single-agent and doublet chemotherapy in the second-line setting has been supported by four meta-analyses in the literature.[39–42]

SCHEDULING OF CHEMOTHERAPY

Three randomized trials (one phase II and two phase III studies) compared weekly docetaxel delivery to the classic schedule of every 3 weeks.[44–46] In the phase II study,[44] response, median survival, and 1-year survival were not significantly different but favored the every 3 weeks regimen. Similarly, the two phase III studies did not show a difference in overall survival or quality of life.[45,46]

The number of cycles of chemotherapy that a patient should receive in the second-line setting is a matter of debate. This question has not been answered, as it has not been formally addressed in a randomized trial. In the trials of both Shepherd et al.[17] and Hanna et al.,[34] patients were treated until disease progression and the mean number of cycles was four. The reason leading to treatment discontinuation has been inconsistently reported in the

literature, but it is most likely due to drug-related toxicity and disease progression. Given that time to progression in randomized phase III trials ranges from 2 to 3 months, corresponding with three or four cycles of chemotherapy, progression may be considered the main reason for discontinuation of second-line treatment. In conclusion, following reviews of four large meta-analyses of second-line trials in the literature, single-agent docetaxel or single-agent pemetrexed administered every 3 weeks remains the gold standard for good performance status patients (without a known treatable oncogenic driver) eligible for chemotherapy. This is detailed in guidelines from both the National Comprehensive Cancer Network and the American Society of Clinical Oncology.[47,48]

THIRD- AND SUBSEQUENT-LINE OF CHEMOTHERAPY

If patients treated with a targeted agent are excluded, there are scanty data regarding the outcomes of patients treated with chemotherapy following first- and second-line chemotherapy for advanced NSCLC. In a retrospective analysis, Massarelli et al.[49] reviewed 700 patient records and identified patients who had received at least two chemotherapy regimens, including at least one course of platinum-based chemotherapy and one course of docetaxel.[49] In this review, the response rate to first-line chemotherapy for all 700 patients was 20.9%; the rates were 16.3%, 2.3%, and 0% for second-line, third-line, and fourth-line chemotherapy, respectively.[49] The disease-control rate also decreased dramatically from first- to fourth-line treatment, although it was higher for second-line treatment (74.4%) than for first-line treatment (62.8%). The median overall survival time from the start of the last chemotherapy, either first- or fourth-line treatment, was 4 months. Patients with stage III disease at initial diagnosis had a longer overall survival from diagnosis than patients with stage IV disease ($p = 0.02$). These data suggest that treating patients with currently available chemotherapy regimens following two lines of chemotherapy should not be standard of care and that further chemotherapy should be explored in the context of a clinical trial.

SECOND-LINE TREATMENT WITH MOLECULARLY TARGETED AGENTS

Many of the molecularly targeted therapies were first investigated as second- or third-line therapy, especially at the time when a reliable biomarker was not available. Here, we review the role of a number of molecularly targeted therapies and their comparative data with single-agent chemotherapy.

Gefitinib

Gefitinib, an EGFR TKI, was the first molecularly targeted therapy investigated as second- or third-line therapy in an unselected population. Early studies were designed and initiated prior to the identification of the *EGFR* mutation. Two such trials, Iressa Dose Evaluation for Advanced Lung Cancer (IDEAL) I and IDEAL II, had as their primary objectives the assessment of tumor response (or tumor regression in IDEAL II) and improvement of lung cancer–related symptoms at two doses (250 mg and 500 mg daily) of gefitinib.[50,51] In these trials, there was no significant difference in treatment outcomes between the two doses. However, it was interesting to note in IDEAL I, in which a majority of patients were of Japanese descent, that tumor response rates were 18.4% and 19% for the two doses, respectively. In contrast, tumor response rates were 12% and 9% in IDEAL II, a predominantly North American–based study. This was the first observation of ethnic difference in treatment response to an EGFR TKI. Another interesting observation in these trials was that select patients had rapid and dramatic responses to gefitinib and this observation became the foundation for the eventual discovery of the *EGFR* mutation. Despite the relatively disappointing overall results of gefitinib in

TABLE 45.1 Randomized Studies That Compared Gefitinib With Single-Agent Docetaxel as Second-Line Therapy for an Unselected Population

Study	No. of Patients	Response Rate[a] (%)	Progression-Free Survival (Mo)	Overall Survival (Mo)
INTEREST[46]	1466	9.1 vs. 7.6	2.2 vs. 2.7	7.6 vs. 8.0
V-15-32[47]	489	22.5 vs. 12.8	2.0 vs. 2.0	11.5 vs. 14.0
ISTANA[49]	161	28.1 vs. 7.6	3.3 vs. 3.4	14.1 vs. 12.2
SIGN[48]	141	13.2 vs. 13.7	3.0 vs. 3.4	7.5 vs. 7.1

[a]Response given as the rate for gefitinib versus the rate for docetaxel.

the general unselected population, the drug was granted accelerated approval by the FDA in May 2003, allowing patients with advanced NSCLC to receive gefitinib if both a platinum-based doublet and single-agent docetaxel had failed. However, a subsequent large-scale randomized phase III study comparing gefitinib with placebo as second- or third-line therapy in an unselected population published in 2005 was negative.[52] This study enrolled 1692 patients in whom one or more lines of chemotherapy had failed. The primary end point of overall survival was 5.6 months for the gefitinib arm and 5.1 months for the placebo arm (HR: 0.89; $p = 0.087$). Only the preplanned subgroup analysis showed a survival benefit among nonsmokers compared with smokers (HR: 0.67; $p = 0.012$) and among Asian as compared with non-Asian study participants (HR: 0.66; $p = 0.01$). As a result of this negative trial, the FDA revoked its approval of gefitinib in this setting in 2005.

A number of randomized studies have compared gefitinib with docetaxel as second-line therapy in an unselected population (Table 45.1). The Iressa NSCLC Trial Evaluating Response and Survival versus Taxotere (INTEREST) was a noninferiority study of 1433 pretreated patients.[53] The primary objective of the study was overall survival, and the coprimary analysis was noninferiority between the two arms. The hazard ratio was 1.02 (95% CI, 0.905–1.150). Three other studies shared a similar trial design but investigated different ethnic populations. V-15-32 was also a noninferiority study but failed to meet the primary end point of overall survival.[54] The upper limit of the 95% CI was 1.40, and the preset limit was less than 1.25. The explanation for this negative finding was the high proportion of patients in the chemotherapy arm who had gefitinib as salvage therapy. Results from the Second-line Indication of Gefitinib in NSCLC (SIGN) study, which was conducted in a Caucasian population, were similar to those of INTEREST; the response rate was 13.2% and 13.7%, for gefitinib and docetaxel, respectively.[55] Overall survival, the primary end point of the study, was also similar (7.5 vs. 7.1 months). Another study from Korea (IRESSA as Second-line Therapy in Advanced NSCLC-Korea [ISTANA]) had a similar study design and sample size but demonstrated a significantly higher response rate for gefitinib (28.1%) compared with chemotherapy (7.6%).[56] This difference is best explained by the difference in the study populations, as the likelihood of tumors harboring *EGFR* mutations is much higher among Korean patients. However, the high tumor response rate did not translate into prolonged PFS or overall survival. These four studies demonstrated that in an unselected population gefitinib is not inferior to single-agent docetaxel; these trials, however, did not directly address the role of EGFR TKIs in patients with known wild-type *EGFR* tumors. Only in subsequent studies of patients with known wild-type *EGFR* tumors has the role of EGFR TKIs in this population become clear.

Erlotinib

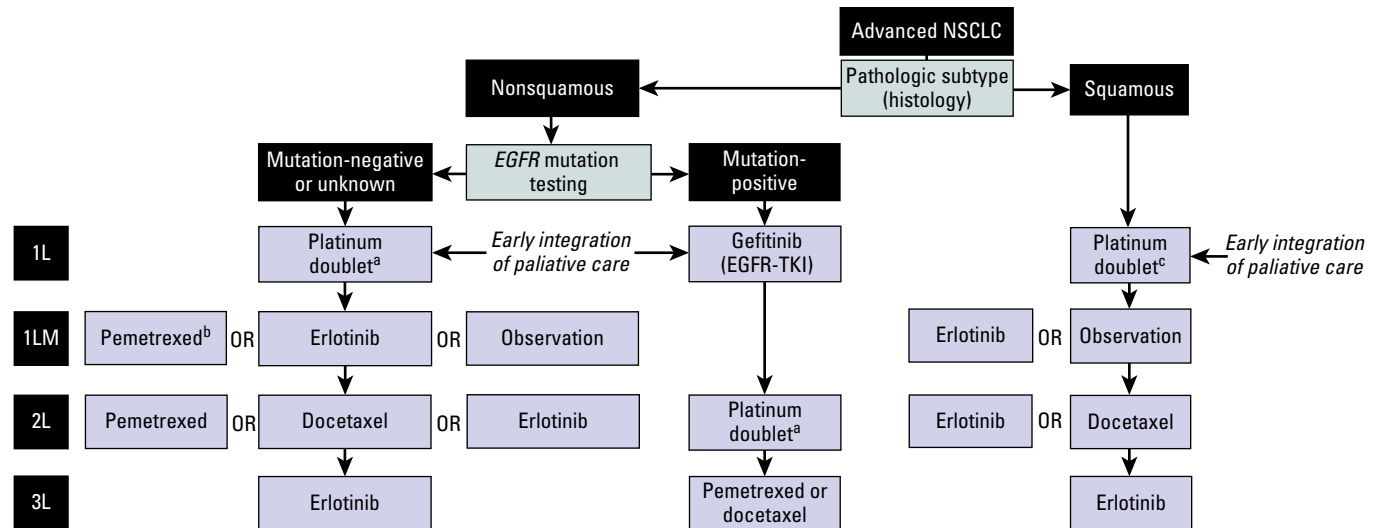
BR.21 is the major study that supports the use of erlotinib as second- or third-line therapy in an unselected population.[57] In this randomized phase III study, 731 patients with tumors of unknown *EGFR* mutation status at enrollment were randomly


Fig. 45.1. Algorithm for first- (1L, 1LM [maintenance]), second- (2L), and third-line (3L) therapy in advanced nonsmall cell lung cancer (NSCLC). Subsequent lines of treatment assume no previous exposure to the agent about to be used. [a]Includes pemetrexed-based doublet. [b]As maintenance after nonpemetrexed-containing doublets only. [c]Excludes pemetrexed doublets. *EGFR*, epidermal growth factor receptor gene; *TKI*, tyrosine kinase inhibitor. *(Reprinted with permission from Leighl NB. Treatment paradigms for patients with metastatic non-small cell lung cancer: first-, second-, and third-line.* Curr Oncol. *2012;19(suppl 1):S52–58.)*

assigned to receive erlotinib or placebo. The tumor response rate in the erlotinib arm was low (8.9%), but the drug was associated with longer PFS (2.2 vs. 1.8 months) and overall survival (6.7 vs. 4.7 months). This study established erlotinib as a worldwide standard of care in second- or third-line therapy for NSCLC. Unfortunately, only 204 tumor samples from this study were available for biomarker analysis.[58] This analysis showed that patients with wild-type *KRAS* tumors had longer overall survival than patients with *KRAS*-mutant tumors, and patients with tumors that were positive for *EGFR* on fluorescent in situ hybridization (FISH) did better than patients with tumors that were negative on FISH. On the other hand, a sensitizing *EGFR* mutation was not a predictor of survival, but this finding could potentially be explained by the limited sample size (37 patients). The tumor response rate to second-line erlotinib was 27% and 7% for patients who had tumors with or without an *EGFR* mutation, respectively (HR: 0.55; 95% CI, 0.25–1.19), but the difference was not significant. However, due to the small number of patients with tumors with known *EGFR* mutations in this trial, these data are not robust and are not likely representative of the true efficacy of second-line erlotinib for patients with *EGFR* sensitizing mutation. A single-arm study of erlotinib for patients with *EGFR*-positive tumors demonstrated response rates of 73.5% and 67.4% as first- and second-line therapy, respectively.[59] For 104 patients receiving a second-line EGFR TKI, the median PFS was 13 months, which, again, was not different from that for first-line therapy. Overall survival was also similar for first- and second-line treatment (28 and 27 months). Therefore, it is fair to conclude that second-line erlotinib shares similar efficacy as first-line erlotinib for patients who have tumors with EGFR mutations.

Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors for Patients With Known Wild-Type *EGFR* Tumors

Although erlotinib was approved as a standard second- or third-line therapy for an unselected population, the role of EGFR TKIs for patients with wild-type *EGFR* tumors remains controversial. Until recently, despite the positive results

against placebo in BR.21, there were no direct comparative data against second-line chemotherapy in an unselected population. Recent studies comparing EGFR TKIs with single-agent chemotherapy for patients with known wild-type *EGFR* tumors have cast doubts on the clinical efficacy of second-line EGFR TKIs. An Italian study (TAILOR) randomly assigned 222 patients with documented wild-type *EGFR* tumors to either single-agent docetaxel or erlotinib. The overall survival was 8.2 months for patients receiving docetaxel and 5.4 months for patients receiving erlotinib (HR: 0.73; $p = 0.05$).[60] The difference in the median PFS was minimal (2.9 vs. 2.4 months), and the tumor response rate was 10% for docetaxel and 3% for erlotinib. The authors concluded that single-agent chemotherapy was superior to erlotinib for patients who had tumors with known wild-type *EGFR*.

A Japanese study randomly assigned 300 unselected patients to receive either erlotinib or docetaxel (at 60 mg/m^2). The primary end point of PFS was similar between the two groups (2.0 vs. 3.2 months for erlotinib and docetaxel, respectively). However, the subgroup analysis on 199 patients with proven wild-type *EGFR* tumors showed that docetaxel was superior to erlotinib (median PFS, 2.9 vs. 1.3 months; HR: 1.45; $p = 0.01$).[61] However, overall survival was similar between the two groups (9.0 vs. 10.1 months). Another study compared gefitinib with pemetrexed in 157 patients with wild-type *EGFR* NSCLC.[62] The primary end point of superior PFS was met (HR: 0.54 favoring the pemetrexed arm). In summary, three randomized studies comparing EGFR TKIs with single-agent chemotherapy have consistently reported superiority of chemotherapy for patients with known wild-type *EGFR* tumors. However, these three studies are all much smaller and less robust than BR.21 and therefore have to be interpreted with circumspection. An algorithm for treatment has been developed on the basis of current guidelines (Fig. 45.1).

Vascular Endothelial Growth Factor Inhibitors

Addition of an antiangiogenic agent may potentially improve treatment outcomes of second-line therapy. The use of bevacizumab, a monoclonal antibody against the ligand of vascular

endothelial growth factor (VEGF), was extensively investigated as first-line therapy. Limited data are available about the use of bevacizumab as second- or third-line therapy. Herbst et al.[63] conducted a small phase II three-arm study in which second-line chemotherapy with or without bevacizumab was compared with erlotinib plus bevacizumab in 120 unselected patients. A median PFS of 4.8, 3.0, and 4.4 months, respectively, was reported. There was also an improvement in overall survival in the subgroup of patients treated with bevacizumab and erlotinib. This study provided the foundation for a randomized phase III study in which investigators compared erlotinib alone with erlotinib plus bevacizumab (BeTa Study).[64] A total of 636 patients were enrolled, and the combination was associated with improved PFS but no significant difference in median overall survival (9.3 vs. 9.2 months). This study was considered to be negative, and no further randomized studies were done to evaluate this combination as second-line therapy.

Multiple VEGF receptor (VEGFR) TKIs were investigated as second- or third-line therapy for lung cancer with unknown biomarker status. Several of these VEGFR TKIs inhibit VEGFR-2 and/or VEGFR-3 and also target EGFR, ret proto-oncogene (RET), c-KIT, and others. Vandetanib, a small-molecule TKI, inhibits VEGFR, EGFR, and RET and was investigated as a single agent or in combination with chemotherapy in three phase III studies. In ZEST, vandetanib was compared with erlotinib as second- or third-line therapy, and progression-free and overall survival were similar for both agents.[65] However, greater toxicity was associated with vandetanib. A second study (ZODIAC) compared the combination of vandetanib plus docetaxel with docetaxel alone.[66] The combination was superior in terms of PFS (4.0 vs. 3.2 months; $p < 0.0001$) but not in overall survival. The third study (ZEAL) was similar to ZODIAC except that the cytotoxic agent was pemetrexed instead of docetaxel.[67] Interestingly, this study demonstrated improvement in the response rate but no difference in progression-free or overall survival. The collective data from these three studies were inconsistent, and this inconsistency may be explained by the largely heterogeneous study population and the lack of an informative biomarker for VEGF inhibition.

Other VEGFR TKIs, including sorafenib, sunitinib, and cediranib, were also investigated in randomized phase III studies. In the MISSION trial, sorafenib was compared with placebo as third- or fourth-line therapy. The improvement in overall survival, the primary end point of the study, was not met (8.2 vs. 8.3 months). However, there was a significant difference in PFS (2.8 vs. 1.4 months) and the subgroup analysis suggested that the small subgroup of patients with activating EGFR mutations had improved in progression-free and overall survival.[68] Sunitinib was investigated in a randomized phase III study that compared the combination of sunitinib plus erlotinib with erlotinib alone. Similarly, there was improvement in PFS (15.5 vs. 8.7 weeks) but not in overall survival (9 vs. 8.2 months).[69] The common finding, noted in many of these studies, of an improvement in PFS suggests that a small subgroup of patients may have benefited from a VEGFR TKI but the scale of benefit was not sufficient to have an impact on overall survival.

Aflibercept is an antiangiogenic fusion protein that prevents VEGF from binding to VEGFR. The protein is composed of VEGFR-1 and VEGFR-2 and a humanized immunoglobulin G1 (IgG1) monoclonal antibody. This drug essentially prevents angiogenesis by trapping the plasma VEGF, thus justifying its other name, VEGF Trap. A large phase III study (VITAL) compared the combination of docetaxel and aflibercept with docetaxel alone for patients in whom first-line chemotherapy had failed. The tumor response rate was 23.3% and 8.9% respectively, and PFS was also improved (HR: 0.82; $p = 0.0035$).[70] However, overall survival, the primary end point, was not significantly better and the drug was not approved for use in NSCLC.

To date, only a limited number of randomized phase III studies testing a VEGF TKI have met the primary end point of prolonged overall survival. The first study involved nintedanib, a multitarget inhibitor of VEGFR 1–3, fibroblast growth factor receptor 1–3, platelet-derived growth factor receptor (PDGFR)-α and PDGFR-β, and RET. The combination of docetaxel and nintedanib was compared with docetaxel alone in 1314 patients in LUME-1.[71] The median PFS was better for the nintedanib arm (3.4 vs. 2.7 months; HR: 0.79; 95% CI, 0.68–0.92; $p = 0.0019$). Benefit was found in both the squamous cell carcinoma and adenocarcinoma subgroups. However, improvement in overall survival was found only in patients with adenocarcinoma (12.6 vs. 10.3 months; $p = 0.03$). Another study with a similar study design using pemetrexed (LUME-2) was prematurely terminated. Despite the positive randomized phase III study, the role of nintedanib in combination with docetaxel remains controversial. A second randomized phase III trial of ramucirumab, an IgG1 monoclonal antibody targeting the VEGFR-2 extracellular domain, was shown to improve survival when combined with docetaxel 75 mg/m^2 in patients with advanced squamous and nonsquamous NSCLC who had progressed after a platinum-containing chemotherapy. In this placebo controlled trial (REVEL), ramucirumab was found to significantly improve both median overall survival (10.5 months vs. 9.1 months, HR: 0.86; 95% CI, 0.75–0.98) and PFS (4.5 months vs. 3.0 months, HR: 0.76; 95% CI, 0.68–0.86).[72] Based on these results, ramucirumab was approved for the treatment of advanced NSCLC in 2014.

NOVEL TARGETS

Second- and Third-Generation Epidermal Growth Factor Receptor Inhibitors

The second-generation EGFR TKIs include canertinib, neratinib, afatinib, and dacomitinib. These irreversible adenosine triphosphate (ATP) competitor inhibitors make covalent bonds with cysteine residues at position 797 in EGFR. They are more potent than gefitinib and erlotinib against EGFR (HER1) and also inhibit other EGFR family members (e.g., HER2 and HER4). They inhibit the common EGFR sensitizing mutations (exon 19 del and exon 21 L858R point mutation) at lower drug concentrations when compared with the T790M mutation and, therefore, eventually select for cancer cells with EGFR T790M. In humans, the concentration of the drug needed to overcome T790 mutation-mediated resistance may not be achievable in the absence of significant toxicity.[73] Among the four drugs, afatinib is the furthest along in development and was approved by the FDA in 2013 for the first-line treatment of patients with metastatic NSCLC with the EGFR exon 19 deletion or L858R point mutation, as detected by an FDA-approved test. The approval of afatinib was based on the demonstration of improved PFS in a multicenter international, open-label randomized trial.[74] As mentioned earlier, afatinib has been evaluated in the third- and fourth-line setting in a phase IIb/III randomized trial of afatinib compared with placebo for patients with advanced metastatic NSCLC after failure of erlotinib, gefitinib, or both, and one or two lines of chemotherapy (LUX-Lung 1) and in a phase II trial in patients with advanced NSCLC that progressed during prior treatment with erlotinib, gefitinib, or both (LUX-Lung 4).[75,76] The results of a recently completed trial comparing afatinib with erlotinib for patients with squamous cell carcinoma of the lung in whom four cycles of first-line platinum-doublet chemotherapy had failed (LUX Lung 8) have demonstrated significant improvement in median PFS (2.4 months vs. 1.9 months, HR: 0.82; 95% CI, 0.68–1.0) and overall survival (7.9 months vs. 6.8 months, HR: 0.81; 95% CI, 0.69–0.95) with afatinib compared with erlonitib in patients

with squamous histology and resulted in afatinib's regulatory approval in 2016 for the treatment of squamous NSCLC in the second-line setting.[77]

Dacomitinib is a pan-erb inhibitor that irreversibly binds to the ATP domain of each of three kinase members of the HER family (EGFR/HER1, HER2, and HER4). In preclinical studies dacomitinib demonstrated higher potency of HER kinase inhibition and greater anticancer activity than gefitinib and erlotinib in sensitive and resistant cell lines and xenograft NSCLC models.[78] In phase I and phase II trials in patients with progressive NSCLC after treatment with an EGFR TKI and/or one or more chemotherapy regimens, dacomitinib showed antitumor activity.[79–81] Subsequently, a randomized phase II open-label study compared dacomitinib with erlotinib in patients with advanced measurable NSCLC who had an ECOG performance status of 0 to 2 and in whom one or two prior chemotherapy regimens for advanced disease had failed.[82] The primary end point of the study was the comparison of PFS between the two arms. Secondary end points included overall response rate, duration of response, overall survival, safety, and patient-reported outcomes of health-related quality of life and disease/treatment-related symptoms. In the study, 188 patients were randomly assigned, and the treatment arms were balanced for most clinical and molecular characteristics. The median PFS was 2.9 months for patients treated with dacomitinib and 1.9 months for patients treated with erlotinib (HR: 0.66; 95% CI, 0.47–0.91; two-sided $p = 0.012$). The median overall survival was 9.5 months for dacomitinib and 7.4 months for erlotinib (HR: 080%; 95% CI, 0.56–1.13; two-sided $p = 0.205$).[82] In exploratory analysis, the median PFS was 3.7 months for dacomitinib and 1.9 months for erlotinib (HR: 0.55; 95% CI, 0.35–0.85; two-sided $p = 0.006$) for patients with wild-type *KRAS* tumors. For patients with both wild-type *KRAS*/wild-type *EGFR* tumors, the median PFS was 2.2 months for dacomitinib and 1.8 months for erlotinib (HR: 0.61; 95% CI, 0.37–0.99; two-sided $p = 0.43$). Common treatment-related adverse events were dermatologic and gastrointestinal and predominantly grade 1 and 2 but occurred more frequently with dacomitinib than with erlotinib.[82] Given these results a multinational, multicenter randomized double-blind phase III study comparing the efficacy and safety of dacomitinib with that of erlotinib as second- or third-line treatment for patients with advanced NSCLC previously treated with at least one prior regimen (the ARCHER study) was undertaken. Despite the encouraging early results, dacomitinib was not found to be superior to erlotinib in terms of PFS in unselected pretreated NSCLC or in those with known *KRAS* wild-type disease.[83] In a separate randomized phase III trial (BR.26) dacomitinib was also found not to improve overall survival compared with placebo (6.83 months vs. 6.31 months, HR: 1.00; 95% CI, 0.83–1.21) in third and subsequent lines of treatment in patients previously treated with chemotherapy and an EGFR TKI, despite delaying disease progression (2.66 months vs. 1.38 months, HR: 0.66; 95% CI, 0.55–0.79).[84] In molecular subgroup analysis, similar results were observed in both *EGFR* mutant and *EGFR* wild-type disease, however patients with *KRAS* mutant disease did worse in terms of overall survival from dacomitinib than did their wild-type counterparts (0.79 months vs. 2.1 months).[84]

The third-generation EGFR inhibitors most advanced in development include AZD9291 (osimertinib),[85] CO1686 (rociletinib),[86] and BI 1482694 (olmutinib).[87] These agents were designed to specifically inhibit the *EGFR* T790 mutation. AZD9291 and CO1686 have been investigated most extensively. Osimertinib (AZD9291) is a third-generation, oral, irreversible selective inhibitor that targets both the *EGFR* sensitizing and the T790M-resistant mutant forms of *EGFR*, while maintaining a margin of selectivity relative to wild-type *EGFR*. Ballard et al.[88] have investigated the metabolism of AZD9291 in

a mouse model and have found that there are two active metabolites, AZ5104, which is approximately seven times more potent than parent AZD9291, and AZ7550, which has similar potency to AZD9291. Osimertinib has been investigated in a phase I, multicenter open-label study in a population with advanced NSCLC who had disease progression after treatment with an EGFR TKI. Among the first 60 patients enrolled to the study, 54 of whom were Asian, the median number of lines of prior therapy was three in the dose-escalation phase of the study and four in the expansion phase.[89] All patients received at least one prior EGFR TKI. The T790M mutation status was known in 28 of the 60 enrolled patients. Of the 26 evaluable patients, 12 had a response; of the 12 evaluable patients with the T790M mutation, 7 had response as measured by RECIST criteria. Grade 3 or greater adverse events occurred in 3 (5%) of 60 patients.[89] Diarrhea occurred in 8 patients (13%) and rash in 8 patients (13%). No dose-limiting toxicity was detected at doses up to 80 mg/day.[89] In updated pooled results from the AURA extension and the AURA phase II studies, which included 411 pretreated patients with *EGFR* T790M mutation-positive NSCLC, once-daily 80-mg osimertinib yielded an overall response rate of 66% (95% CI, 61% to 71%) with a median PFS of 11 months (95% CI, 9.6–12.4 months).[90] Based on these results, osimertinib has received regulatory approval in the treatment of patients with *EGFR* T790M positive NSCLC patients progressing after prior EGFR TKI therapy.[91] In an ongoing phase III trial comparing osimertinib with second-line platinum-based chemotherapy (AURA 3) in 419 patients with *EGFR* T790M mutation-positive NSCLC progressing after prior EGFR TKI, osimertinib has recently demonstrated improved PFS,[92] with full study results to be presented later this year.

In a preliminary report of the first-in-human phase I evaluation of rociletinib (CO1686), the investigators noted that among the first 42 patients enrolled (median number of previous regimens = 4) the T790M mutation was present in the tumors of 31 patients (74%), with an exon 19 deletion or L858R point mutation present in the tumors of 95% of patients.[93] At doses up to 900 mg twice daily and 400 mg three times per day, rociletinib was well tolerated and the maximum tolerated dose had not been reached. The minimum plasma concentration was greater than 200 mg/mL or more for at least 16 hours in 12 patients; 6 of these patients with a T790M mutation had tumor shrinkage of at least 10%.[93] In this initial study, the safety profile of CO1686 appeared to differ from that of the first- and second-generation EGFR inhibitors, with a mild transient rash developing in only 1 of 42 patients and grade 1 or 2 diarrhea occurring in 6 patients. However, hyperglycemia was reported as occurring in 21%.[93] Based on these results, rociletinib (CO1686) received breakthrough designation in mutant NSCLC with T790M mutations from prior EGFR TKI therapy. Updated data on 345 previously treated *EGFR* mutant NSCLC patients showed an overall response rate of 48% in T790M-positive NSCLC patients and 33% to 36% among T790M-negative patients.[94] However, despite these encouraging results, clinical development of rociletinib has been stopped, based on lower efficacy than projected and the side effect profile of the maturing data from the phase I and phase II trials.

Finally, olmutinib (BI 1482694) has also recently demonstrated clinical activity in a phase II trial of patients with EGFR TKI–resistant NSCLC with centrally confirmed T790M mutations.[95] In the 76 patients T790M+ patients who were treated with daily 800-mg olmutinib, AE grade ≥3 were limited to rash (5%) and pruritis (1%), with 3 patients (4%) discontinuing treatment due to abdominal pain ($n = 1$), interstitial lung disease ($n = 1$), and neuropathy peripheral ($n = 1$). Of the 71 patients evaluable for response, 44% had a confirmed objective response. The median duration of response was 8.3 months

(5.6–not reached) in these heavily pretreated patients, 75% of whom had received ≥2 prior lines of systemic therapy (including EGFR TKI).[95] Based on these promising results, the ELUXA trial program has been launched, aimed at investigating the therapeutic potential of olmutinib as a monotherapy, and in combination with program death 1 (PD1) pathway inhibitors, antiangiogenic agents and targeted agents, with larger phase III trials also being planned.

ANAPLASTIC LYMPHOMA KINASE

Advanced NSCLC harboring an *ALK* gene arrangement accounts for approximately 4% of cases.[96] Crizotinib is an oral small molecule inhibitor that targets *ALK*, *MET*, and *ROS1*.[97] Phase I and phase II trials have reported objective response rates of 60% in advanced ALK-positive NSCLC patients.[98,99] In randomized phase III trials, crizotinib has been shown to be superior to single-agent chemotherapy in the second-line setting.[100] In the upfront management of patients with *ALK*-positive NSCLC, improved PFS has recently been reported with crizotinib over platinum-based doublet chemotherapy (10.9 months vs. 7.0 months, HR: 0.45; 95% CI, 0.35–0.60) and has become the treatment of choice in the management of these patients.[101] As with most targeted therapies, drug resistance invariably develops in patients treated with crizotinib.

Second-generation ALK inhibitors have been developed, aimed at improving antitumor activity and providing treatment options for patients with acquired resistance to crizotinib. A selective novel oral ALK inhibitor, ceritinib (LDK378), provides a 20-fold greater potency than crizotinib in enzymatic assays. In a phase I trial, ceritinib demonstrated substantial clinical activity in patients with *ALK*-positive NSCLC. A total of 130 patients were enrolled to the trial, 68% of whom had been previously treated with crizotinib.[102] Fifty-nine patients were enrolled to the dose-escalation phase, where 750 mg daily was established as the maximum tolerated dose, with the remaining 71 patients being enrolled in the expanded cohort at a dose of 750 mg/day. Among the 114 patients with NSCLC who received ceritinib at doses from 400 to 750 mg/day, the response rate was 58%. In the 80 patients with crizotinib-resistant tumors, the response rate was 56%.[102] The median PFS in patients receiving at least 400 mg of ceritinib daily was 7.0 months (95% CI, 5.6–9.5). The most common adverse advents were nausea (82%), diarrhea (75%), vomiting (65%), and fatigue (47%). The most common grade 3 or 4 adverse advents were elevation of serum alanine aminotransferase levels (21%), elevation of serum aspartate aminotransferase (11%), and diarrhea (7%).[102] These results suggest that ceritinib is a potent and safe ALK inhibitor with activity in crizotinib-resistant ALK-positive NSCLC. Based on the emerging results from this trial, ceritinib was approved for the treatment of patients with *ALK*-positive NSCLC, progressing after crizotinib.[103] In a recent update of this phase I trial that reported on 255 patients enrolled to the study, the response rate was 72% among the 83 patients that had not previously received crizotinib and 56% in the 183 patients that had acquired resistance to crizotinib.[104] Importantly, in patients with confirmed brain metastases, intracranial disease control was 79% and 65%, in crizotinib-naive and crizotinib-resistant patients, respectively.[104] With these results as background, a number of phase I and phase II monotherapy and combination trials in *ALK*-positive biomarker select NSCLC with ceritinib are ongoing, both in patients with crizotinib resistance and in ALK-inhibitor naive populations, including those with brain metastases.

Alectinib, another selective second-generation ALK inhibitor, has demonstrated efficacy in *ALK*-rearranged NSCLC resistant to crizotinib. In a phase I dose-escalation trial of oral alectinib (300–900 mg twice daily), an objective response was noted in 24 (55%) of the 44 patients evaluable for activity.[105] Among patients with baseline CNS metastases (*n* = 21), 52% had an objective response.[105] Overall, alectinib was well tolerated, with common adverse events being fatigue (30%), myalgia (17%), and peripheral edema (15%) almost all grade 1 to 2.[105] Based on activity, tolerability, and drug pharmacokinetics, 600 mg twice daily was established as the recommended dose for the subsequent phase II trials of alectinib.

In the first alectinib phase II single-arm trial, patients with *ALK*-positive NSCLC progressing after crizotinib were enrolled to the trial and treated with 600 mg twice daily until progression, death, or withdrawal. Among the first 87 patients enrolled to study, responses were observed in 33/69 (48%) patients with measurable disease.[106] Adverse events were similar to the phase I trial, with constipation (36%), fatigue (33%), myalgia (24%), and peripheral edema (23%) noted as the most common adverse events. Grade 3 and 4 were primarily limited to changes in blood parameters, including increases in blood creatine phosphokinase (8%), alanine aminotransferase (6%), and asparate aminotransferase (4%).[106] In a second larger phase II trial in crizotinib-refractory *ALK*-positive NSCLC, 138 patients received 600 mg twice-daily oral alectinib, 84 (61%) of whom had baseline CNS metastases.[107] Among the 122 patients evaluable for response, the overall response rate was 50% (95% CI, 41% to 59%), with a median duration of response of 11.2 months. The CNS control rate was 83% and the CNS overall response rate was 57% among the 35 patients with baseline measurable CNS lesions.[107] Common adverse events with alectinib were similar to those previously reported. Based on the combined data from these phase II trials, alectinib received regulatory approval in 2014 for the treatment of crizotinib-resistant *ALK*-positive NSCLC. Alectinib is currently being compared with crizotinib in a randomized phase III head to head trial as first-line therapy in the management of *ALK*-positive NSCLC (NCT02075840), which has recently closed to accrual, with results expected early in 2017.

Finally, brigatinib (AP26113) has also demonstrated substantial antitumor activity in phase I/II trials of *ALK*+ NSCLC, including patients with crizotinib-resistant disease.[108–110] In an ongoing open-label phase I/II trial in advanced NSCLC, enriched for *ALK*+ NSCLC, in patients receiving daily oral brigatinib (30–300 mg) the objective response rate among crizotinib-resistant *ALK*+ NSCLC patients was 72% (51/71).[108] In the phase II component of this trial, response was found to differ by dosing regimen, with objective response rates of 77%, 80%, and 65% for the 90 mg daily, 90 mg daily for 7 days followed by 180 mg daily (90 mg to >180 mg), and 180 mg total daily regimens, daily.[108] As a result of these findings, a randomized phase II trial comparing the 90 mg daily to the 90 mg daily for 7 days followed by 180 mg dosing regimens is currently underway (ALTA), preliminary results of which have recently been reported.[110] Among the 222 *ALK*+ crizotinib-resistant NSCLC patients enrolled to the trial, investigators assessed overall response rate in ARM A (90 mg qd) was 46% with a PFS of 8.8 months and in ARM B (90 mg qd to >180 mg qd) was 54% with a PFS of 11.1 months.[110] In this trial, dose reductions and adverse events for ARM A versus B were 3% versus 6% and 7% versus 18%, respectively.[110] Given its greater efficacy and acceptable safety profile, the escalating dose of brigatinib (90 mg qd to >180 mg qd) is being brought forward in a planned head-to-head trial against crizotinib in the upfront management of *ALK*+ NSCLC.[110] Unlike the newer generation EGFR inhibitors where response depends on the presence of induced *EGFR* T790M mutations, brigatinib activity in criztonib-resistant *ALK*+ NSCLC has subsequently been established as independent of secondary ALK mutations.[109]

ROS1

Approximately 2% of lung cancers harbor ROS fusion proteins.[111] Several different ROS proto-oncogene 1, receptor tyrosine kinase (*ROS1*) rearrangements have been described in NSCLC, and FISH detects the presence of *ROS1* rearrangement with a ROS1 break-apart probe. *ROS1* rearrangements are nonoverlapping with other oncogenic mutations found in NSCLC.[112] Preclinical data suggest that NSCLC tumors harboring *ROS1* rearrangements may be sensitive to crizotinib. Crizotinib has been shown to bind with high affinity to both ALK and ROS1, and cell-based assays of target inhibition of different kinase targets have demonstrated sensitivity of both ALK and ROS1 to crizotinib.[113,114] Patients whose tumors harbored the ROS1 gene rearrangement were enrolled in an expansion cohort in the original dose-escalation trial of crizotinib (ClinicalTrials.gov identifier: NCT00585195). Most patients were heavily pretreated and received crizotinib 250 mg twice daily. A total of 50 patients were enrolled to the *ROS1* expansion cohort. The majority of patients were never-smokers (78%), and most patients had been treated with at least one line of standard cytotoxic therapy prior to receiving crizotinib.[115] For the full study population, the overall objective response was 72% (95% CI, 58–84%), with a median duration of response of 17.6 months. The safety profile of crizotinib in patients with ROS1-rearrangment was similar to the previously reported trials in ALK-positive NSCLC, with most treatment-related adverse events being mild, of grade 1 or 2.[115] Based on these results, crizotinib received breakthrough therapy designation and regulatory approval in the treatment of ROS1-rearranged NSCLC in 2016, thus defining a second molecular subgroup benefiting from the multitargeted agent, crizotinib.

B-Raf Kinase

v-Raf murine sarcoma viral oncogene homolog B1 (*B-RAF*) is a gene that codes a protein B-Raf, which is a serine/ threonine-protein kinase. Activating *BRAF* V600E mutations in NSCLC are present in less than 2% of adenocarcinomas of the lung.[116] A number of B-Raf inhibitors are in development, including vemurafenib,[117] sorafanib,[118] dabrafenib,[119] and AZD628. The United States FDA has already approved both dabrafenib and vemurafenib for the treatment of metastatic melanoma. Dabrafenib 150 mg twice daily has recently been evaluated in a phase II open-label single-arm study in *BRAF*-positive NSCLC, most of whom (78/84) had received prior systemic treatment.[120] Among the pretreated patients, the overall response rate was 33% (95% CI, 23–45%) and 4/6 treatment-naive patients had a treatment response.[120] Despite these encouraging preliminary results, a high frequency of serious adverse events was reported in this trial 35/84 (42%) including pyrexia (6%), decreased ejection fraction (2%), and pneumonia (2%).[120] The toxicity profile, combined with the low mutation rate of *B-raf* in NSCLC, may therefore limit the clinical utility of this compound in NSCLC.

KRAS

Kirsten rat sarcoma (*KRAS*) mutations are the most common oncogenic alterations in NSCLC, occurring in approximately 20% to 30% of adenocarcinomas of the lung.[121] It has been difficult to target and inhibit the KRAS receptor, and, therefore, recent efforts have concentrated on inhibiting downstream pathways.[122] One such pathway is the mitogen activated protein kinase (MAPK) pathway, and MEK is a member of the MAPK kinase-signaling cascade.[123] A number of MEK inhibitors are in development,[124] including selumetinib (AZD6244, ARRY142866), which inhibits MEK1 and MEK2 signaling downstream of KRAS.[125] This drug has been evaluated in the second-line setting in combination with docetaxel in a randomized phase II study of patients with stage IIIB and IV *KRAS*-mutant NSCLC who had received prior chemotherapy.[125] The patients were randomly assigned to receive docetaxel 75 mg/m^2 intravenously every 3 weeks with either selumetinib 75 mg twice daily or placebo twice daily. The primary end point was overall survival, and secondary end points include PFS, response rate, duration of response, change in tumor size, proportion of patients alive and free of progression at 6 months, and safety and tolerability. Of 422 patients who were screened, 103 were documented as having *KRAS*-mutant NSCLC, and 87 were randomly assigned to treatment. Baseline characteristics, which included performance status, gender, and *KRAS* codon 12 mutations, were balanced between the arms. The median number of cycles was four in the docetaxel plus placebo arm and five in the docetaxel plus selumetinib arm. The most frequent grade 3 or 4 hematologic toxicities were neutropenia, occurring in 54% of patients treated with placebo and in 67% treated with selumetinib, and febrile neutropenia, occurring in 0% and 16% of patients treated with placebo and selumetinib, respectively. The most common nonhematologic toxicities include dyspnea (11% and 2.3%), acneiform dermatitis (0% and 7%), and respiratory failure (5% and 7%) in the placebo versus selumetinib arms respectively. Overall survival was longer in the selumetinib plus docetaxel arm (9.4 vs. 5.2 months) but this difference was not significant (HR: 0.8; 80% CI, 0.56–0.14; one-sided p = 0.2). All secondary end points were significantly improved in the selumetinib plus docetaxel compared with the docetaxel plus placebo arm, including response rate (0% vs. 37%; p > 0.0001) and PFS (2.1 vs. 5.3 months; HR: 0.58; 80% CI, 0.42–0.79; one-sided p = 0.013).[125] A multicenter open-label nonrandomized phase I and phase II study of selumetinib in combination with gefitinib 250 mg daily in patients who failed an EGFR TKI is open for accrual at the time of writing (ClinicalTrials.gov identifier: NCT02025114). Also, a phase III double-blind randomized placebo-controlled study (SELECT-1) is underway to assess the efficacy and safety of selumetinib in combination with docetaxel for patients receiving second-line treatment for *KRAS*-mutant locally advanced or metastatic NSCLC (NCT01933932). Lastly, the results of two substudies in a randomized phase II study comparing selumetinib with selumetinib plus erlotinib in patients who had either wild-type *KRAS* or *KRAS*-mutant tumors have recently been published. In the first substudy, previously treated patients with *KRAS* wild-type NSCLC were randomized to erlotinib (150 mg daily) or a combination of erlotinib (100 mg daily) without selumetinib (150 mg daily), and the primary outcome was PFS. In the second substudy, pretreated patients with *KRAS* mutant NSCLC were randomized to selumetinib (75 mg BID) alone or the combination of erlotinib (100 mg) and selumetinib (150 mg), and the primary outcome was objective response rate in the second study.[126] In both substudies, selumetinib failed to improve treatment outcomes, with comparable PFS noted in the first trial (2.4 months vs. 2.1 months) and overlapping objective response rates between treatment arms noted in the latter trial (0% [95% CI, 0–33.6%] vs. 10% [95% CI, 2.1% to 26%]).[126] Given these findings, selumetinib does not appear to enhance the erlotinib sensitivity, irrespective of KRAS status.

MET

c-MET is a gene that encodes a transmembrane tyrosine kinase receptor, the hepatocyte growth factor receptor, which is commonly altered in NSCLC tumor tissue.[127] *MET* activation increases the expression of some EGFR ligands, and coactivation of *EGFR* and *MET* has been reported in a distinct subset of NSCLCs.[128] *MET* overexpression is one of the potential mechanisms of acquired resistance to EGFR TKIs in tumors with

EGFR activating mutations, and resistance to erlotinib has been noted in wild-type *EGFR* NSCLC cell lines through MET activation. Thus, *EGFR* and *MET* may cooperate in driving tumor carcinogenesis. *MET* is activated on binding hepatocyte growth factor, also known as scatter factor, which is the only ligand for the MET receptor.[129]

A number of small-molecule TKIs and monoclonal antibodies are in development,[130] and tivantinib, a selective small-molecule MET inhibitor, and onartuzumab, a Met monoclonal antibody, have been evaluated in a phase III study. Onartuzumab was initially explored in a double-blind, placebo-controlled, randomized trial in which patients with advanced NSCLC received oral erlotinib 150 mg daily continuously plus onartuzumab 15 mg/kg intravenously every 3 weeks or erlotinib plus placebo intravenously every 3 weeks. Eligibility requirements included advanced stage IIIB or IV NSCLC, an ECOG performance status of 2 or less, and failure of one or two previous systemic regimens (including platinum-based chemotherapy). The trial enrolled 137 patients who were randomly assigned to the onartuzumab plus erlotinib arm (69 patients) or to the erlotinib plus placebo arm (68 patients).[131] Baseline characteristics were well-balanced between the treatment arms in the intent-to-treat population, with the exception of EGFR mutation status. The coprimary end points of the study were PFS in the intent-to-treat population and in the subgroup of patients with MET-positive tumors; additional end points included overall survival, response rate, and safety. There was no improvement in PFS or overall survival in the intent-to-treat population. However, patients with tumors that were strongly positive for MET on immunohistochemistry (IHC) who were treated with erlotinib plus onartuzumab had improved PFS (HR: 0.53; p = 0.04) and overall survival (HR: 0.37; p = 0.002). Conversely, clinical outcomes were worse for patients with MET-negative tumors (as defined by weakly staining or absent staining on IHC) who were treated with onartuzumab plus erlotinib.[131] These findings led to a randomized double-blind phase III study of onartuzumab plus erlotinib compared with placebo plus erlotinib for patients with advanced MET-positive NSCLC (METLung). At least one, but no more than two, prior lines of platinum-based chemotherapy for advanced NSCLC must have failed. With a sample size of 490, the trial was designed to detect an improvement in overall survival of 41% with the addition of onartuzumab to erlotinib. This trial was stopped early for futility following an interim analysis after 244 deaths had occurred, which showed no improvement in overall survival (6.8 months vs. 9.2 months, HR: 1.27; p = 0.068), PFS (2.7 months vs. 2.6 months, HR: 0.99; p = 0.63), or response rate (8.4% vs. 9.6%, p = 0.63) with the addition of onartuzumab.[132] Ongoing exploratory analysis based on molecular subgroups may elucidate why these results did not support phase II trial findings.

Tivantinib has been explored in a randomized phase III study in combination with erlotinib (MARQUEE trial). This trial enrolled 1048 patients who were randomly assigned to receive tivantinib and erlotinib or placebo and erlotinib.[133] In order to be eligible, patients had to have nonsquamous NSCLC and previous treatment with at least one line of platinum-based chemotherapy. The study failed to meet its primary end point of overall survival (median 8.5 months for tivantinib and erlotinib vs. 7.8 months for placebo and erlotinib; HR: 0.98; p = 0.81). Subset analysis demonstrated that, among patients who had tumors with at least 2+ positive MET immunostaining in more than 50% of tumor cells, PFS favored the tivantinib and erlotinib arm (3.6 vs. 1.9 months; HR: 0.74; p < 0.0001).[133]

Recently, *MET* exon 14 skipping (*METex14*) has been described as a potential driver alteration in lung cancer targetable by MET TKIs.[134,135] In a retrospective analysis on 11,205 formalin fixed paraffin embedded (FFPE) lung cancer specimens, hybrid-capture–based comprehensive genomic profiling revealed *METex14* alterations in 298 (2.7%) lung carcinoma samples including sarcomatoid (7.7%), adenosquamous (7.2%), histology not otherwise specified (3.0%), adenocarcinoma (2.9%), squamous cell (2.1%), large cell (0.8%), and small cell (0.2%). Acinar features were present in 24% of the *METex14* samples. The median age of *METex14* patients was 73 years (range: 43–95) and 60% were female. No obvious difference in these patient characteristics was observed among *METex14* patients with varying histologies, and overall *METex14* alterations were found in 2.7% of all lung cancer samples examined.[136]

Crizotinib, an oral small molecule inhibitor that targets ALK, MET, and ROS1 that is currently approved in the treatment of *ALK*-positive and *ROS1*-positive NSCLC, has recently also demonstrated antitumor activity in patients with *MET exon 14*–altered NSCLC. In an ongoing phase I trial (PROFILE 1001) among the first 15 patients treated at a dose of 250 mg who were evaluable for response there were 10 patients with antitumor activity by RECIST.[137] Common treatment-related adverse events were edema (35%), nausea (35%), vision disorder (29%), brachycardia (24%), and vomiting (24%), which were comparable with previous reports in ALK-positive and ROS1-rearranged NSCLC.[137] These results support earlier clinical case reports of off-label crizotinib in patients harboring *MET exon 14* splice site mutations[138] and suggest the need for further evaluation of crizotinib in this patient population.

In summary, while MET inhibition appears to be a promising therapeutic strategy in several malignancies, including lung cancer, it is unclear which of several biomarkers of efficacy is the most appropriate and which patients should be considered for anti c-MET therapy

HEAT SHOCK PROTEIN 90 INHIBITORS

Heat shock protein 90 (HSP90) is a molecular chaperone for multiple proteins that are considered important oncogenic drivers in NSCLC and recognized as a key facilitator of cancer cell growth and survival.[139] There are a number of second-generation, nongeldanamycin HSP90 inhibitors currently in clinical development, including AUY922[140] and ganetespib.[141] A phase I study of AUY922 in advanced solid tumors established a recommended phase II dose of 70 mg/m^2.[140] AUY922 was explored in a phase II study in patients with previously treated advanced NSCLC stratified by molecular status.[142] Patients in whom at least two prior lines of chemotherapy had failed received AUY922 at a dose of 70 mg/m^2 by a 1-hour infusion once weekly. Four strata were considered in enrolling patients: tumors with *EGFR* activating mutations, tumors with *KRAS* mutations, tumors with *ALK* rearrangements, and wild-type *EGFR/KRAS/ALK* tumors. The study included 112 patients, 35 with *EGFR*-mutant tumors (31%), 14 with *ALK*-positive tumors (12%), and 31 with wild-type *EGFR/KRAS/ALK* tumors (28%); most had already received three or more prior systemic regimens. Diarrhea, visual disturbances, and nausea were the most common side effects. Six (18%) of 33 *EGFR*-positive tumors, 2 of 8 *ALK*-positive tumors, 4 of 30 wild-type *EGFR/KRAS/ALK* tumors, and none of 26 *KRAS*-positive tumors responded to treatment according to RECIST criteria.[142]

In phase I studies, ganetespib has demonstrated a favorable safety profile and single-agent activity in previously treated patients with advanced NSCLC.[141] Based on synergistic preclinical interactions between docetaxel and ganetespib, a randomized open-label phase II study of docetaxel with or without ganetespib was undertaken. Eligible patients with good performance status had advanced adenocarcinoma of the lung and had received one prior systemic therapy. Docetaxel was given at 75 mg/m^2 on day 1 every 3 weeks, and, in the experimental arm, ganetespib was given intravenously on days 1 and 15 at a dose of 150 mg/m^2 in a 3-week cycle.[143] Coprimary end points of

the study were PFS for patients with an elevated serum lactate dehydrogenase level or for patients with tumors harboring *KRAS* mutations. In the first 225 patients enrolled, the median number of cycles in the docetaxel plus ganetespib arm was five, compared with four in the docetaxel arm. Neutropenia, fatigue, diarrhea, and fever were the most frequent adverse events. According to a preliminary report, overall survival was better in the docetaxel plus ganetespib arm (HR: 0.69; 90% CI, 0.48–0.99; *p* = 0.093), as was PFS (HR: 0.7; 90% CI, 0.93–0.94; *p* = 0.012).[143] Because of an increased risk of hemoptysis in nonadenocarcinoma noted early in the trial, the trial was subsequently limited to patients with adenocarcinoma. In the final analysis, while no improvement was noted in the patients with an elevated lactate dehydrogenase (eLDH) (HR: 077; *p* = 0.1134) or the *KRAS*+ (HR: 1.11; *p* = 0.3384) subgroups, there was a PFS trend favoring combination therapy (HR: 0.82; *p* = 0.078) in the intent-to-treat population (*n* = 253) and a statistically nonsignificant improvement in overall survival (HR: 0.84; *p* = 0.11).[144] A phase III combination trial of docetaxel and ganetespib is being planned for patients with adenocarcinoma NSCLC diagnosed >6 months prior to study enrollment, based on added benefit of combination therapy noted in this predefined subgroup in GALAXY-1. Given these results and others, preliminary and encouraging data suggest that second-generation HSP90 inhibitors are worthy of further investigation in advanced NSCLC.

IMMUNE CHECKPOINT INHIBITORS

Several genetic and epigenetic alterations are inherent to most cancer cells and provide tumor-associated antigens that the immune host system can recognize, thereby requiring tumors to develop specific immune-resistant mechanisms. An important immune-resistant mechanism involves immune inhibitory pathways termed immune checkpoints that normally mediate immune tolerance and mitigate collateral tissue damage.[145]

CYTOTOXIC T-LYMPHOCYTE ASSOCIATED ANTIGEN 4

Ipilimumab is a fully humanized monoclonal antibody that specifically blocks the binding of the T-cell receptor cytotoxic T-lymphocyte associated antigen 4 (CTLA-4) to its ligands, CD80 (B7-1) and CD86 (B7-2).[146,147] This blockade augments T-cell activation and proliferation, which leads to tumor infiltration by T cells and tumor regression.[148] Early clinical trials with ipilimumab have shown activity in a broad range of cancers.[149,150] Ipilimumab has been the first agent of this class to demonstrate a significant improvement in overall survival in patients with previously treated as well as previously untreated metastatic melanoma.[151,152] To assess the activity of ipilimumab in patients with lung cancer Lynch et al.[153] undertook a randomized phase II three-arm study in chemotherapy-naive patients with NSCLC. Patients were randomly assigned to receive either carboplatin and paclitaxel with placebo or ipilimumab at two different doses. The first was concurrent ipilimumab (four doses of ipilimumab plus paclitaxel and carboplatin followed by two doses of placebo plus paclitaxel and carboplatin) or phased ipilimumab (two doses of placebo plus paclitaxel and carboplatin followed by four doses of ipilimumab plus paclitaxel and carboplatin). Treatment was administered intravenously every 3 weeks for 18 weeks. Eligible patients continued on ipilimumab or placebo every 12 weeks as maintenance therapy. Response was assessed using immune related response criteria and modified World Health Organization (WHO) criteria. The primary end point was immune-related PFS. The study met its primary end point of improved PFS for phased ipilimumab compared with the control (HR: 0.72; *p* = 0.05) but not for concurrent ipilimumab (HR: 0.81; *p* = 0.13).[153] Phased ipilimumab also improved PFS according to modified WHO criteria (HR: 0.69;

p = 0.02). Overall rates of grade 3 and 4 immune-related adverse events were 15%, 20%, and 6% for phased ipilimumab, concurrent ipilimumab, and control, respectively.[153] These results have led to a randomized multicenter, double-blind phase III trial comparing the efficacy of ipilimumab plus paclitaxel and carboplatin versus placebo plus paclitaxel and carboplatin in patients with stage IV chemotherapy-naive or recurrent squamous NSCLC (ClinicalTrials.gov identifier: NCT01285609). Tremelimumab, an IgG2 antibody with high affinity to CTLA-4, in an open-label phase II study in advanced NSCLC has also achieved an objective response of 5%.[154] Tremelimumab is being developed in combination with other targeted agents and immunotherapies, including the checkpoint inhibitors listed below.

Anti-Program Death 1 and Program Death 1 Ligand

PD1 is a key immune checkpoint receptor expressed by activated T cells, and it mediates immunosuppression. PD1 functions primarily in peripheral tissue were T cells may encounter immune suppressive PD1 ligand (PDL1) that is expressed by tumor cells, stromal cells, or both.[155,156] Inhibition of the interaction between PD1 and PDL1 can enhance T-cell responses in vitro and mediate preclinical antitumor activity.[157,158] There are a number of PD1 and PDL1 inhibitors in preclinical and clinical development, including the PD1 inhibitors nivolumab and pembrolizumab (MK 3475) and the PDL1 inhibitors durvalumab (MEDI4736), atezolizumab (MPDL3280A), amplimmune (AMP-224), and BMS-936559. In a dose-escalation study, the anti-PD1 monoclonal antibody nivolumab (BMS936558) was administered as a single dose in 39 patients with advanced solid tumors demonstrating a favorable safety profile and provided preliminary evidence of clinical activity.[159] This led to a multidose study where nivolumab was administered intravenously every 2 weeks of an 8-week treatment cycle and patients received treatment for up to 2 years. Objective responses were observed in a substantial proportion of patients with NSCLC, melanoma, or renal cell cancer, and they were seen at all dose levels. In the patients with lung cancer, 14 objective responses were observed at doses of 1.0, 3.0, or 10.0 mg/kg with a response rate of 6%, 32%, and 18% respectively. Objective response rates were observed across all NSCLC histologic types including 6 (33%) of 18 patients with squamous cell tumors, 7 (12%) of 56 with nonsquamous tumors, and 1 of 2 with lung tumors not otherwise specified. Sixty-one pretreatment tumor specimens from 42 patients were analyzed for PDL1 expression, and 25 were positive for PDL1 expression by IHC. Of these 25 patients, 9 had an objective response whereas none of the 17 patients with PDL1-negative tumors had an objective response suggesting that PDL1 expression by IHC may be a biomarker of efficacy. In the phase I dose-escalation and expansion study, 127 NSCLC patients were treated with nivolumab and 122 were evaluable for response, with 20 (16%) patients demonstrating a response by RECIST criteria. While responses were noted across all histologic subtypes, they were more common in patients with squamous NSCLC. Specifically, objective responses were observed in 6 out of 18 patients (33%) with squamous tumors and 7 out of 56 (12%) with nonsquamous tumors. Across all NSCLC histologies and doses evaluated, the response rate was 26% at 2 years, suggesting that there are durable responses in this heavily pretreated population.[160] In a subsequent open-label phase III trial in squamous NSCLC patients who had progressed following first-line chemotherapy (Checkmate 017), nivolumab was shown to improve overall survival compared with docetaxel (9.2 months vs. 6.0 months, HR: 0.59 months; 95% CI, 0.44–0.79), with 1-year response rates of 42% and 24% for nivolumab and docetaxel, respectively.[161] In addition, nivolumab had greater tolerability than docetaxel, with grade 3 and 4 treatment-related

adverse events being 7% and 55% for nivolumab and docetaxel, respectively.[161] Similar results were obtained in an open-label randomized phase III trial of nivolumab versus docetaxel in patients with nonsquamous histology progressing after up front chemotherapy.[162] The median overall survival was better with nivolumab as compared with docetaxel (12.2 months vs. 9.4 months, HR: 0.73; 95% CI, 0.59–0.89) and 1-year survival for patients treated with nivolumab or docetaxel was 51% and 39%, respectively. As in patients with squamous histology, nivolumab was more tolerable than docetaxel in the second-line setting, with lower rates of grade 3 and 4 treatment-related toxicity reported as compared with docetaxel (10% vs. 54%).[162] Based on the results of Checkmate 017 and Checkmate 057, nivolumab has received regulatory approval in patients with both squamous and nonsquamous histology.

Pembrolizumab (MK3475), a humanized IgG4 anti-PD1 monoclonal antibody, has demonstrated safety and efficacy in an ongoing phase I trial (KEYNOTE-001, NCT01295827). Early clinical and safety data of the first 38 patients with squamous or nonsquamous NSCLC treated with pembrolizumab demonstrated an overall response rate of 24% (9 patients). Patients with a high level of PDL1 expression had an overall response rate of nearly 70% while patients with lower rates of expression experienced a lower response rate.[163] With the aim to define and validate PDL1 expression levels associated with response to pembrolizumab, the phase I trial was expanded to include a training group (*n* = 182) or a validation cohort (*n* = 313) treated with either 2 mg/kg or 10 mg/kg every 3 weeks or 10 mg/kg every 2 weeks. PDL1 expression was assessed in all tumor samples and reported as the percentage of cells staining for PDL1 (proportion score). The overall response rate to pembrolizumab in all the NSCLC patients was 19.4%.[8] In the training group, a proportion score of 50% was identified as the threshold that defined pembrolizumab sensitivity. In the validation cohort, 45.2% of patients with a proportion score of at least 50% responded to pembrolizumab, supporting high PDL1 protein expression as a biomarker of pembrolizumab sensitivity. Pembrolizumab has since received regulatory approval in patients with advanced NSCLC whose tumors express PDL1, based on the companion diagnostic, the PDL1 IHC 22C3 pharmDx test.

Atezolizumab is an IgG1 antibody PDL1 inhibitor that in a phase I trial of 85 patients with NSCLC reported a 23% best overall response rate, with only 11% drug-related grade 3 or 4 adverse events. The majority of responses were observed within 14 weeks and all patients who had a response completed 1 year of treatment without disease progression.[164,165] Atezolizumab was subsequently investigated in phase II trials in patients with previously treated advanced NSCLC, in a single-arm trial in PDL1 expression–positive select patients (NCT01846416), and against docetaxel in a randomized controlled trial irrespective of PDL1 status (POPLAR), which was assessed prospectively and used as a stratification factor (NCT01903993). In 205/1009 patients preselected by PDL1 status enrolled to the single-arm trial (BIRCH), the highest response rates were noted in previously untreated patients (*n* = 142), with the highest score of PDL1 expression on tumor cells (TC3) or tumor infiltrating immune cells (IC3) in patients receiving second-line atezolizumab after failing chemotherapy (*n* = 271) and in patients receiving third-line atezolizumab (*n* = 254) with response rates of 29%, 27%, and 25%, respectively.[9] In the randomized trial, compared with second-line docetaxel, atezolizumab has found improved overall survival in the full study cohort (12.6 months vs. 9.7 months, HR:

0.73; 95% CI, 0.53–0.99).[166] In this trial, the efficacy of atezolizumab was associated with PDL1 expression, with greater efficacy noted in patients with higher PDL1 expression (HR: 0.49 in TC3/IC3, HR: 0.54 in TC2/TC3 and IC2/IC3 vs. HR: 0.59 in TC1/TC2/TC3 or IC1/IC2/IC3).[166] In both phase II trials, atezolizumab was well tolerated with safety profiles comparable with other checkpoint inhibitors. Atezolizumab received a breakthrough therapy designation in 2015 for the treatment of PDL1 expression–positive NSCLC progressing after first-line chemotherapy. Atezolizumab is currently being evaluated as a monotherapy against docetaxel in the second-line setting in a phase III randomized trial and in phase I trials in combination with targeted agents such as erlotinib and alectinib (NCT02013219) and in combination with chemotherapy (NCT02813785). Finally, durvalumab, MEDI4736, an IgG4 antibody to PDL1, has also been evaluated in patients with advanced solid malignancies, including NSCLC. In a phase I dose escalation trial, 0.1–10 mg/kg doses of durvalumab every 2 weeks and 15 mg/kg doses every 3 weeks were evaluated in patients with advanced solid malignancies.[167] No dose-limiting toxicities or maximum tolerated doses for either regimen were identified. Treatment-related adverse events in the first 26 patients enrolled to the trial were 34%, which were all of grade 1 and 2. In the 26 heavily pretreated patients, 4 partial responses were observed (3 NSCLC, 1 melanoma).[167] Among 198 NSCLCs (82 squamous, 116 nonsquamous) enrolled to an expansion cohort using a 10 mg/kg dose every 2 weeks, drug-related adverse events occurred in 48% and included fatigue (14%), decreased appetite (9%), and nausea (8%).[168] In the 149 patients evaluable for response (>24 weeks follow-up), the overall response rate was 14% among all patients and 23% in patients whose tumors were PDL1-positive using the Ventana PDL1 IHC (SP263) assay. Notably, the overall response rate was higher in patients with squamous histology (21%) than in patients with nonsquamous histology (10%).[168] A single-arm phase II trial (ATLANTIC) limited to patients with PDL1-positive NSCLC is currently ongoing (NCT02087423) evaluating durvalumab in the third-line setting. Durvalumab is also being evaluated in a randomized phase III trial alone and in combination with the anti-CTLA-4 agent tremelimumab (ARCTIC) against standard of care in PDL1-positive NSCLC patients who have failed two prior lines of therapy (NCT02352948)[169] and in a phase I study in combination with gefitinib in previously treated *EGFR* mutation-positive NSCLC (NCT02088112).[170]

CONCLUSION

Many ongoing phase II and phase III clinical trials are directly comparing or combining a host of these novel therapies. In particular the immune checkpoint inhibitors are being combined with chemotherapy, other targeted molecules, and as immune checkpoint doublets (Table 45.2). As a consequence the evaluation of new therapies in the second-line setting has become both extremely competitive and complex. The results of these trials will contribute to our understanding of the molecular etiology of lung cancer and the biology of progression and resistance and provide us with the next generation of targets. Ultimately, this plethora of activity will lead to significant improvement in patient survival and outcomes.

TABLE 45.2 Selection of Ongoing Phase II and Phase III Clinical Trials Directly Comparing or Combining Novel Therapies With Standard Platinum-Based Chemotherapy in Patients With Nonsmall Cell Lung Cancer

Phase	Study Design	Treatment Line	Treatments	Sponsor	ClinicalTrials.gov Identifier
Phase II	Randomized, open-label, two-arm	Second-line (Mandated first line of docetaxel, carboplatin, and bevacizumab)	Bevacizumab + pemetrexed vs. pemetrexed alone	Milton Hershey Medical Center	NCT00735891
Phase III	Randomized, double-blind, two-arm	Second-line	Docetaxel + ramucirumab vs. docetaxel + placebo	Eli Lilly and Co.	NCT01168973
Phase III	Randomized, open-label, two-arm	Second-line	Pemetrexed vs. erlotinib	NCI	NCT00738881
Phase II	Randomized, open-label, three-arm	Second-line	Pemetrexed vs. sunitib vs. pemetrexed + sunitib	NCI	NCT00698815
Phase Ib/II	Randomized, open-label	Second-line	Eribulin mesylate + pemetrexed vs. pemetrexed	NCI	NCT01126736
Phase II (TARGET)	Randomized, open-label, three-arm	Second-line (pts must be folate-receptor positive ++)	EC145 vs. EC145 + docetaxel vs. docetaxel alone	Merck Sharp and Dohme Corp	NCT01577654
Phase II (TASLISMAN)	Randomized, open-label, two-arm	Second-line (pts must be male former smokers)	Erlotinib vs. intermittent dosing of erlotinib + docetaxel	Hoffman-La Roche	NCT01204697
Phase II	Randomized, open-label, two-arm	Second-line	Suramin + docetaxel vs. docetaxel	University of Wisconsin	NCT01671332
Phase III	Randomized, open-label, two-arm	Second-line	Polyglutamate paclitaxel (CT-2103) vs. docetaxel	Cell Therapeutics	NCT00054184
Phase III (SUNRISE)	Randomized, double-blind, two-arm	Second-line	Bavituximab + docetaxel vs. docetaxel + placebo	Peregrine Pharmaceuticals	NCT01999673
Phase III	Randomized, open-label, two-arm	Second-line	Custirsen (TV-1011/OGX-011) vs. docetaxel	Teva Pharmaceuticals	NCT01630733
Phase II	Randomized, open-label, two-arm	Second-line (pts must have KRAS, NRAS, BRAF, or MEK1 mutations)	GSK1120212 vs. docetaxel	GlaxoSmithKline	NCT01362296
Phase II	Randomized, open-label, two-arm	Second-line	Gefitinib vs. pemetrexed	Gachon University Gil Medical Center	NCT01783834
Phase III	Randomized, open-label, two-arm	Second- or third-line	Paclitaxel + bevacizumab vs. docetaxel	Intergroupe Francophone de Cancerologie Thoracique	NCT01763671
Phase II	Randomized, open-label, two-arm	Second-line	Pemetrexed + (carboplatin or cisplatin) + erlotinib vs. pemetrexed + (carboplatin or cisplatin)	Vanderbilt-Ingram Cancer Center	NCT01928160
Phase II	Nonrandomized, open-label, two-arm	Third-line	Vorinostat (SAHA, Zolinza) vs. bortezomib (PS341, Velcade)	University of Wisconsin	NCT00798720

BRAF, v-Raf murine sarcoma viral oncogene homolog B; *KRAS,* V-Ki ras2 Kirsten rat sarcoma viral oncogene homolog; *MEK1,* dual-specificity mitogen-activated protein kinase 1; *NRAS,* neuroblastoma RAS viral oncogene homolog; *pts,* patients.

46 Maintenance Chemotherapy for Nonsmall Cell Lung Cancer

Maurice Perol, Heather Wakelee, and Luis Paz-Ares

SUMMARY OF KEY POINTS

- Maintenance therapy offers the possibility of continued active treatment to delay disease progression and symptom deterioration and, more importantly, improved overall survival of patients with advanced nonsmall cell lung cancer (NSCLC) already treated with induction chemotherapy.
- The target population for maintenance are patients who achieved objective response or disease stabilization with induction chemotherapy with minimal cumulative toxicity.
- Meta-analyses and patients' preference support the use of maintenance in advanced NSCLC.
- Maintenance chemotherapy doesn't impair quality of life nor generate an additional cost compared with the benefits achieved.
- Excluding targeted agents with known driver mutations, no predictive biomarkers are available to select better candidates for maintenance therapy with chemotherapy.
- In this setting new treatment opportunities with immunotherapy and other agents represent a research priority.

The quest to control NSCLC has been long and remains frustrating, but since the 2000s, substantial advances have been made in therapeutic options for patients with this disease. The most striking advances have been in treatments linked to the identification of molecular changes acting as so-called drivers of malignancy for many patients, but optimization of the delivery of chemotherapy, particularly with maintenance therapy, has also led to improved survival for patients.

The concept of maintenance therapy was initially rejected after several studies published in the early 2000s demonstrated that continuation of a platinum-based doublet beyond four cycles did not result in a significant survival advantage but did cause progressive toxicity.[1,2] Around the same time, studies demonstrated the efficacy of second-line chemotherapy, most notably with docetaxel.[3,4] The overall interpretation of these results led to the standard treatment paradigm of treatment with a platinum-based doublet for four cycles (six for patients who had response) followed by a so-called treatment holiday until the time of progression, at which point standard second-line chemotherapy was offered. The widespread belief was that patients benefited from a break from chemotherapy and that close surveillance would provide the opportunity for patients to receive beneficial future treatments.

This approach began to be questioned, however, with the development of new agents. For example, some new chemotherapy drugs, such as pemetrexed, could be given on a continuous basis with a lower risk of long-term toxicities such as neuropathy, which had limited the long-term use of other agents, such as the taxanes.[5] In addition, the era of targeted agents began, and almost all of these agents (such as bevacizumab, erlotinib, and gefitinib) are administered continuously until progression.

The maintenance approach is currently defined as continuation or switch maintenance treatment. With continuation maintenance, one or two of the agents administered as part of a first-line combination regimen are continued beyond the four to six cycles. This concept is not completely new because it was extensively investigated in several trials starting in the 1980s, but it was only in 2006, with the licensing of bevacizumab, that an approved drug was available in a continuous maintenance setting.[6] More recently, strongly positive data with pemetrexed given as continuation maintenance therapy after four cycles of a platinum-based doublet further contributed to a change in the treatment paradigm.[7] Less compelling data support the use of gemcitabine as continuous maintenance therapy.

The concept of switch maintenance is more recent and is based on switching to an alternative agent (i.e., one that was not part of the first-line regimen) after completion of four to six cycles of doublet chemotherapy in the absence of disease progression. Definitive data support the use of pemetrexed and erlotinib,[8,9] and less robust data are available for docetaxel.[10] It could be argued that such an approach may be simply considered early initiation of second-line treatment. Although the agents investigated in this setting, namely pemetrexed, erlotinib, and docetaxel, are indeed all approved agents for standard second-line therapy, their use for patients who had an objective response or disease stabilization after completion of first-line chemotherapy is biologically different from their use after disease progression. The term early second-line treatment is therefore inaccurate and should not be used.

The results of the Sequential Tarceva in Unresectable NSCLC (SATURN) and JMEN trials were the true impetus for maintenance therapy, which led to guidelines in support of maintenance therapy, issued in 2011,[11,12] and increased awareness about the benefits of this approach. Clinical investigations in this area have helped demonstrate that second-line chemotherapy is subsequently given to about two-thirds of patients who have a treatment holiday after disease stabilization with four to six cycles of chemotherapy.[10,14] Maintenance therapy, either as continuation or switch, leads to improved survival for patients with NSCLC.

HISTORICAL MAINTENANCE TRIALS

In 1989, a study to evaluate the effect of prolonging chemotherapy for patients with stable disease beyond two or three cycles of a four-drug regimen (methotrexate, doxorubicin, cyclophosphamide, and lomustine) found no benefit for a longer duration.[15] The study was small, with 74 patients randomly assigned to maintenance chemotherapy or to discontinuation of chemotherapy, and the results showed a nonsignificant trend toward longer overall survival of nearly 4 months for maintenance chemotherapy, but cast doubt on the use of prolonged first-line chemotherapy or maintenance therapy.[15] Despite this uncertainty, patients and physicians seemed to favor continued therapy, as evidenced by difficulty in recruiting to a randomized trial of six

courses of mitomycin-C, vinblastine, and cisplatin compared with observation after three cycles of the same regimen. The authors noted that most patients who declined to enroll in the study said they refused because they preferred to continue treatment.[16] However, despite this challenge, the trial was completed and it showed no improvement in survival for prolonged chemotherapy and demonstrated an increase in fatigue and other types of toxicities, further supporting the idea that less is better when considering the continuation of combination cytotoxic regimens.[2] At that time, the number of treatment cycles varied, as did the regimens used for first-line therapy.

Socinski et al.[1] published the results of a practice-changing trial in 2002. The backbone regimen for this trial was carboplatin and paclitaxel, based on the findings of multiple phase III studies performed in the United States and Europe that had demonstrated the tolerability and efficacy of this regimen.[17–20] All patients received four cycles of carboplatin (area under the curve [AUC] of 6) and paclitaxel (200 mg/m^2) on a 21-day regimen, with disease assessment after every two cycles. Patients in one arm of the trial had a break from treatment after four cycles, with assessments for progression done every 6 weeks, and patients in the other arm received chemotherapy every 3 weeks until disease progression or until the decision was made to end treatment. It was planned that all patients were to receive second-line therapy with weekly paclitaxel (80 mg/m^2) given at the time of progression. A total of 230 patients were enrolled, predominantly between 1998 and 1999. Response rates were 22% and 24%, respectively, in the two arms, with no additional responses after four cycles for patients who had received continued chemotherapy. The median survival times were 6.6 and 8.5 months, respectively, but the difference was not significant ($p = 0.63$). Of note, 45% of patients received second-line chemotherapy, and more patients received continued chemotherapy than were given a treatment holiday. Toxicities, particularly neuropathy, were higher among patients who received continued chemotherapy, but there was no clear difference in quality of life between the two treatment arms. The conclusion drawn from this trial was that treatment beyond four cycles of a platinum-based doublet did not lead to improved survival and could lead to increased toxicity.[1] Thus, the standard practice shifted toward this approach, with an additional two cycles offered to patients who had a response, such that four to six cycles of a platinum-based doublet, followed by a treatment holiday, was the standard approach. Two subsequent studies addressed the question of four versus six cycles of first-line chemotherapy, and both failed to show a clear benefit with the additional two cycles, thus supporting four cycles of first-line doublet therapy as the standard of care.[21,22]

Another contemporary phase III study compared three cycles with six cycles of carboplatin (equivalent to AUC of 5) given on day 1 and vinorelbine (25 mg/m^2) on days 1 and 8 every 3 weeks. A total of 297 patients were enrolled, and the median survival was 28 weeks for three cycles and 32 weeks for six cycles (hazard ratio [HR], 1.04; 95% confidence interval [CI], 0.82–1.31; $p = 0.75$), casting further doubt on the additional benefit of prolonged cycles of first-line chemotherapy.[23]

All of these studies evaluated continuation of the initial regimen beyond four to six cycles compared with a true maintenance approach assessing prolongation of chemotherapy only in patients benefiting from platinum-based chemotherapy. An early maintenance study comparing a continuation and a switch approach enrolled 493 patients in 2000–2004 to receive three cycles of a triplet regimen (gemcitabine, ifosfamide, and cisplatin) on an every-3-week schedule. After three cycles, the 281 patients who did not have disease progression were randomly assigned to receive continued chemotherapy until disease progression or intolerability, or to receive switch maintenance therapy with paclitaxel (225 mg/m^2) every 3 weeks, also continued until disease

progression or intolerability. The progression-free survival was similar in both arms (4.4 vs. 4.0 months; $p = 0.56$). Although numerically the median overall survival favored continued chemotherapy (11.9 vs. 9.7 months), the difference was not significant ($p = 0.17$). The 1-year survival rate was 49% for continued chemotherapy and 42% for switch therapy. Putting this trial into context with other maintenance studies is challenging, as patients in both arms continued with treatment until disease progressed, the randomization occurred after only three cycles of a platinum-based combination, and a substantial number of patients in each arm received the opposite regimen at the time of disease progression (69 of the 140 patients in the continued chemotherapy arm subsequently received paclitaxel).[24]

One of the first true maintenance studies evaluated switch maintenance therapy with vinorelbine after four cycles of mitomycin, ifosfamide, and cisplatin.[25] The study registered 573 patients with advanced stage NSCLC treated either with chemoradiation therapy for stage III disease or chemotherapy for stage IV disease, but only 181 were randomly assigned to the treatment arms of maintenance therapy with vinorelbine or no maintenance therapy. Of the 91 patients in the maintenance therapy arm, 7 died as a result of toxicity. No survival advantage was noted, which dampened enthusiasm for this approach.[26]

A randomized phase II trial demonstrated more robust activity with continuation maintenance therapy with paclitaxel. The trial included 401 patients who were randomly assigned to one of three treatment groups: weekly paclitaxel with every-4-week carboplatin or weekly paclitaxel with weekly carboplatin according to two different schedules.[26] Patients who did not have disease progression at week 16 were further randomly assigned to maintenance therapy with weekly paclitaxel (70 mg/m^2) for 3 of 4 weeks or to observation (65 patients in each group). The every-4-week carboplatin regimen was superior in terms of response, and the maintenance therapy resulted in a 9-week longer time to progression, a 15-week improvement in median survival, and improvements in 1- and 2-year survival rates. This study was conducted to determine the optimal weekly regimen of paclitaxel and carboplatin, and the efficacy of maintenance therapy was not a key question. However, these results led to adoption of maintenance therapy in the subsequent phase III trial, in which 444 patients were randomly assigned to weekly paclitaxel (100 mg/m^2) for 3 of 4 weeks plus carboplatin (AUC of 6) on day 1 of an every-4-week cycle or to standard every-3-week paclitaxel (225 mg/m^2) on day 1 with carboplatin (AUC of 6).[25] Patients in both treatment groups subsequently received maintenance therapy with paclitaxel (70 mg/m^2) for 3 of 4 weeks until disease progressed. Although the toxicity profiles differed, the efficacy outcomes did not. Because maintenance therapy with paclitaxel was given to patients in both groups, its contribution is not clear.[27]

Positive results with a continuation maintenance approach were found in a trial evaluating gemcitabine.[28] Of the 352 patients enrolled who received cisplatin (80 mg/m^2) on day 1 and gemcitabine (1250 mg/m^2) on days 1 and 8 every 3 weeks, 206 patients had no disease progression and were eligible for random assignment to continuation with gemcitabine or to no further treatment (2:1 randomization). Maintenance therapy with gemcitabine was associated with a significantly improved time to progression and a trend in favor of overall survival that did not reach statistical significance (median, 13.0 vs. 11.0 months; $p = 0.195$). Because of the lack of a significant improvement in overall survival, the results did not have a major impact on clinical practice.

Although study findings suggested a benefit with maintenance therapy, particularly continuation maintenance with paclitaxel or gemcitabine,[26,28] additional positive results were not reported until 2008. The tolerability of docetaxel, gemcitabine, and, more recently, pemetrexed, led to continued exploration of the concept of maintenance therapy.

TABLE 46.1 Recent Trials of Switch Maintenance Treatment With Chemotherapy

	Induction Treatment[a]	Maintenance Treatment					
Author/Trial	Regimen	Regimen	Median Age (Y)	PS 2 (%)	SCC Histology (%)	Never-Smokers (%)	Women (%)
Fidias et al.[10]	Carboplatin AUC 5 on day 1; gemcitabine 1000 mg/m² on days 1 & 8, every 3 wk × 4	Docetaxel 75 mg/m² every 3 wk × 6 (n = 153) Observation (n = 156)	65.4 65.5	5.9 10.3	16.3 18.8	NR NR	37.9 37.8
JMEN[8]	Platinum-based doublet (without pemetrexed) every 3 wk × 4	Pemetrexed 500 mg/m² every 3 wk + best supportive care (n = 441) Placebo + best supportive care (n = 226)	60.6 60.4	0 0	26 30	26 28	27 27

[a]In the trial by Fidias et al. 566 patients received induction treatment, and 309 (54.6%) were randomly assigned to maintenance therapy; the number of patients in JMEN who received induction treatment was not recorded.

AUC, area under the curve; *HR*, hazard ratio; *NR*, not recorded; *PS 2*, performance status of 2; *SCC*, squamous cell carcinoma.

MODERN MAINTENANCE TRIALS

Switch Maintenance With Chemotherapy (Table 46.1)

Fidias et al.[10] pioneered the modern use of the switch maintenance approach in a clinical trial in which 309 (54.6%) of 566 patients with nonprogressive disease after four cycles of first-line gemcitabine and carboplatin were randomly assigned to second-line treatment with docetaxel (maximum of six cycles) either immediately or at the time of disease progression. The median progression-free survival was longer for patients treated with immediate docetaxel than for patients treated with delayed docetaxel (5.7 vs. 2.7 months; HR, 0.71; $p = 0.0001$). The difference in median overall survival between the two treatment approaches did not reach significance (12.3 vs. 9.7 months; HR, 0.84; $p = 0.0853$) in this undersized trial. Overall survival was the primary end point of the trial, which lessened the impact of the other results. Approximately 37% of the patients assigned to receive delayed docetaxel never received it because of substantial symptomatic deterioration, death, or the investigator's decision. A subanalysis restricted to patients who did receive docetaxel in both arms showed that overall survival was identical in both arms (12.5 months), suggesting that the trend toward improved outcomes was associated with more patients in the immediate group receiving docetaxel. The toxicity profiles were similar for the two treatment approaches, and no differences in quality-of-life factors were found.

The JMEN trial evaluated pemetrexed as single-agent switch maintenance therapy. The trial design did not incorporate mandatory poststudy therapy, randomization was 2:1, and progression-free survival was the primary end point, which drew criticisms compared with the trial by Fidias et al.,[8] in which overall survival was the primary end point. However, the advantages of the JMEN trial were that its statistical assumptions were more realistic and the sample size allowed for more robust comparisons. In this trial, 663 patients with stage IIIB or IV disease who did not have disease progression during four cycles of platinum-based chemotherapy (without pemetrexed) were randomly assigned to receive best supportive care with or without pemetrexed until disease progression. Maintenance therapy with pemetrexed significantly improved the median progression-free survival (4.3 vs. 2.6 months; HR, 0.50; 95% CI, 0.42–0.61; $p < 0.0001$) and overall survival (13.4 vs. 10.6 months; HR, 0.79; 95%

CI, 0.65–0.95; $p = 0.012$) (Fig. 46.1A). Of note, relatively fewer patients in the pemetrexed group received systemic postdiscontinuation therapy (51% vs. 67%; $p = 0.0001$), and 19% of patients in the control group received salvage treatment with pemetrexed. A prespecified analysis showed a significant interaction between treatment and histology, consistent with the findings in similar prior trials in different NSCLC settings.[28] For patients who had tumors with nonsquamous cell histology, pemetrexed was associated with a greater benefit in terms of both progression-free survival (4.4 vs. 1.8 months; HR, 0.47; 95% CI, 0.37–0.60; $p < 0.00001$) and overall survival (median, 15.5 vs. 10.3 months; HR, 0.70; 95% CI, 0.56–0.88; $p = 0.002$), compared with patients who had tumors with squamous cell histology (Fig. 46.1B). In a subgroup analysis, the overall survival advantage with pemetrexed was greater for patients with stable disease at the end of induction chemotherapy (HR, 0.61) than for patients who had a partial or complete response (HR, 0.81). Treatment discontinuations due to drug-related toxic effects were more frequent with pemetrexed than with placebo (5% vs. 1%), as were drug-related grade 3 or 4 adverse events (16% vs. 4%; $p < 0.0001$), particularly fatigue (5% vs. 1%; $p = 0.001$) and neutropenia (3% vs. 0%, $p = 0.006$). No pemetrexed-related deaths occurred. Quality-of-life evaluations showed no global differences but a significant delay in worsening of pain and hemoptysis.[29] As a result of this trial, both the Food and Drug Administration (FDA) and the European Medicines Association (EMA) approved pemetrexed as switch maintenance therapy for metastatic NSCLC, specifically for patients with non-squamous cell tumors in whom disease has not progressed after first-line platinum-based chemotherapy.

Continuation Maintenance With Chemotherapy (Table 46.2)

Since the 2006 publication of a phase III trial of continuation maintenance with gemcitabine,[28] this approach has been evaluated in two additional studies.[31,32] In the first of these studies, patients with stable or responsive disease after carboplatin plus gemcitabine were assigned to either gemcitabine with best supportive care or best supportive care alone (control). The study closed after 6 years because of slow accrual, with 225 patients randomly assigned instead of the planned 332. Of note, most patients had a performance status of 2 at study entry (64%) and of 2 or 3 at the time of randomization (57%). Maintenance treatment with gemcitabine was generally well tolerated,

TABLE 46.1 (Continued)

Poststudy Treatment (%)		Progression-Free Survival			Overall Survival				
Study Drug	Any	HR (95% CI)	Median (Mo)	p	HR (95% CI)	Median (Mo)	p	Toxicity	Quality of Life
NR	NR	0.71 (0.55–0.92)	5.7	0.0001	0.84 (0.65–1.08)	12.3	0.0853	Neutropenia: 27.6%; febrile neutropenia: 3.5%; fatigue: 9.7%	No differences (LCSS)

however there was a higher incidence of grade 3 or 4 toxicity, namely, anemia, neutropenia, thrombocytopenia, or fatigue. The treatment arms did not differ in terms of progression-free survival (HR, 1.09; 95% CI, 0.89–1.45) or overall survival (HR, 0.97; 95% CI, 0.72–1.30). The trial outcomes appeared to have been influenced by the unfitness of the study population; for example, the rate of poststudy treatment was 16% in the gemcitabine arm and 17% in the control arm. Indeed, patients with a poor performance status had a significantly worse outcome than patients with a performance status of 1 (HR, 1.50; 95% CI, 1.10–2.03; $p < 0.009$). Based on these and similar results, there is agreement that maintenance treatment should not be recommended to patients with a poor performance status. The implications of these results on the adoption of continuation maintenance with gemcitabine for other patients are less clear, as it is likely the negative findings were based more on the general fitness of the enrolled patients than on a lack of effectiveness of gemcitabine per se.

In the second of the studies, the IFCT-GFPC 0502 trial, patients were randomly assigned to observation or one of two different drugs for maintenance therapy, gemcitabine or erlotinib, if they did not have disease progression after four courses of induction therapy with cisplatin plus gemcitabine.[32] Progression-free survival was the primary end point, and no comparison between the two maintenance arms was planned. The study design imposed the same second-line treatment (pemetrexed) in all three arms to avoid bias in the survival analysis as a result of an imbalance in subsequent treatments. Independently assessed progression-free survival was almost 2 months longer in the gemcitabine arm than in the observation arm (HR, 0.55; 95% CI, 0.54–0.88; $p = 0.003$), and the benefit was consistent across all clinical subgroups, including different histologies. Preliminary survival analysis did not show any meaningful differences among the study arms, but patients who received second-line pemetrexed or who had a performance status of 0 appeared to derive greater benefit. Exploratory analysis showed that the magnitude of response to induction chemotherapy may affect the overall survival benefit of maintenance therapy with gemcitabine. Among patients with an objective response to induction chemotherapy, the median overall survival was 15.2 months with gemcitabine compared with 10.8 months with observation (HR, 0.72; 95% CI, 0.51–1.04). Maintenance with gemcitabine was well tolerated, with grade 3 or 4 treatment-related adverse events (mostly neutropenia and thrombocytopenia) reported more commonly in the gemcitabine arm (27%) than in the observation arm (2%).

The TFINE study evaluated the role of docetaxel in the continuation maintenance setting. In this study, 378 patients were initially randomly assigned (1:1) to receive cisplatin (75 mg/m^2) plus docetaxel (75 mg/m^2 or 60 mg/m^2) for four cycles.[32] Patients with stable disease after first-line treatment were subsequently randomly assigned (1:2) to best supportive care or maintenance therapy with docetaxel (60 mg/m^2) for up to six cycles. The two docetaxel doses yielded similar response rates as induction treatment, but the higher dose was associated with higher rates of diarrhea and neutropenia. Continuation maintenance therapy with docetaxel significantly prolonged progression-free survival at a magnitude similar to that in the switch setting (median, 5.4 vs. 2.8 months; $p = 0.002$).

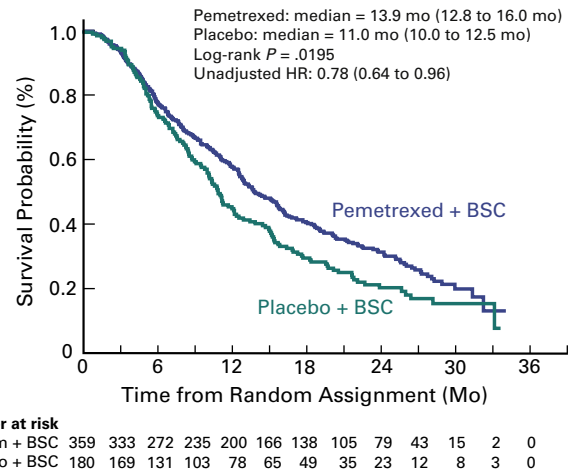
The PARAMOUNT trial was designed to determine if maintenance therapy with pemetrexed would improve efficacy compared with placebo after four courses of cisplatin and pemetrexed in patients with advanced nonsquamous cell NSCLC.[33] Of the 939 patients enrolled, 57% were randomly assigned (2:1) after the induction phase to continuation maintenance therapy with pemetrexed plus best supportive care or placebo plus best supportive care. The primary objective of this study, progression-free survival, was improved in the maintenance therapy arm compared with the placebo arm (median, 4.1 vs. 2.8 months, HR, 0.62; p


Fig. 46.2. Overall survival from date of randomization to maintenance therapy in the PARAMOUNT trial of continuation maintenance therapy with pemetrexed. *BSC*, best supportive care; *HR*, hazard ratio. *(Reprinted with permission from Paz-Ares LG, de Marinis F, Dediu M, et al. PARAMOUNT: Final overall survival results of the phase III study of maintenance pemetrexed versus placebo immediately after induction treatment with pemetrexed plus cisplatin for advanced nonsquamous non-small cell lung cancer.* J Clin Oncol. *2013;31(23):2895–2902.)*

= 0.0001). An independent review of progression-free survival (88% of patients) confirmed the investigator-assessed results. The mature survival analysis confirmed the superiority of maintenance therapy with pemetrexed (median overall survival, 13.9 vs. 11.0 months; HR, 0.78; $p = 0.0195$; Fig. 46.2).[7] Pemetrexed improved survival consistently, including response to induction therapy (HR, 0.81) and stable disease (HR, 0.76). Use of postdiscontinuation therapy was similar: 64% and 72% in the maintenance therapy arm and placebo arm, respectively. Pemetrexed remained tolerable for the vast majority of patients, even in the long-term; however, the rates of anemia, fatigue, and neutropenia were higher in the maintenance therapy arm than in the placebo arm. No significant differences in health status were found during maintenance therapy between the arms, as assessed with the EQ-5D questionnaire.[34] The EMA approved pemetrexed as continuation maintenance therapy based on the findings of this study.

Another trial (AVAPERL) analyzed the contribution of pemetrexed maintenance in combination with bevacizumab in patients exposed to both drugs in a cisplatin-based triplet as induction therapy.[36] The trial included 376 patients with nonsquamous cell NSCLC, 253 of whom were randomly assigned to maintenance therapy. Compared with bevacizumab alone, pemetrexed plus bevacizumab significantly prolonged progression-free survival from the time of induction therapy (median, 10.2 vs. 6.6 months; HR, 0.50; 95% CI, 0.37–0.69; $p < 0.001$) and from the time of randomization (median, 7.4 vs. 3.7 months; HR, 0.48; 95% CI, 0.35–0.66; $p < 0.001$). This benefit was confirmed in all major subgroups analyzed, including patients with stable disease or response after induction therapy. An updated evaluation on overall survival, a secondary end point, showed a nonsignificant 4-month advantage in favor of the combined maintenance treatment (median, 13.1 vs. 17.2 months; HR, 0.87; $p = 0.29$).[36] More severe toxicity occurred in the pemetrexed plus bevacizumab arm, including grade 3–5 hematologic events (10.4% vs. 0%) and nonhematologic events (31.2% vs. 21.7%). A smaller trial assessed the same experimental arm with the combination of pemetrexed and bevacizumab as maintenance therapy after a carboplatin-pemetrexed-bevacizumab induction regimen in comparison

with the same induction regimen followed by pemetrexed alone; the primary end point was the progression-free survival rate at 1 year.[38] The study was clearly underpowered and 1-year progression-free survival did not significantly differ between the two arms. However, there was a trend favoring the combined maintenance arm with a median progression-free survival measured from enrollment of 11.5 months compared with 7.3 months in the pemetrexed maintenance arm (HR, 0.73; 95% CI, 0.44–1.19; p = 0.198). Two other trials have provided further information on the role of continuation maintenance therapy with pemetrexed, one with bevacizumab and one without. The PointBreak trial randomly assigned 939 patients with advanced nonsquamous cell NSCLC to receive induction treatment with pemetrexed, carboplatin, and bevacizumab followed by maintenance therapy with pemetrexed and bevacizumab or to induction treatment with paclitaxel, carboplatin, and bevacizumab followed by bevacizumab.[39,40] In contrast to expectations, this trial showed superimposable survival curves for both treatment arms (HR, 1.00; p = 0.949), with a modest benefit in progression-free survival (HR, 0.83; 95% CI, 0.71–0.96; p = 0.012) favoring the pemetrexed and bevacizumab arm. It must be noted, however, that the induction phase of the study is important to the final overall analysis, as when the analysis is restricted to the 590 patients who were followed up after maintenance therapy (292 who received pemetrexed and bevacizumab and 298 who received bevacizumab alone), the separation of the progression-free survival curve (median, 8.6 vs. 6.9 months) as well as the overall survival curve (median, 15.7 vs. 17.7 months) is more apparent, although not of the magnitude seen in the AVAPERL study.

The toxicity was as expected based on the known profiles of the agents, including more anemia and fatigue for patients who received pemetrexed as part of induction therapy, and more neuropathy and hypertension for patients who received paclitaxel. Patient-reported changes in quality of life did not differ according to treatment, with the exception of neurotoxicity and alopecia, which were less frequently associated with pemetrexed.[41]

The PRONOUNCE study also compared two combined induction plus maintenance strategies in advanced nonsquamous NSCLC. The primary end point, progression-free survival without grade 4 toxicity, has controversial clinical relevance.[42] Patients were assigned to receive four courses of pemetrexed and carboplatin followed by pemetrexed (182 patients) or paclitaxel, carboplatin, and bevacizumab followed by bevacizumab (179 patients). There were no differences in progression-free survival (HR, 1.06; p = 0.610) or overall survival (HR, 1.07; p = 0.616). Therefore, this undersized trial did not demonstrate a difference in efficacy between the two approaches, but equivalence cannot be claimed, as the trial did not robustly rule out differences of moderate or small magnitude. There were no unexpected findings in terms of safety profile for either regimen.

Another trial, ERACLE (NCT00948675), compared cisplatin and pemetrexed maintenance with pemetrexed maintenance to carboplatin, paclitaxel, and bevacizumab with bevacizumab maintenance.[43] This trial is similar to PRONOUNCE, with three exceptions: the platinum agent used (cisplatin vs. carboplatin), the number of induction chemotherapy cycles (6 vs. 4), and the primary end point (differences in quality of life between the two arms vs. progression-free survival without grade 4 toxicity). This underpowered randomized study only showed a nonsignificant trend favoring the pemetrexed arm for EuroQoL 5 Dimensions-Index.

We await a large phase III trial of continuation versus switch maintenance therapy. Two small phase II trials have addressed this debate, but neither was large enough to provide conclusive findings. In one of these studies,[50] patients were randomly assigned to four cycles of either carboplatin and paclitaxel or carboplatin and gemcitabine; patients in both arms who had no disease progression subsequently received gemcitabine (1000 mg/m²) on days 1 and 8 every 3 weeks.[44] The progression-free

survival was 4.6 months in the paclitaxel (switch) arm and 3.5 months in the gemcitabine (continuation) arm, and there was no difference in the median overall survival (approximately 15 months in both arms; HR, 0.79; p = 0.60). In the other study, conducted in Japan, patients who had disease control after four cycles of induction chemotherapy with carboplatin and pemetrexed were randomly assigned to receive either continuation therapy with pemetrexed or switch therapy with docetaxel.[45] The study enrolled 85 patients, 51 of whom subsequently received maintenance therapy. The median progression-free survival from the time of randomization was 4.1 months for continuation therapy with pemetrexed compared with 8.2 months for switch therapy with docetaxel (HR, 0.56; 95% CI, 0.28–1.08; p = 0.084). The overall survival from the time of randomization was 20.6 months for continuation therapy compared with 19.9 months for switch therapy (HR, 0.79; 95% CI, 0.3–2.00; p = 0.622). Although no firm conclusions can be drawn from such a small study, the results are intriguing and do not make a clear argument in favor of switch versus continuation maintenance. It is interesting to note that more than 30% of patients in the switch therapy arm received pemetrexed as second-line therapy and 45% of patients in the continuation therapy arm subsequently received docetaxel as second-line therapy.[43] Larger trials of this nature are needed to help resolve this question.

Maintenance With Noncytotoxic Agents

Epidermal Growth Factor Receptor Inhibitors (Table 46.3)

Maintenance therapy with cytotoxic drugs evolved in parallel with the development of targeted therapy agents with mechanisms of action and toxicity profiles supporting long-term use. The use of these agents tended to continue until disease progression rather than be stopped after a predefined number of cycles. Many targeted therapy agents are taken daily by mouth.

The original approval of the epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor erlotinib was for once daily oral administration in the second- or third-line setting, with treatment continued until disease progression.[46] The question of duration of therapy was not addressed, as the toxicity profile did not necessitate discontinuation. Initial trials with the EGFR inhibitor gefitinib were similar. Trials to address duration of therapy in patients with stable disease have not been conducted, nor are such studies likely in the future. The questions surrounding duration of therapy now focus on the concept of continuation beyond disease progression. A discussion of EGFR inhibitor therapy must address its use for patients who have tumors with EGFR-activating mutations (EGFR mutation-positive tumors) compared with patients who have EGFR wild-type tumors. Studies of continuation of EGFR inhibitor therapy beyond disease progression have centered on patients with EGFR mutation-positive tumors. The use of EGFR inhibitors as first-line therapy is now considered standard for patients with EGFR mutation-positive NCSLC, and three agents have been approved for use in the United States: erlotinib, afatinib, and more recently gefitinib. In all trials that have evaluated EGFR inhibitors, the agent was continued until disease progression.

Continuation maintenance with an EGFR inhibitor after first-line concurrent use with doublet chemotherapy was evaluated in four large placebo-controlled phase III global trials (two with erlotinib and two with gefitinib): TRIBUTE, TALENT, INTACT1, and INTACT 2.[46–48] In these early trials, the EGFR inhibitor was given concurrently with a first-line platinum-based doublet and then continued until disease progression, with cessation of chemotherapy after a maximum of six cycles. None of these trials demonstrated a survival benefit for the combination arm, even with the maintenance approach.[46–48] Concern was raised about antagonism when the chemotherapy

and EGFR inhibitor were given concurrently, and thus, later maintenance trials focused solely on a switch maintenance strategy.

Between 2003 and 2005, the phase III West Japan Thoracic Oncology Group Trial 0203 randomly assigned patients to either six cycles of a platinum-based doublet or three cycles of a platinum-based doublet followed by gefitinib (250 mg orally daily).[50] More than 600 patients were enrolled, and the study demonstrated a benefit in progression-free survival in the gefitinib arm (HR, 0.68; 95% CI, 0.57–0.80; $p < 0.001$), but no overall survival benefit for the trial as a whole (HR, 0.86; 95% CI, 0.72–1.03; $p = 0.11$). There was a significant overall survival benefit for patients with adenocarcinoma, but it must be noted that this study was conducted in Japan prior to routine EGFR mutation testing and likely included a large percentage of patients with EGFR-activating mutations. At final analysis, 54% of the patients in the chemotherapy-only arm subsequently received an EGFR inhibitor, compared with 75% in the chemotherapy followed by gefitinib arm. (Only 58% of patients in the gefitinib arm received the chemotherapy followed by maintenance with gefitinib.) It is noteworthy that of the entire study population, 68% were female, 78% had adenocarcinoma, and 30% had never smoked.[50]

The SATURN trial changed the use of EGFR inhibitors in the maintenance setting.[9] This study enrolled 1949 patients over 2.5 years, ending in May 2008, to a run-in of four cycles of platinum-based chemotherapy. The 889 patients who did not have disease progression after completion of the four cycles were then randomly assigned to receive erlotinib (150 mg orally daily) or placebo until disease progression or treatment-ending toxicity. Patients were stratified according to the results of EGFR expression on immunohistochemistry (IHC) but not by EGFR mutation status or response to induction chemotherapy (objective response vs. stable disease). The primary end points were progression-free survival in all patients and in patients who had tumors with overexpression of EGFR. The progression-free survival was longer with erlotinib (12.3 vs. 11.1 weeks; HR, 0.71; 95% CI, 0.62–0.82; $p < 0.001$), and the difference was slightly greater among patients with tumors that overexpressed EGFR (12.3 vs. 11.1 weeks; HR, 0.69; 95% CI, 0.58–0.82; $p < 0.0001$). The largest benefit in progression-free survival was found in the small group of patients who had EGFR mutation-positive tumors (18 patients who received erlotinib and 22 who received placebo) (HR, 0.10; 95% CI, 0.04–0.25; $p < 0.0001$). The progression-free survival benefit associated with erlotinib was also significant for the group of patients who had EGFR wild-type tumors (165 who received erlotinib and 163 who received placebo) (HR, 0.78; 95% CI, 0.63–0.96; $p = 0.0185$). The benefit in progression-free survival translated into a benefit in overall survival for all patients in the trial (HR, 0.81; 95% CI, 0.7–0.95; $p = 0.088$) as well as for patients who had EGFR wild-type tumors (HR, 0.77; 95% CI, 0.61–0.97; $p = 0.0243$) (Fig. 46.3). Toxicity was as expected, with rash and diarrhea as the major toxicities reported with erlotinib maintenance.

In a subset analysis of SATURN, investigators sought to determine whether response to first-line chemotherapy could predict the effectiveness of maintenance erlotinib for individual patients. In this subset analysis, the progression-free survival benefit with erlotinib was more pronounced for patients who had stable disease as their best response to first-line chemotherapy. More significantly, an overall survival benefit was found only for patients with stable disease (HR, 0.72; 95% CI, 0.59–0.89; $p = 0.0019$) compared with patients who had had a previous response to chemotherapy (HR, 0.94; not significant).[51] This pattern, however, has not been consistently reported in other maintenance trials.

Number at risk

Erlotinib	438	400	329	261	204	168	118	76	53	35	14	2	0
Placebo	451	404	326	256	196	157	102	63	42	24	11	1	0

Number at risk

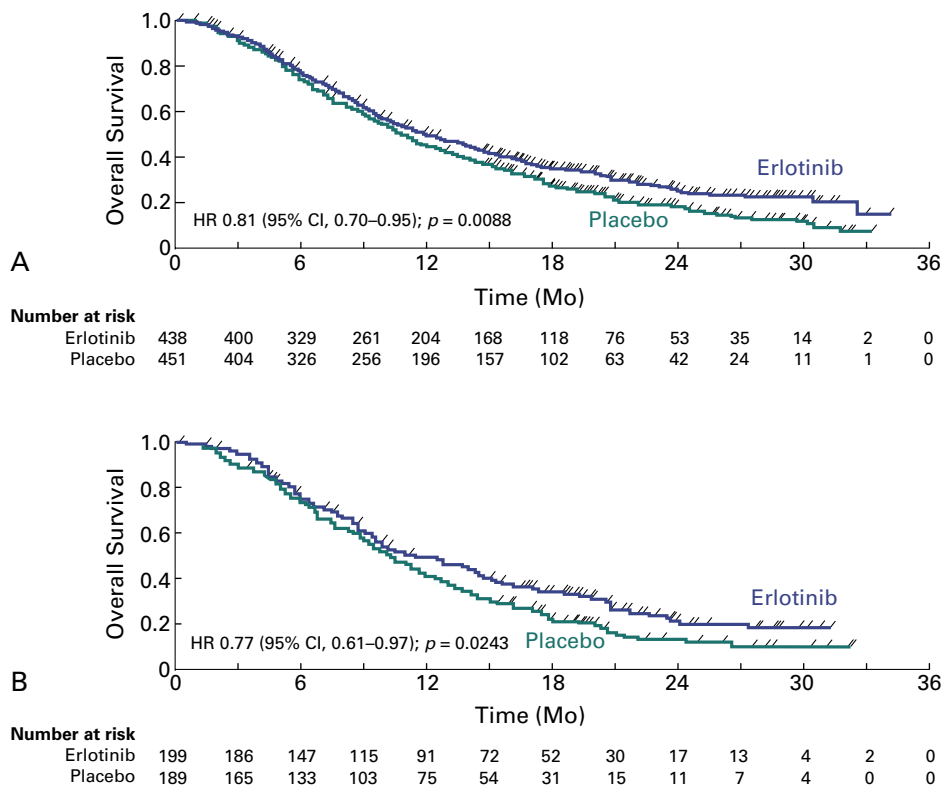
Placebo	189	165	133	103	75	54	31	15	11	7	4	0	0


Fig. 46.3. Kaplan-Meier estimates of overall survival in the intention-to-treat population (A) and in patients with EGFR wild-type tumors (B) in the SATURN trial of switch maintenance therapy with erlotinib. *CI,* confidence interval; *HR,* hazard ratio. *(Reprinted with permission from Cappuzzo F, Ciuleanu T, Stelmakh L, et al. Erlotinib as maintenance treatment in advanced non-small cell lung cancer: a multicentre, randomised, placebo-controlled phase 3 study.* Lancet Oncol. *2010;11(6):521–529.)*

All 889 patients randomly assigned in the SATURN trial provided tissue for biomarker testing.[50] Neither EGFR expression by IHC nor EGFR testing with fluorescent in situ hybridization (FISH) predicted for benefit in progression-free or overall survival. For the 49 patients with EGFR-mutation positive tumors, the progression-free survival favored erlotinib (HR, 0.10; 95% CI, 0.04–0.25; $p < 0.001$). Although the progression-free survival significantly favored maintenance therapy with erlotinib in the 388 patients with EGFR wild-type tumors (HR, 0.78; 95% CI, 0.63–0.98, $p = 0.0185$), the interactive $p < 0.001$ demonstrated that EGFR mutation status is predictive of a greater progression-free survival benefit. Despite the progression-free survival effect, the overall survival benefit was more pronounced in the group of patients with EGFR wild-type tumors, which was likely confounded by the fact that 67% of the patients with EGFR-mutation positive tumors in the placebo arm subsequently received treatment with an EGFR inhibitor. The progression-free survival was lower for the 90 patients who had tumors with V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS) mutation compared with the 403 patients who had KRAS wild-type tumors, regardless of treatment (HR, 1.50; 95% CI, 1.06–2.12; $p = 0.02$), and there was a trend toward a shorter overall survival. However, the progression-free survival curves favored erlotinib for both the patients with KRAS wild-type tumors and patients with KRAS-positive tumors, although the benefit was significant for patients with KRAS wild-type tumors (HR, 0.70; 95% CI, 0.57–0.87; $p = 0.0009$) but not for patients with KRAS-positive tumors (HR, 0.77; not significant). In a subset analysis of 126 Asian patients in the SATURN trial, progression-free survival was significantly longer for patients in the erlotinib arm who had EGFR-positive tumors according to IHC (HR, 0.50; $p = 0.0057$) and there was a trend toward increased overall survival in the erlotinib arm, which was significant for the subgroup with EGFR-positive tumors on IHC ($p = 0.0233$).[51] The overall response rate was significantly higher in the erlotinib arm (24%) than in the placebo arm (24% vs. 5%; $p = 0.0025$).

The phase III ATLAS trial also randomly assigned patients who did not have disease progression after four cycles of a platinum-based doublet to maintenance erlotinib (150 mg orally daily) or placebo, but, unlike SATURN, bevacizumab was given during induction chemotherapy and was continued during the maintenance phase in both arms. The progression-free survival was significantly better in the bevacizumab and erlotinib arm (HR, 0.71; $p = 0.0012$), but this finding did not translate into an overall survival benefit (median, 14.4 vs. 13.3 months; not significant).[54] Similarly to the SATURN trial, EGFR IHC, EGFR FISH, and EGFR/KRAS mutation status were not predictive of outcome.[53]

As discussed in the section on chemotherapy, the IFCT-GFPC 0502 trial randomly assigned patients with stable disease after four courses of induction chemotherapy with cisplatin and gemcitabine to observation or to one of two different maintenance regimens: continuation gemcitabine or switch erlotinib.[31] The progression-free survival for the 155 patients assigned to switch erlotinib was significantly better than that for the 155 assigned to observation (HR, 0.69; 95% CI, 0.54–0.88; $p = 0.003$). However, overall survival was not significantly different between the 155 patients assigned to switch erlotinib and the 155 patients assigned to observation, given that the study was not powered to demonstrate a survival difference.[32] Unlike the SATURN trial, there was no differential benefit in progression-free or overall survival depending on whether patients had a response or stable disease with induction therapy; in fact, the overall survival trend was better for patients who had a response to chemotherapy.

On April 16, 2010, the US FDA approved erlotinib for use as maintenance therapy for patients who did not have disease progression after four cycles of platinum-based first-line chemotherapy. Overall survival was a secondary end point of the trial's sponsor but was the primary regulatory end point for this approval recommendation.[60] The European Medicines Agency gave an approval for erlotinib as maintenance agent restricted to patients with stable disease after induction chemotherapy. Nevertheless, the benefit of erlotinib maintenance therapy in patients with EGFR wild-type NSCLC was reassessed and questioned by the IUNO trial (NCT01328951), which was a randomized, double-blind, placebo-controlled, phase III study of maintenance erlotinib versus erlotinib at the time of disease progression in EGFR wild-type patients who have not progressed following 4 cycles of platinum-based chemotherapy. Detailed results of the trial are not known yet but overall survival (primary end point) was not superior in patients randomized to receive maintenance erlotinib compared with patients assigned to receive maintenance placebo followed by erlotinib upon progression (HR, 1.02; 95% CI, 0.85–1.22, $p = 0.82$). In the maintenance phase, erlotinib did not provide a progression-free survival benefit compared with placebo (HR, 0.94; 95% CI, 0.80–1.11, $p = 0.48$). Based on these results, the benefit-risk of erlotinib was reconsidered as negative for maintenance treatment in patients whose tumors do not have an EGFR activating mutation explaining that erlotinib approval for maintenance therapy was withdrawn by EMA.

Gefitinib has been evaluated in other maintenance studies. The largest of these studies, INFORM, enrolled 296 patients with stable disease after four cycles of cisplatin-based induction chemotherapy and randomly assigned them to receive gefitinib (250 mg orally daily) or placebo as switch maintenance treatment.[56] Toxicities were as expected, with one confirmed death from interstitial lung disease. The progression-free survival was 4.8 months for patients who received gefitinib compared with 2.6 months for patients who received placebo (HR, 0.42; 95% CI, 0.33–0.55; $p < 0.0001$). EGFR mutation testing was not required and was known only for 79 patients. Overall survival was similar for gefitinib and placebo arm in the intention to treat population (HR, 0.88; 95% CI, 0.68–1.14; $p = 0.335$) and in subgroups with wild-type EGFR (HR, 1.27; 95% CI, 0.7–2.3; $p = 0.431$) or unknown EGFR mutations (HR, 0.92; 95% CI, 0.68–1.25; $p = 0.603$). In the EGFR mutation–positive subgroup, the gefitinib arm showed a higher overall survival than the placebo arm (HR, 0.39; 95% CI, 0.15–0.97; $p = 0.036$).[57] A smaller phase III trial of maintenance therapy with gefitinib compared with placebo in patients with no disease progression after four cycles of a platinum-based doublet similarly demonstrated a significant benefit in progression-free survival with gefitinib, despite early closing of the trial due to low accrual.[55] EORTC 08021 closed after enrolling only 173 patients; it showed a significantly better progression-free survival for gefitinib than for placebo (HR, 0.61; 95% CI, 0.45–0.83; $p = 0.0015$), but only a trend toward better overall survival.

Another trial included compared pemetrexed plus cisplatin followed by maintenance gefitinib with gefitinib monotherapy in 236 East Asian patients with advanced nonsquamous NSCLC and unknown epidermal growth EGFR mutation status but did not reveal any significant progression-free or overall survival difference in the entire study population. Nevertheless, retrospectively, the pemetrexed-cisplatin followed by gefitinib arm provides a better survival for patients with wild-type EGFR while patients with EGFR activating mutations benefited from front-line gefitinib treatment.[59] All these data strongly support that the benefit coming from gefitinib maintenance treatment is restricted to patients with EGFR activating mutations.

EGFR targeted antibodies, such as cetuximab, have also been evaluated in NSCLC, always with a continuation maintenance approach after concurrent use in first-line therapy. In the best-known trial, FLEX, cetuximab was added to first-line cisplatin and vinorelbine for patients with advanced stage NSCLC that overexpressed EGFR on IHC. Although there was no clear response nor progression-free survival benefit, this large study of more than 1000 patients did show an approximately 1-month overall survival advantage for the cetuximab arm ($p = 0.044$).[61] Another randomized phase III trial explored platinum and taxane combinations

with concurrent cetuximab followed by continuation maintenance cetuximab, and showed that the addition of cetuximab improved response but did not offer advantages in survival end points.[62] Cetuximab for NSCLC is still under investigation for continuation maintenance therapy. The largest ongoing trial has been conducted by the Southwest Oncology Group (SWOG 0819 trial) (NCT00946712) and includes concurrent and continuation maintenance cetuximab in the study arm, as well as concurrent and continuation maintenance bevacizumab for appropriate candidates of that drug in both the control and study arms. EGFR expression by FISH is used as a biomarker in the study.[63] This large phase III study failed to meet its two coprimary end points with no benefit in overall survival for the entire study population ($N = 1333$, HR, 0.94; 95% CI, 0.84–1.06; $p = 0.34$) and no significant progression-free survival improvement for patients with EGFR FISH positive tumors ($N = 400$, HR, 0.91; 95% CI, 0.74–1.12; $p = 0.37$). There was a trend toward an overall survival benefit in EGFR FISH positive patients (HR, 0.83; 95% CI, 0.67–1.04; $p = 0.10$) and for the subgroup of EGFR FISH positive patients who did not receive bevacizumab ($N = 234$, HR, 0.75; 95% CI, 0.57–0.998; $p = 0.048$). An exploratory analysis suggested a significant improvement of overall survival for patients with FISH positive squamous cell carcinoma ($N = 321$, HR, 0.56; 95% CI, 0.37–0.84; $p = 0.006$). However, the contribution of the maintenance part of cetuximab treatment cannot be assessed with this study design.

Another EGFR targeted antibody, necitumumab, has been assessed in squamous cell carcinoma given both concurrently and as continuation maintenance on a weekly basis with cisplatin and gemcitabine (maximum of six cycles) in a large open-label phase III study (SQUIRE trial, NCT00981058).[64] The addition of necitumumab to chemotherapy led to a significant improvement of overall survival (HR, 0.84; 95% CI, 0.74–0.96; $p = 0.01$), corresponding to a median survival of 11.5 months vs. 9.9 months in the control arm. Once again, the study was not designed to evaluate the role of the maintenance part of necitumumab treatment, given that 275 out of the 545 patients continued necitumumab after chemotherapy with a median of four additional cycles. EGFR expression as assessed by semiquantitative evaluation (H-score) was not predictive of survival benefit. An exploratory analysis in a subgroup of patients with available FISH testing suggested a larger survival benefit in patients with EGFR amplification ($N = 208$; HR, 0.70; 95% CI, 0.52–0.96).[65] The toxicity profile was similar to that of cetuximab, knowing that a parallel trial with pemetrexed and cisplatin plus necitumumab for patients with nonsquamous NSCLC, however, was stopped early for toxicity, primarily hypercoagulability.[66] An ongoing phase III trial (NCT01769391) is evaluating necitumumab with carboplatin and paclitaxel for patients with squamous cell NSCLC, and studies in Asia are investigating use of the agent in combination with cisplatin and gemcitabine for the same population of patients.

Vascular Endothelial Growth Factor Targeted Agents

Bevacizumab remains the only vascular endothelial growth factor (VEGF) targeted agent approved for the first-line treatment of NSCLC. Both registration trials in which bevacizumab was added to first-line chemotherapy involved continuation maintenance with bevacizumab for patients who did not have progressive disease after four to six cycles of a platinum-based doublet given concurrently with bevacizumab.[64–66] In the E4599 trial, 878 patients with newly diagnosed NSCLC were treated with carboplatin and paclitaxel with or without bevacizumab; there was a significant improvement in overall survival, the primary end point, for patients receiving bevacizumab (12.3 vs. 10.3 months; HR, 0.79; 95% CI, 0.67–0.92; $p = 0.003$). Additionally, the response rate and progression-free survival were significantly higher in the bevacizumab arm, whether the agent was given concurrently with chemotherapy or as continuation maintenance therapy. The placebo-controlled AVAiL trial randomly assigned more than 1000 patients to receive first-line cisplatin and gemcitabine with bevacizumab or placebo, again given both concurrently with chemotherapy and as continuation maintenance therapy. This study also showed significant improvements in response and progression-free survival, but not in overall survival.

Thus, bevacizumab continues as maintenance therapy beyond completion of a platinum-based doublet in all standard treatment protocols. The contribution of the maintenance component, however, has not been established. A secondary retrospective landmark analysis of E4599 evaluated patients who were alive without progression for at least 21 days after completion of six cycles of chemotherapy. The progression-free survival after induction therapy was longer for patients in the bevacizumab arm (who were receiving bevacizumab maintenance) compared with patients in the chemotherapy arm (4.4 vs. 2.8 months; HR, 0.64; $p < 0.001$). The median overall survival after induction therapy was 12.8 months in the bevacizumab maintenance arm and 11.4 months in the chemotherapy arm (HR, 0.75; $p = 0.03$).[63] In a retrospective analysis of 272 patients with advanced NSCLC who were treated in community practices, 27% of patients had received maintenance bevacizumab. As expected, these patients tended to be younger and more fit. Landmark and propensity score analyses supported a reduced risk of death with bevacizumab maintenance (landmark: HR, 0.52; 95% CI, 0.37–0.73; propensity: HR, 0.70; 95% CI, 0.39–1.28). Thus, the maintenance therapy contributed to an overall benefit in this retrospective sample, even after statistical adjustments were made for selection bias.[71] Nonrandomized studies have been done in which bevacizumab was given with chemotherapy but not continued as maintenance therapy; however, the results of these trials have not advanced knowledge about the effectiveness of this approach because of the heterogeneity of patients enrolled and the various chemotherapy regimens, as well as the lack of randomization.[72,73]

In other disease settings, maintenance therapy with bevacizumab improves outcomes. For example, in a randomized phase III trial of ovarian cancer (GOG-0218), bevacizumab was added to carboplatin and paclitaxel either as concurrent therapy only or as concurrent and continuation maintenance therapy. The progression-free survival was significantly better for the arm with continuation maintenance therapy compared with the control arm (no bevacizumab) (HR, 0.72; 95% CI, 0.63–0.82; $p < 0.0001$). However, the progression-free survival did not differ between patients who received only concurrent bevacizumab and patients in the control arm.[74] Recent data have also suggested benefit with continuation maintenance therapy with bevacizumab beyond disease progression in colon cancer.[75] In that phase III trial, patients who had disease progression during first-line chemotherapy plus bevacizumab were randomly assigned at the time of progression to receive second-line chemotherapy with or without bevacizumab; bevacizumab was associated with a significantly longer overall survival (11.2 vs. 9.8 months; HR, 0.81; 95% CI, 0.69–0.94; $p = 0.0062$). These findings have led to an ongoing trial to evaluate the role of continuation bevacizumab beyond progression in combination with second-line therapy for patients with advanced stage NSCLC.[76]

There is uncertainty about whether bevacizumab is needed beyond the completion of chemotherapy. That question will be addressed by the E5508 trial, which is enrolling patients with EGFR wild-type NSCLC who have not had disease progression after four cycles of carboplatin, paclitaxel, and bevacizumab (E4599 regimen). The patients will be randomly assigned to receive continuation of the bevacizumab, pemetrexed in addition to bevacizumab, or pemetrexed alone. Other recent maintenance trials with bevacizumab (PointBreak, PRONOUNCE) have evaluated different chemotherapy regimens, but have included concurrent and continuation maintenance with bevacizumab in all arms.

Multiple VEGF receptor (VEGFR) inhibitors are being studied in NSCLC, several as concurrent therapy with a first-line platinum-based doublet and continuation maintenance therapy. Although many studies have shown an improvement in response and progression-free survival with this strategy, none have demonstrated an overall survival benefit compared with standard first-line chemotherapy without maintenance therapy with a VEGFR inhibitor. The usefulness of maintenance therapy with these agents has therefore not been clearly addressed, as the trials to date have evaluated VEGFR inhibitors in combination with chemotherapy and continued without a randomization to maintenance therapy or no maintenance therapy. In a phase III placebo-controlled study, sorafenib given concurrently with carboplatin and paclitaxel and as maintenance therapy after four cycles failed to improve overall survival and increased mortality among patients who had tumors with squamous cell histology.[77] Similarly, the phase III MONET1, which randomly assigned patients to carboplatin and paclitaxel, with or without motesanib (AMG 706) followed by continuation maintenance therapy with motesanib, did not meet its primary end point of improved overall survival (HR, 0.89; p = 0.137).[78] The findings of a randomized phase II study with vandetanib for advanced stage NSCLC hinted that maintenance with vandetanib was of benefit, but the results of the study were not conclusive. All patients received chemotherapy plus vandetanib, with randomization to maintenance vandetanib or placebo for patients who did not have disease progression after completion of four cycles; the progression-free survival was similar to that for historical controls for chemotherapy alone in both arms.[79]

Ongoing trials are evaluating other VEGFR inhibitors given concurrently and then as maintenance therapy for advanced NSCLC, including a trial in which axitinib is given with either cisplatin and pemetrexed (for nonsquamous cell NSCLC, NCT007687855) or cisplatin and gemcitabine (for squamous cell NSCLC). The combination of cisplatin, gemcitabine, and axitinib has been shown to be feasible, but without a control arm, it remains difficult to assess the role for axitinib in this schedule.[80] Because of the toxicity associated with sunitinib given with concurrent chemotherapy, this agent has been studied as true switch maintenance therapy. A phase II study in which sunitinib (50 mg/d orally for 4 weeks followed by 2 weeks off) was given after four cycles of carboplatin and paclitaxel was not randomized and did not meet its primary end point.[81] However, the phase III CALGB 30607 study comparing sunitinib given orally daily on a continuous schedule with placebo as maintenance therapy after four cycles of platinum-based first-line chemotherapy demonstrated an improvement of progression-free survival without prolongation of overall survival.[82] Two hundred and ten patients were randomized with a progression-free survival of 4.3 months for patients assigned to the sunitinib arm versus 2.8 months for the placebo arm (HR, 0.58; 95% CI, 0.42–0.79; p = 0.0004), irrespective of histology; overall survival was not different (HR, 1.08; p = 0.64).

Unfortunately, other efforts at maintenance therapy with vascular pathway agents have been disappointing. A large phase III placebo-controlled trial of carboplatin and paclitaxel with or without the vascular disrupting agent vadimezan (ASA404) included maintenance therapy with vadimezan as part of the study design. The outcomes did not differ between the two arms, so it is unclear whether maintenance therapy was of any benefit.[83] Thalidomide was also studied as a continuous maintenance agent given orally for 2 years after four cycles of induction chemotherapy with carboplatin and gemcitabine. All results favored the placebo arm, leading to abandonment of further exploration of maintenance therapy with thalidomide.[84] Another agent with antiangiogenic properties, tested as a maintenance therapy in a large phase III placebo-controlled trial, is the oral agent carboxyaminoimidazole (CAI), a carboxyamide-amino-triazole. Treatment with CAI or placebo was started after completion of first-line chemotherapy and, although the trial had accrual issues and included only 186 patients, the results indicated increased toxicity but no improvements in efficacy end points.[85]

Immunotherapy

Although none has demonstrated efficacy in NSCLC to date, vaccine and other immune-based strategies are being studied as a form of continuation maintenance therapy. Older trials focused on interferon gamma and interleukin-2, with encouraging preliminary results, but no further development.[86,87] The true vaccines studied in larger trials in NSCLC include belagenpumatucel-L and BLP-25, among others. In patients with stage IV NSCLC, these agents are often given as switch maintenance therapy, started after completion of chemotherapy. Encouraging results from a randomized phase II study of belagenpumatucel-L, a transforming growth factor beta-2 allogeneic tumor cell vaccine,[88] led to a recently completed randomized phase III trial of the vaccine as switch maintenance therapy for patients who had a response to six cycles of platinum-based chemotherapy for advanced stage NSCLC. The results of that trial were not available at the time of publication. L-BLP-25, a vaccine against MUC-1, also showed encouraging results as a maintenance approach for patients with stable or responding disease after first-line chemotherapy for advanced stage NSCLC. Although initial studies have focused on patients with inoperable stage III NSCLC, it is possible that future research will evaluate L-BLP-25 as maintenance treatment for stage IV NSCLC.[89] Other ongoing vaccine trials in the stage IV maintenance arena include a trial that has recently completed accrual (NCT00415818), in which TG4010, a MUC-1 and interleukin-2 vaccine, is being given to patients with MUC-1-expressing tumors during six cycles of a platinum-based doublet and continuing after that treatment. Another vaccine trial, ongoing in the United Kingdom (NCT01444118), seeks to validate work done in Cuba with a compound composed of an adjuvant plus humanized recombinant antigen EGF (cyclophosphamide and recombinant human rEGF-P64K/Montanide ISA 51) vaccine. In a phase III trial of the immunotherapy agent racotumomab, the agent will be studied in patients with advanced stage NSCLC who have had a response to standard first-line chemotherapy (NCT01460472). Although most of the patients will have stage III disease, approximately 30% of the more than 1000 patients in the trial will have stage IV disease.

Another ongoing phase III trial is evaluating the CTLA-4 targeted antibody ipilimumab in combination with carboplatin and paclitaxel, with continuation maintenance therapy with ipilimumab. This phase III trial was initiated based on a phase II trial of the combination that showed that the addition of ipilimumab as maintenance therapy to carboplatin and paclitaxel was superior to chemotherapy alone as well as to ipilimumab given concurrently with the first cycle of chemotherapy.[90]

Other key components of inhibitory immune checkpoints include PD-1 and its ligands PD-L1 and PD-L2. PD-1 mainly affects T-cell activity in peripheral tissues through interaction with PD-L1 and PD-L2. Targeting PD-1/PD-L1 interaction with PD-1 or PD-L1 antibodies can restore tumor-related immune responses, leading to tumor shrinkage and long-lasting responses in approximately 15% to 20% of pretreated NSCLC patients.[91] PD-1/PD-L1 inhibitors have been evaluated in a second-line setting in comparison with docetaxel. Twin phase III trials showed significantly improved survival for the PD-1 inhibitor nivolumab compared with docetaxel in squamous and nonsquamous carcinoma, respectively.[92] Pembrolizumab, another PD-1 inhibitor, also demonstrated a significant improvement of overall survival in comparison with docetaxel in patients with tumors expressing PD-L1 in at least 1% of tumor cells.[94] Similarly, the PD-L1 inhibitor atezolizumab showed an improvement of overall survival in a randomized phase II study with docetaxel as the control arm.[95] PD-L1 expression was correlated with improved survival

in nonsquamous patients, but use of PD-L1 expression to guide therapy remains controversial. Optimal duration of anti-PD-1/PD-L1 therapy is actually unknown as most of these compounds are still continued as maintenance agents until toxicity or disease progression after obtaining maximal response.

At this point, PD-1 inhibitors are becoming the standard of care for second-line therapy of advanced NSCLC but they will soon move toward the frontline therapy. Many phase III studies are ongoing or have completed their accrual and have been published, which evaluate platinum based chemotherapy versus either anti-PD-1/PD-L1 as a single agent in PD-L1 positive tumors or in combination with chemotherapy or anti-CTLA4 for PD-L1 positive and PD-L1 negative tumors. All these studies are designed with the continuation of PD-1/PD-L1 inhibitors until toxicity or disease progression, in particular after cessation of chemotherapy or anti-CTLA4 in combination studies. None of these trials specifically address the role of anti-PD1/anti-PD-L1 inhibitors as maintenance treatment except for the SAFIR02 lung trial (NCT02117167) in which patients with disease control at the end of platinum-based induction chemotherapy and without targetable genetic alteration are randomized between standard maintenance treatment or durvalumab (anti-PD-L1 antibody). The role of immune checkpoints inhibitors is rapidly increasing in the treatment of advanced NSCLC, with many unresolved issues including the important question of the optimal duration of treatment.

META-ANALYSES

Over the last few years, several meta-analyses have been conducted in an effort to summarize the impact of maintenance treatment strategies on efficacy and toxicity and to analyze the value of the different approaches (continuation or switch) and treatment agents (chemotherapy or targeted agents).[29,82–85] Lima et al.[82] performed a meta-analysis of seven randomized controlled trials (1559 patients) comparing different durations of first-line treatment for advanced stage NSCLC. Patients receiving more chemotherapy had significantly longer progression-free survival (HR, 0.75; 95% CI, 0.60–0.85; $p < 0.0001$) than patients who had a shorter duration of treatment, but there were no differences in relative mortality (HR, 0.97; 95% CI, 0.84–1.11; $p = 0.65$). In addition, there was no difference in the overall response rate between the groups (odds ratio, 0.78; 95% CI, 0.60–1.01; $p = 0.96$). Longer treatment was associated with more severe leukopenia but with no significant increase in nonhematologic toxicities. Almost concurrently, Soon et al.[83] published their meta-analysis of 13 trials (3027 patients) that not only included studies with varying durations of combination first-line chemotherapy, but also available randomized controlled trials evaluating continuation and switch maintenance approaches with chemotherapy. Consistently, they found that extending chemotherapy improved progression-free survival significantly (HR, 0.75; 95% CI, 0.69–0.81; $p < 0.00001$) and also resulted in a modest but still clinically significant improvement in overall survival (HR, 0.92; 95% CI, 0.86–0.99; $p = 0.03$). Subgroup analysis demonstrated that effects on progression-free survival were greater with third-generation regimens and with switch maintenance strategies. Extending chemotherapy was again associated with more frequent adverse events, and impaired health-related quality of life in two of seven trials.

A third meta-analysis, which comprised eight trials and 3736 patients (three trials of continuation maintenance and five trials of switch maintenance) of chemotherapy or targeted agents, was published in 2011.[84] A clinically substantial and statistically significant improvement in progression-free survival was found with both maintenance strategies (switch maintenance therapy: HR, 0.67; 95% CI, 0.57–0.78; continuous maintenance therapy: HR, 0.53; 95% CI, 0.43–0.65; interaction $p = 0.128$). Switch maintenance therapy significantly improved overall survival compared with placebo or observation (HR, 0.85; 95% CI, 0.79–0.92; $p = 0.001$), and the continuation maintenance approach resulted in a similar

improvement in overall survival (HR, 0.88; 95% CI, 0.74–1.04; $p = 0.124$), despite lacking statistical significance, probably because of low statistical power (779 patients included in three trials; Fig. 46.4). Indeed, the interaction test suggested that the magnitude of the benefit from the two maintenance strategies was similar ($p = 0.777$). Subgroup analyses showed no significant differences in overall or progression-free survival between switch maintenance therapy with cytotoxic agents or tyrosine kinase inhibitors. In general, toxicity was greater with maintenance therapy.

Three further meta-analyses were reported in 2012 and 2013, with data from 10 randomized controlled trials (3451 patients) or 11 randomized controlled trials (3686 patients and 4790 patients), and the outcomes were comparable to those in the earlier meta-analyses.[30,99,100] In one analysis, Cai et al.[100] found a significant improvement in overall survival with switch maintenance (HR, 0.80; 95% CI, 0.72–090; $p = 0.0002$), but only a trend toward better overall survival with continuation maintenance (HR, 0.82; 95% CI, 0.66–1.01; $p = 0.06$). Both strategies improved progression-free survival, and the greatest benefit was found for tumors with nonsquamous cell histologies. A more recent meta-analysis did not alter these results: Zhou et al.[101] also reported a meta-analysis of 13 trials with 4960 patients showing a significant overall survival benefit for maintenance therapy (HR, 0.84; 95% CI, 0.78–0.89; $p < 0.001$) without significant differences for switch and continuation maintenance strategy (HR, 0.83 vs. 0.86; $p = 0.631$ [for interaction]). Another meta-analysis of 14 randomized control trials involving 5841 patients provided very similar results.[102] A recent systematic review of 14 randomized trials assessing systemic maintenance therapy confirmed the significant survival benefit related to pemetrexed maintenance treatment in nonsquamous lung carcinoma (HR, 0.74; 95% CI, 0.64–0.86; $p = 0.0003$), which was larger than that of EGFR tyrosine kinase inhibitors (HR, 0.84; 95% CI, 0.75–0.94; $p = 0.002$).[103] On the other hand, gemcitabine and docetaxel maintenance chemotherapy did not provide any significant survival advantage, which is consistent with the results of another meta-analysis dedicated to the role of pemetrexed and gemcitabine maintenance therapy.[104]

Several meta-analyses focused solely on the benefit of maintenance therapy with EGFR inhibitors have also been published recently. The three randomized trials with switch maintenance erlotinib (SATURN, Atlas, IFCT-GFPC 0502) were pooled (1942 patients), and the HR was 0.76 ($p < 0.00001$) for progression-free survival and 0.87 ($p = 0.003$) for overall survival, but the analysis did not include individual patient data.[105] Chen et al.[88] included five trials of either maintenance erlotinib or gefitinib (2436 patients) and found an increase in progression-free survival (HR, 0.63; 95% CI, 0.76–0.93) compared with placebo or observation; the HR for overall survival was 0.84 (95% CI, 0.76–0.93) regardless of stage, sex, ethnicity, performance status, smoking status, EGFR mutation status, or prior response to therapy.[88] Nevertheless, none of these meta-analyses include the recent data of the negative IUNO trial.

No large randomized trials have compared maintenance erlotinib with pemetrexed. There have been some efforts to carry out an indirect comparison, including one analysis that identified five randomized controlled trials that were then included in an indirect comparison meta-analysis. The findings suggested superiority of pemetrexed in terms of progression-free survival (HR, 0.71; 95% CI, 0.6–0.85; $p = 0.0001$). However, the difference in overall survival was not significant (HR, 0.88; 95% CI, 0.71–1.08; $p = 0.22$), although there was a trend in favor of pemetrexed.[107] Tan et al.[108] used a network meta-analysis to define the best maintenance option according to patients characteristics (EGFR status, performance status [PS], histology, and response to induction). This method allows comparing different therapeutic interventions across a trial's network sharing the same control arm (no maintenance treatment) and ranking the impact of different maintenance strategies. The meta-analysis confirmed the positive impact of a good PS on the survival benefit from maintenance therapy and that of a response to induction chemotherapy for

Fig. 46.4. Comparison of overall survival between continuous maintenance therapy and placebo or observation (A) and between switch maintenance therapy and placebo or observation (B). *CI,* confidence interval; *HR,* hazard ratio; *NR,* not recorded; *OS,* overall survival. *(Reprinted with permission from Zhang X, Zang J, Xu J, et al. Maintenance therapy with continuous or switch strategy in advanced non-small cell lung cancer: a systematic review and meta-analysis. Chest. 2011;140(1):117–126.)*

gemcitabine continuation maintenance. However, the heterogeneity of studies according to the proportion of patients receiving second-line treatments and the low level of EGFR testing in most of the maintenance trials may limit the scope of these results.

COST-EFFECTIVENESS

A discussion of maintenance therapy is incomplete without addressing financial implications. There have been multiple evaluations of costs of maintenance pemetrexed and erlotinib, some of which have been crucial to the approval or disapproval of maintenance therapy in many European countries. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) standard willingness-to-pay range is approximately £20,000 to £30,000 per quality-adjusted life year (QALY).

Using the results from the JMEN trial, the incremental cost-effectiveness ratios for pemetrexed were more than £30,000 and, per NICE, were closer to £50,000 per QALY. Despite this assessment, NICE approved switch (but not continuation) maintenance with pemetrexed for nonsquamous NSCLC in 2010.[109] In the United States, researchers used a semi-Markov model utilizing Medicare reimbursement rates for drug costs estimates and found an incremental cost per life-year gained for nonsquamous cell NSCLC of US $133,371 for pemetrexed compared with observation and nearly US $150,000 for erlotinib maintenance.[110] Switch maintenance therapy with pemetrexed is approved in the United States. From a Swiss health-care system perspective, a Markov model was constructed based on the results of the JMEN trial, and the incremental cost-effectiveness ratio of adding pemetrexed until disease progression was calculated as cost per QALY

gained. When an assumption was made for a reduction of the costs for best supportive care by 25% in the pemetrexed arm, the incremental cost-effectiveness ratio was €47,531 per QALY, which was below the Swiss cut point, but was considered by the authors as not cost-effective.[111] An analysis of estimated costs in China for continuation maintenance therapy with pemetrexed was estimated at more than US$100,000 per QALY gained.[112]

Maintenance therapy with erlotinib is also expensive, but a comprehensive analysis published in 2012 estimated that switch maintenance therapy with erlotinib had an incremental cost per life-year gained of €20,711 (UK) and €25,124 (Germany), which was considered to be cost-effective.[113] A separate analysis performed with a model based on the national health-care payers in France, Germany, and Italy, using a probabilistic sensitivity analysis, also concluded that this approach was cost-effective. The authors estimated that the cost per life-year gained with maintenance erlotinib was €39,783 in France, €46,931 in Germany, and €27,885 in Italy.[114] In the UK, for patients with stable disease after four cycles of first-line chemotherapy with a platinum-based doublet, the use of switch maintenance erlotinib was not thought to be cost-effective, with prices of more than £40,000 per QALY gained; NICE did not approve switch maintenance erlotinib.[115] From a US perspective, the additional costs of maintenance therapy with erlotinib were analyzed in the context of a health-care plan with 50,000 members, and the authors concluded that, assuming that a high number of patients would receive erlotinib as second- or third-line therapy, the costs of changing to a maintenance approach were minimal.[116] Few analyses have attempted to estimate the financial implications of pemetrexed versus erlotinib maintenance. One analysis limited to direct costs (drug acquisition, administration, and treatment of adverse events) that was conducted from the perspective of national health-care decision makers in France, Germany, Italy, and Spain estimated a total monthly per-patient treatment cost for erlotinib of €2140 in France, €2732 in Germany, €1518 in Italy, and €2048 in Spain; the corresponding per-patient treatment costs for pemetrexed were €3453, €5534, €2921, and €3164. The authors concluded that, given similar efficacy, erlotinib was more cost-effective.[117] Clearly, further similar analyses will be needed to fully assess the cost of maintenance therapy. The cost-utility analysis of the IFCT-GFPC 0502 French study showed that ICERS of gemcitabine- or erlotinib maintenance therapy varied as a function of histology, PS, and response to first-line chemotherapy.[118]

PATIENT SELECTION

The selection of patients to receive maintenance therapy remains controversial. Despite early support of the concept, prior response to chemotherapy does not seem to be an indicator of benefit from switch maintenance. In the trials by Fidias et al.[10] and Perol et al.,[32] which evaluated switch maintenance with docetaxel and continuation maintenance with gemcitabine, respectively, patients with a prior response appeared to have the greatest benefit from maintenance therapy. In contrast, in the erlotinib arm of the trial by Perol et al.,[32] the benefit was similar regardless of prior response and in the SATURN trial, the majority of benefit with switch maintenance erlotinib appeared to be in patients with stable disease during first-line chemotherapy.[9,32] Thus, although a few criteria are available to help select an agent (e.g., nonsquamous cell histology for pemetrexed and EGFR mutation status for erlotinib), little information is available to help guide the more important decision of whether to consider maintenance therapy or not for an individual patient. Perhaps the strongest caution comes from a trial of continuation maintenance with gemcitabine, which enrolled a substantial number of patients with a poor performance status and, unlike most other maintenance trials, was negative.[31]

Some experts have advocated imaging, including fluorode-oxyglucose-positron emission tomography, to help determine which patients are more likely to benefit from maintenance therapy,[119,120] and others have recommended that patients with a higher symptom burden are more likely to benefit from maintenance therapy.[14,121] In one retrospective analysis from a single institution, it was noted that socioeconomically disadvantaged patients were more likely to be lost to follow-up before initiation of second-line therapy and were therefore in greater need of maintenance therapy because they may not receive beneficial second-line treatment if there is a delay.[14]

Patient preferences for maintenance therapy have not been studied extensively. However, a pilot study was done with 30 patients who answered a 10-question survey about patient attitudes toward maintenance therapy before chemotherapy and after two and four cycles. Of the patients, 83%, 67%, and 43% considered maintenance therapy to be worthwhile for an overall survival benefit of 6, 3, or 1 month, respectively.[122] Another study conducted a thematic content analysis of focus groups for patients who were receiving, but had not completed, first-line chemotherapy. Patients discussed survival benefits, disease control, "buying time," and the importance of doing something as reasons to consider maintenance therapy.[123]

Based on available data, the choice for maintenance therapy remains an individual decision for each patient. Tolerance of first-line chemotherapy and performance status after completion of first-line chemotherapy must be weighed against competing patient desires for a treatment break and reluctance to be not receiving treatment. The 2015 American Society of Clinical Oncology (ASCO) updated guidelines on maintenance therapy state that for patients with stable disease or response after four cycles of a first-line pemetrexed-containing regimen, pemetrexed continuation maintenance may be used; if initial regimen does not contain pemetrexed, an alternative chemotherapy (switch) may be used, or a break from chemotherapy may be recommended until disease progression.[11] The European Society for Medical Oncology (ESMO) 2014 guidelines are similar to those of ASCO for switch maintenance strategy; however, continuing pemetrexed following completion of first-line cisplatin plus pemetrexed chemotherapy is recommended in patients with nonsquamous histology.[12] Both ASCO and ESMO guidelines were anterior to the release of erlotinib IUNO trial results. In its 2011 guidelines, the Italian Association of Thoracic Oncology suggests that maintenance therapy be discussed with patients with no disease progression who have a good performance status and minimal toxicity after four to six cycles of first-line chemotherapy.[13]

REMAINING QUESTIONS AND FUTURE STUDIES

The current evidence supports the use of maintenance treatment—continuation and switch with chemotherapy or targeted agents—as a means to improve the outcomes of patients with advanced NSCLC. However, the evidence does not indicate that all patients are appropriate candidates or that all patients should receive maintenance therapy. Indeed, patient preferences, convenience, and cost are factors to be considered. In addition, toxicity and the robustness of the efficacy evidence vary across the different approaches and drugs used in the trials performed so far, as the design, sample size, and end points have also varied. This situation sets a number of remaining questions to be answered in ongoing and future research.

Many clinicians and investigators question whether the results of the maintenance trials would persist if six rather than four courses were given as induction treatment. Studies to date have failed to demonstrate a clear benefit of six cycles,[1,2] and it is unlikely that a new trial will be designed to answer the question. Some patients, especially those who have a response, benefit from additional platinum-based chemotherapy courses after four cycles, but the experimental data to support this clinical habit are

scarce, if they exist at all.[1,97] An across-trial comparison of cisplatin and pemetrexed (JMDB and PARAMOUNT trials) suggests no additional benefit for the fifth and sixth induction courses in terms of efficacy but some increase in neurotoxicity and ototoxicity, toxicities that in fact may jeopardize the prolonged delivery of maintenance treatment.[7,29,124] Indeed, the shape of the curves in maintenance trials suggest the benefit is most obvious not in the first 2 months (as one would expect from continuation to six cycles), but after 6 to 12 months, suggesting most of the benefit occurs in patients who receive prolonged therapy.

The evidence on the efficacy of switch maintenance is solid in terms of delaying disease progression (30% to 50%) and in decreasing the risk of death (15% to 30%).[84,125] It is doubtful that this advantage would remain, at least in a clinically significant way, if all patients were treated at the time of disease progression after a treatment break as it has been shown in the negative IUNO study comparing switch maintenance with erlotinib to erlotinib at the time of disease progression for patients with wild-type EGFR tumors.[10,32] Following the suggested hypothesis that the amount and number of therapies are more important than the timing, progress in the early identification of disease reactivation in this context is needed.

A number of questions remain unresolved concerning the strategy of continuation maintenance therapy, as the only data on improved overall survival were found for pemetrexed in patients with nonsquamous cell tumors in the PARAMOUNT trial.[7] Indeed, the findings of this trial have been questioned, as only a small proportion of patients in the control arm, all with proven sensitivity to pemetrexed during induction chemotherapy, were rechallenged with the antifolate. This strategy is occasionally used in clinical practice, and data to support the approach are limited, although it is supported by some positive experiences with the reintroduction of EGFR inhibitors in patients initially sensitive to these therapies and in mesothelioma.[126,127] One must question whether other drugs such as gemcitabine and docetaxel would be equally effective for continuation maintenance. These drugs have been shown to improve progression-free survival but not overall survival in poorly powered trials. The most recent meta-analyses have provided some evidence, but larger trials are needed, particularly with squamous cell tumors. The CECOG and IFCT trials included a reasonable number of patients with tumors of this histology (40% and 21%, respectively), and the overall results did not differ by the pathologic subtype.[28,32]

As discussed earlier, there is a lack of data to guide decision making about continuation versus switch maintenance therapy. Pemetrexed has yielded superimposable effects when used as switch or continuation maintenance treatment.[7,8,10,128] Intuitively, continuation maintenance therapy should be superior, as it allows for all of the potential benefit from the current treatment before giving a second drug. A biologically plausible hypothesis is that patients with substantial remission during induction chemotherapy may further benefit from prolonged administration of the nonplatinum agent of the first-line regimen, whereas patients with less sensitive disease would be candidates for early switch maintenance with a non–cross-resistant agent. In fact, the SATURN, JMEN, and IFCT trials provided experimental support for continuation maintenance for patients who had a response to induction chemotherapy and preferential benefit for switch maintenance for patients with stable disease.[9,32] The PARAMOUNT trial, however, showed no influence in outcome dependent on the initial response to a platinum agent and pemetrexed followed by pemetrexed.[7] Similarly, the meta-analysis does not bring any additional data favoring the selection of the maintenance strategy (continuation vs. switch) according to the response to first-line chemotherapy.[101] The ongoing NCT01631136 trial from the IFCT group is comparing an overall treatment strategy of cisplatin plus pemetrexed followed by pemetrexed to a response-tailored approach of cisplatin plus gemcitabine followed by gemcitabine (objective response) or pemetrexed (stable disease).

There is general agreement on the need for useful tools to select patients who will benefit from maintenance therapy, to minimize the number of patients who are exposed to continuous treatment and its associated toxicities and costs. Unfortunately, few trials to explore predictive biomarkers have been done. Only EGFR mutation is an appropriate predictor, in this case for treatment with an EGFR inhibitor.[9,52] As mentioned, nonsquamous histology is predictive for benefit from pemetrexed, but with a relatively lower positive predictive value.[8] In future trials, investigators should further intensify their efforts in the molecular characterization of tumors for known prognostic and predictive indicators. For example, it may be helpful to know how many tumors had anaplastic lymphoma kinase translocations and EGFR-activating mutations in the pemetrexed studies; the outcome for these patients may have been different if they had not been included but instead treated with specific agents such as crizotinib, erlotinib, or gefitinib.[129]

Given the modest benefits provided at present by maintenance treatments, many efforts are concentrated on the search for new therapies and combinations to be tested in this setting. The days of four cycles of a platinum-based doublet, followed by a chemotherapy holiday until progression, are behind us, but many questions about how best to optimize maintenance therapy remain. It appears now clear that new approaches with immunotherapy will soon change the way of treating a significant proportion of advanced NSCLC patients in frontline and maintenance settings.

47 Pharmacogenomics in Lung Cancer: Predictive Biomarkers for Chemotherapy

George R. Simon, Rafael Rosell Costa, and David R. Gandara

SUMMARY OF KEY POINTS

- Discussed are tumor factors that affect treatment responses and outcome and host genetic elements that affect drug metabolism. Only pharmacogenomics elements that interact with chemotherapeutic agents are described.
- Prognostic biomarkers describe a specific tumor characteristic that allows for dichotomization of a cohort of patients into different groups based on an outcome that is independent of the treatment rendered.
- How biomarkers are measured and what is defined as positive or negative are crucial considerations pertinent to their use.
- At least 50% of patients with lung cancer have actionable driver mutations.
- Although the epidermal growth factor receptor (EGFR) signaling cascades are complex, tyrosine kinase in the EGFR intracellular domain is the key factor that triggers signaling.
- Anaplastic lymphoma kinase (ALK) activation occurs primarily via three different mechanisms: (1) fusion protein formation, (2) ALK overexpression, and (3) activating *ALK* point mutations.
- Crizotinib yields high response rates (exceeding 60%) and improves survival when used in patients with advanced nonsmall cell lung cancer who have *ALK* gene rearrangements and have progressed on previous therapy.
- The clinical uses of markers such as *ERCC1* and *RRM1* remain to be elucidated.
- *KRAS* mutational status is predictive of lack of therapeutic efficacy with EGFR tyrosine kinase inhibitors.
- MET and ROS1 genomic alterations are more rare driver mutations that, when detected, may enable more precise treatment for patients with lung cancer.
- Molecular biomarkers such as *ERCC1*, *RRM1*, *BRCA1*, thymidylate synthase, and others remain investigational.

Effective treatment strategies for advanced stage lung cancer continue to be elusive despite substantial advances in the treatment of specific subsets of patients. Over the past decade, however, our understanding of the molecular mechanisms that underlie cellular transformation and the development of lung cancer has increased greatly. This knowledge has led to the development of therapeutic agents targeted against specific intracellular or extracellular targets presumed to be critical in the molecular pathways of carcinogenesis. For example, tyrosine kinase inhibitors, which have demonstrated increased efficacy and tolerability compared with chemotherapy in patients with metastatic lung cancer and epidermal growth factor receptor (*EGFR*) mutations or anaplastic lymphoma kinase (*ALK*) translocations, are now first-line treatment for patients with these tumor markers.[1]

Host germline genetic variations can affect the pharmacokinetics and pharmacodynamics of individual drugs and thus affect patient outcomes.[2] Thus, genetically determined pharmacokinetic variations may affect both the antitumor efficacy and host toxicities. In addition to genetic determinants in the host, environmental factors can affect the way drugs are metabolized, which in turn can affect their efficacy. In lung cancer, the primary example is smoking. Smoking is reported to alter the metabolism of several chemotherapeutic drugs and targeted agents, such as erlotinib.[3] However, the extent of the effect smoking has on the pharmacokinetics of individual drugs may be determined by individual host genetics.[4,5]

Researchers in the field of pharmacogenetics seek to gain a better understanding of the association between human/host genetics and drug response and toxicity. Advances in knowledge about tumor genomics, afforded by the genome-wide integrative analysis possible in the postgenomic era, when integrated with the field of pharmacogenetics, provide a modern basis for the field of pharmacogenomics. Thus, pharmacogenomic research is designed to determine host genetic variations, the genomic make-up of a tumor, the interaction between host genetic variations and tumor make-up, and the net effect on treatment responses and outcome. This chapter discusses tumor factors that affect treatment responses and outcome and host genetic elements that affect drug metabolism and its implications for routine clinical practice. As the title of the chapter indicates, only pharmacogenomics elements that interact with chemotherapeutic agents are described.

TUMOR-RELATED FACTORS

Tumor-related molecular determinants are broadly divided into two categories: prognostic biomarkers and predictive biomarkers.[6] Each of these characteristics of a molecular determinant can have therapeutic implications. A prognostic biomarker is an indicator of the innate aggressiveness of the tumor and is indicative of patient survival independent of treatment, whereas a predictive biomarker is an indicator of therapeutic efficacy. A prognostic biomarker describes a specific tumor characteristic that allows for the dichotomization of a cohort of patients into different groups based on outcome that is independent of the treatment rendered; for example, overall survival is better for patients with biomarker-positive tumors compared with patients with biomarker-negative tumors. Predictive biomarkers, on the other hand, suggest benefit or lack of benefit for a specific treatment based on the presence, absence, or overexpression or underexpression of the predictive biomarker, and thus, these biomarkers directly affect treatment decision-making. Some biomarkers may have both a prognostic and predictive function. Such so-called panoramic biomarkers make interpretation of data in different settings nuanced, and the dual prognostic-predictive value of the biomarker must be taken into account. Prototypic examples of biomarkers with both prognostic and predictive functions are excision repair cross-complementing 1 (ERCC1) and ribonucleotide reductase M1

(RRM1). In stage I and II nonsmall cell lung cancer (NSCLC), the prognostic function of ERCC1 and RRM1 may predominate, suggesting that overall survival will be better for patients with tumors positive for these markers after surgical resection than for patients with tumors negative for the markers. However, in stage IV NSCLC, the predictive function is most relevant, suggesting that tumors positive for ERCC1 or RRM1 will have inferior responses to cisplatin or gemcitabine, respectively, compared with cancers that are ERCC1- or RRM1-negative. Stage III NSCLC presents a challenge, as the dual function of ERCC1 and RRM1 makes interpretation of their significance difficult in a setting in which cisplatin is typically used, potentially in combination with other drugs such as paclitaxel, pemetrexed, or etoposide, as well as radiotherapy. It is unclear whether the prognostic function or the predictive function predominate or if a predominant function is relevant when additional treatment modalities are used.[7] These issues have confounded and confused the interpretation of several studies done with these and other markers.[8]

Measurement of Molecular Biomarkers

Another crucial consideration pertinent to the use of biomarkers, whether prognostic, predictive, or panoramic, is how they are measured and what is defined as positive or negative. For some biomarkers, it can be clearly discerned whether the marker is present or absent in the tumor; classic examples of this type of biomarker are mutations of the *EGFR* gene or translocations of the echinoderm microtubule-associated protein-like 4 (*EML4*) and *ALK* genes. Because the molecular aberrations can be clearly and unambiguously measured, the effect of these mutations on patient outcomes is clear.

However, most biomarkers are present on a continuum in almost all tumors, and, as such, variations in measurement techniques and interpretation of values are more likely. Typically, a lower expression of these biomarkers is considered negative and a higher expression is considered positive. The challenge is that the level of expression corresponding to positive or negative is often arbitrary and, for ease of interpretation, the cutoff point is often the statistical median. This approach artificially renders a continuous variable into a discrete one, which potentially confounds the strength of the association being measured. The strength of the association may be particularly vulnerable around the median. Investigators have attempted to partially offset this problem by dichotomizing the results in a particular cohort into quartiles and examining the association between a marker and an outcome by comparing the highest quartile with the lowest quartile.[9]

The measurement technique is crucial to successful incorporation of biomarkers into clinical decision-making. Discrete biomarkers (i.e., those that are either present or absent) are best measured at the DNA level. Mutations, translocations, and copy number gains fall into this category. Mutations and translocations are best measured by sequencing the gene of interest, preferably in its entirety, and this technique will identify common and rare mutations, as well as mutations that are as yet unidentified. Multiplexed polymerase chain reaction (PCR)-based techniques will identify common mutations but will only detect mutations for which the primers are included in the multiplex panel.

Nondiscrete biomarkers are best measured at the RNA or protein level. As an example, most epithelial tissue expresses the EGFR protein, with the expression higher in some tissues than in others. Increased EGFR expression is not a consequence of an abnormality of the *EGFR* gene at the DNA level but is most likely a consequence of increased transcription of the normal *EGFR* gene to RNA and then eventual translation of the RNA to protein. Thus, the increased expression of a particular gene may be measured at the RNA or the protein level.

Measurement at the RNA or protein level each is associated with advantages and disadvantages. Measurement at the RNA level is more technically complex and thus could be more challenging to accomplish in the routine clinical setting. The expression of a gene is measured relative to the expression of a housekeeping gene and expressed as a unitless ratio. The values derived also depend on the use of specific standardization techniques and procedures, which can vary from laboratory to laboratory. Because of this potential variation, numerically similar values may not be congruent across different laboratories and platforms. Additionally, the cutoff values for high versus low must be individually established for each laboratory and validated by clinical data. Nevertheless, measuring RNA through quantitative PCR, if done with proper controls and standardization procedures, is precise, reproducible, and quantifiable. Hence, despite the technical difficulties, quantitative PCR has been the favored approach by several investigators. Controversy also exists as to the optimal sample for quantitative PCR. Most investigators consider a fresh frozen sample to be ideal, but it is not practical to obtain fresh frozen biopsy specimens in the clinical setting, especially from patients with advanced NSCLC. However, most investigators now believe that good-quality mRNA can be extracted from formalin-fixed paraffin-embedded (FFPE) tissue, and thus, such samples can be used for quantitative PCR. However, the process used to make the FFPE samples may potentially alter the message, which raises questions about the relevance of quantitative PCR measurements in FFPE samples.[10]

Immunohistochemistry (IHC) is most commonly used to measure protein levels in clinical samples. IHC has several advantages, including relative ease of use, widespread availability in most clinical pathology laboratories, and the capability of evaluating FFPE samples. The performance characteristics of IHC, however, are critically dependent on having a good antibody that effectively binds only to the antigen of interest. Additionally, the intensity of the staining is arbitrarily graded as 0 through 3 (0 = no staining, 1= weak staining, 2 = moderate staining, and 3 = strong staining) or by the H score (the H score is a product of staining intensity and the percent of cells stained; for example, if 50% of the slides show an intensity of more than 3, 20% show an intensity of more than 2, and 30% are negative, then the H score would be 150 + 40 = 190). Despite these scoring methods and the use of rigorous (positive and negative) controls, these techniques can still lead to variation in interpretation. The definition of positive is also arbitrary and if, for example, 2+ or higher is considered positive, the arbitrariness between a score of 1 or 2 thus jeopardizes the very definition of positive versus negative.

To partially counteract the arbitrary nature of IHC grading methods, the automated quantitative analysis of in situ protein expression (AQUA) method was developed.[11] The AQUA method involves the use of fluorescent microscopic technology that measures the expression of proteins of interest by quantifying the intensity of antibody-conjugated fluorophores within a specific cellular compartment (such as the nucleus or cytoplasm) in a tumor. A quantitative score is thus generated based on the intensity of immunofluorescence. The AQUA method thus provides a more continuous scoring of protein expression in tissue samples.[12] Even though the AQUA method eliminates some of the subjectivity in the interpretation of IHC, the method is still associated with some of the same challenges as IHC. For example, AQUA also depends on an antibody that binds only to the protein of interest and the cutoff point to define positive and negative is arbitrary.

Driver Mutations in Lung Adenocarcinomas

The recognition of *EGFR* and *ALK* oncogenes as predictive biomarkers in lung cancer has led an ongoing investigation to identify additional oncogenic drivers with predictive and prognostic importance. Certain subsets of NSCLC can now be further defined at a molecular level by driver mutations in multiple

oncogenes that lead to constitutive activation of mutant signaling proteins, causing induction and sustaining tumorigenesis. Mutations can be detected in all NSCLC histologies, including adenocarcinoma, squamous cell carcinoma, and large cell carcinoma, and in current-, former-, and never-smokers (defined as individuals who smoked fewer than 100 cigarettes in a lifetime).[13]

It is estimated that at least 50% of patients with lung cancer have actionable driver mutations.[14,15] Actionable driver mutations are defined as molecular abnormalities with downstream effects that initiate or maintain the neoplastic process, which can be negated by agents directed against each genomic alteration.[19] Some of the evidence of the driver mutations of significance in lung cancer comes from research conducted by the 14-member Lung Cancer Mutation Consortium (LCMC), which has investigated metastatic lung adenocarcinomas since 2009 to identify and study driver genomic alterations. Between 2009 and 2012 more than 1000 patients underwent genotyping to determine the frequency of oncogenic drivers in lung cancer and demonstrate the practicality of using routine genetic analyses to inform treatment with targeted therapies.[16]

In the LCMC patient cohort actionable driver mutations were found in 64% of tumors from patients with lung adenocarcinomas.[16] Table 47.1 lists the driver mutations the LCMC investigators identified. Most of these driver mutations were found in a small percentage of patients. The most common driver mutations detected were in the *EGFR*, *KRAS*, and *ALK* genes.[16]

The *ALK* fusion oncogene and sensitizing *EGFR* mutations have become accepted predictive biomarkers in lung cancer. The National Comprehensive Cancer Network (NCCN) recommends genotyping for *EGFR* mutations and *ALK* rearrangements in its algorithm for patients with metastatic disease.[1]

Epidermal Growth Factor Receptor

EGFR (also known as HER1) is a transmembrane receptor for the epidermal growth factor with intrinsic tyrosine kinase activity. It is encoded by a gene located on chromosome 7.[17] EGFR belongs to a family of receptor tyrosine kinases, which upon activation result in stimulation of multiple downstream pathways within the cell, including those involved in cell survival, proliferation, and resistance to apoptosis.[18,19]

In normal cells the tyrosine kinase activity of the EGFR is strictly regulated, and therefore cell growth is controlled. Although the EGFR signaling cascades are complex, tyrosine kinase in the EGFR intracellular domain is the key factor that triggers signaling. If tyrosine kinase activity is blocked (i.e., via

TABLE 47.1 Driver Mutations in Lung Adenocarcinomas[16]

Mutation	Incidence (%)
ALK rearrangements	8
BRAF	2
EGFR, sensitizing	17
EGFR, other	4
ERBB2, formerly HER2	3
KRAS	25
MEK1	<1
MET amplification	<1

PIK3CA	<1

ALK, anaplastic lymphoma kinase; *BRAF*, v-raf murine sarcoma viral oncogene homolog B; *EGFR*, epidermal growth factor receptor; *ERBB2*, erb-B2 receptor tyrosine kinase 2; *HER2*, human epidermal growth factor receptor 2; *KRAS*, Kirsten rat sarcoma viral oncogene homolog; *MEK1*, mitogen-activated protein kinase kinase; *MET*, hepatocyte growth factor receptor; *NRAS*, neuroblastoma RAS viral oncogene homolog; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3 kinase catalytic subunit alpha.

a molecular targeted agent), EGFR is unable to transduce signals to the cell nucleus.[20] In cancer cells, various mechanisms of EGFR activation have been identified, including receptor overexpression, ligand overexpression, and *EGFR* gene amplification.

EGFR Overexpression

EGFR expression refers to measurement of levels of receptor protein (either normal [wild-type] protein or abnormal [meaning from the mutated gene]) by IHC and is distinct from detection of an actual EGFR mutation. EGFR expression is detectable in approximately 80% to 85% of patients with NSCLC, although the levels of expression vary widely on a continual scale.[21]

Approximately 40% to 80% of NSCLC tumors overexpress EGFR.[19] This wide range in the frequency of EGFR overexpression may be due to differences in the techniques used to determine EGFR overexpression, the criteria used to define overexpression levels, and the differences in study populations. Wild-type is the term used to describe EGFR that is overexpressed but not mutated. The result of overexpression is an overabundance of receptors that are available to interact with ligands. Wild-type EGFR becomes activated by binding to ligands. Ligand binding induces receptor dimerization, and the ligand-bound EGFR activates tyrosine kinase-mediated signaling pathways, leading to tumor proliferation, survival, and resistance to apoptosis.[18]

Tumor cells can overexpress EGFR as well as its ligands. Ligand overexpression increases EGFR dimerization, activation, and tyrosine kinase-mediated signaling, which can lead to uncontrolled tumor growth.[22]

EGFR overexpression is more common in squamous cell carcinoma and adenocarcinoma, and to a lesser extent in large-cell carcinoma.[19] Although the clinical significance of overexpression in NSCLC remains controversial, some investigators have found that overexpression of EGFR is associated with more aggressive tumors, a poor clinical prognosis, and, in certain tumor types, the development of resistance to radiation and cytoxic agents.[19]

Among patients with NSCLC, wild-type EGFR is more common than mutated EGFR. Compared with mutated EGFR, patients who harbor wild-type EGFR show reduced benefit for EGFR tyrosine kinase inhibitors such as erlotinib and gefitinib. This may be because the wild-type EGFR typically sends a downstream signal that ultimately stimulates the growth of tumor cells that are dependent on the receptor, and gefitinib or erlotinib can modestly inhibit this relatively weak signal. In contrast, the mutated EGFR is constitutively activated with a prominent downstream signal that can be dramatically inhibited by gefitinib and erlotinib.[18]

EGFR Mutations

Somatic mutations of *EGFR* genes can result in the production of mutated receptors.[23] About 10% to 15% of Caucasian patients with NSCLC and 30% to 40% of Asian patients have tumor-associated *EGFR* mutations.[17] These mutations occur within *EGFR* exons,[15–18] which encode a portion of the EGFR kinase domain.[19] The majority (about 90%) of these mutations are exon 19 deletions or exon 21L858R point mutations.[18,25] Regardless of ethnicity, *EGFR* mutations are more often found in tumors from women, never-smokers (defined as less than 100 cigarettes in a patient's lifetime), or former-smokers with adenocarcinoma histology.[17]

Mutant EGFR does not require a ligand for receptor dimerization and activation. Thus, EGFRs that harbor mutations remain constitutively activated without ligand binding. Although the mutated receptor needs no growth factor for signaling, ligand binding increases receptor activity. Cancer cells harboring *EGFR* gene mutations often become highly dependent on the EGFR pathway, a state referred to as "oncogene addiction."[27]

There are several consequences of EGFR mutations, including: (1) constitutive activation of the EGFR tyrosine kinase activity and resulting hyperactivation of downstream targets; (2) diminished affinity for ATP; (3) increased sensitivity to tyrosine kinase inhibitors; or, conversely, (4) development of resistance to tyrosine kinase inhibitors for certain types of mutations.[24]

EGFR-activating mutations are found to be favorable prognostic markers of survival and predictive markers of response in terms of tumor shrinkage.[19] EGFR mutation status correlates strongly with the probability of response to an EGFR tyrosine kinase inhibitor, as well as a more favorable prognosis in patients with advanced lung adenocarcinoma.[23,25]

This association between EGFR-activating mutations and increased clinical responses seen with EGFR tyrosine kinase inhibitors has been investigated in multiple clinical studies. Evidence shows that the growth and downstream signaling inhibition of cells with EGFR-activating mutations is consistently more sensitive to treatment with EGFR tyrosine kinase inhibitors than the signaling in cells with wild-type EGFR. Moreover, EGFR tyrosine kinase inhibitors bind with higher affinity to the mutant receptors compared with the wild-type receptor.[18]

The randomized, phase, open-label Iressa Pan-Asia Study marked a seminal moment in the treatment of patients with EGFR-activating mutations. In this study of previously untreated patients with NSCLC, a significant interaction was found between treatment and *EGFR* gene mutation with respect to progression-free survival. In the subset of 261 patients with *EGFR* gene mutations, progression-free survival was significantly longer among patients receiving the tyrosine kinase inhibitor gefitinib than among those receiving chemotherapy (hazard ratio [HR] for progression or death, 0.48; 95% CI, 0.36–0.64; $p < 0.001$). Conversely, in the subgroup of 176 patients who were negative for the mutation, progression-free survival was significantly longer among those who received carboplatin–paclitaxel (HR for progression or death with gefitinib, 2.85; 95% CI, 2.05–3.98; $p < 0.001$).[26]

Even though patients with lung cancer harboring *EGFR* gene mutations generally exhibit a favorable response to EGFR tyrosine kinase inhibitors, certain *EGFR* gene mutations are associated with resistance to tyrosine kinase inhibitors. The T790M mutation, which results in a substitution of methionine for threonine at position 790 of the EGFR tyrosine kinase domain, leads to biochemical and structural alteration that causes resistance to therapy with a tyrosine kinase inhibitor.[23] The T790M mutation has been reported in about 60% of patients with disease progression after initial response to erlotinib, gefitinib, or afatinib.[27–29] The T790M mutation also has been identified as an oncogenic mutation, promoting oncogenesis especially when the T790M mutation occurs in combination with other EGFR-activating mutations.[30]

Other, less-common *EGFR* gene mutations (approximately 10%) located in the kinase domain that may have significance with regard to sensitivity and resistance to EGFR tyrosine kinase inhibitors have been identified (Table 47.2).

TABLE 47.2 Less-Common EGFR Mutations in NSCLC[31,32]

Mutation	Frequency (%)	Clinical Significance
Exon 21 mutation (L861X[a])	2	TKI sensitivity
Exon 18 mutation (G719X)	3	TKI sensitivity
Exon 19 insertion	1	TKI sensitivity
Exon 20 insertion	4–9	TKI resistance

[a]The "X" is used to designate that several amino acid substitutions are possible at the site.

EGFR, Epidermal growth factor receptor; *NSCLC*, nonsmall cell lung cancer; *TKI*, tyrosine kinase inhibitor.

Anaplastic Lymphoma Kinase

The *ALK* gene encodes a tyrosine kinase receptor that is normally expressed in central and peripheral nervous systems, testes, skeletal muscle, basal layer keratinocytes, and the small intestine. ALK appears to function in neuronal development and differentiation during embryogenesis and its expression falls to low levels at age three weeks and remains low throughout adult life.[33]

ALK activation occurs primarily via three different mechanisms: (1) fusion protein formation, (2) ALK overexpression, and (3) activating *ALK* point mutations. In *ALK* translocations, the fusion partner regulates ALK expression levels, its subcellular location, and when it is expressed. Multiple different *ALK* gene rearrangements have been described in NSCLC. The majority of these *ALK* fusion variants are comprised of portions of the echinoderm microtubule-associated protein-like 4 (*EML4*) gene.[33] Dimerization of the ALK fusion product, which is mediated by the fusion partner, results in constitutive activation of the ALK tyrosine kinase. Signaling downstream of ALK fusions results in activation of cellular pathways known to be involved in cell growth and cell proliferation. An estimated 2% to 7% of patients with NSCLC have *ALK* gene rearrangements.[34]

ALK gene rearrangements tend to occur mutually exclusive of *EGFR* mutations. Thus, the presence of *ALK* gene rearrangements is associated with resistance to EGFR tyrosine kinase inhibitors. Patients with *ALK* gene rearrangements have similar clinical characteristics to those with EGFR mutations (including adenocarcinoma histology and nonsmoking or light smoking histories) except they are more likely to be men and may be younger.[35] Rarely are *ALK* gene rearrangements detected in patients with squamous cell carcinoma.[36]

Crizotinib is a dual ALK/MET tyrosine kinase inhibitor approved for ALK-positive and ROS1-positive NSCLC.[13] Crizotinib has been shown to yield very high response rates (exceeding 60%) and improve survival when used in patients with advanced NSCLC who have *ALK* gene rearrangements and have progressed on previous therapy, including those with brain metastases.[37–39] The NCCN recommends crizotinib for first-line and subsequent therapy in patients with ALK-positive NSCLC. Ceritinib and alectinib are newer ALK inhibitors recommended for use in patients who progress on crizotinib or are intolerant of crizotinib.[1]

KRAS

RAS binding proteins, including KRAS, are central mediators downstream of growth factor receptor signaling. In its mutated form, KRAS is constitutively active, able to transform immortalized cells and promote cell proliferation and survival.

KRAS gene mutations are detected in tumors from former-, current-, and never-smokers, although they are rarer in never-smokers. Approximately 25% of patients with lung adenocarcinoma in North America have KRAS mutations, making KRAS the most common mutation.[40,41] The exact role of KRAS as a predictive or prognostic biomarker in metastatic lung cancer remains undetermined as few prospective trials have examined the utility of using KRAS mutational status to inform treatment with targeted agents. Nevertheless, *KRAS* gene mutations are predictive of lack of therapeutic efficacy with tyrosine kinase inhibitors that target EGFR, such as erlotinib and gefitinib.[40,42] Moreover, patients with *KRAS* gene mutations appear to have a shorter survival than patients with wild-type KRAS.[43,44] EGFR and KRAS mutations appear to occur mutually exclusive of each other.[45,46]

MET

The *MET* gene encodes a receptor tyrosine kinase, which becomes activated upon binding of its ligand, hepatocyte growth

factor. Consequently multiple downstream pathways within the cell become activated, including those involved in cell survival and proliferation. In cancer, aberrant signaling through the MET receptor promotes pleiotropic effects, including growth, survival, invasion, migration, angiogenesis, and metastasis.

In NSCLC, multiple mechanisms of MET activation have been reported, including both gene amplification and mutation. Overexpression of MET protein in tumor tissue relative to adjacent normal tissues occurs in 25% to 75% of NSCLC and is associated with a poor prognosis.[47] Data suggest MET protein expression and activation predict poor response to subsequent treatment with EGFR tyrosine kinase inhibitors, despite the presence of tyrosine kinase inhibitor–sensitizing mutations within the *EGFR* gene.[47]

ROS1

ROS1 is a receptor tyrosine kinase of the insulin receptor family that is involved in chromosomal translocations in lung cancer. ROS1 fusions, which have been found to be potential driver mutations in a NSCLC cell line, lead to constitutive kinase activity and are associated with sensitivity in vitro to tyrosine kinase inhibitors. Signaling downstream of ROS1 fusions results in activation of cellular pathways known to be involved in cell growth and cell proliferation. Approximately 2% of NSCLC tumors harbor alterations in the *ROS1* gene.[48] Patients positive for a *ROS1* rearrangement have a typical clinical profile, including young age at onset and nonsmoking history. *ROS1* fusions are associated with sensitivity to tyrosine kinase inhibitors that have "off-target" activity against ROS1; an example of this is crizotinib.[48]

ERCC1 and RRM1

Cisplatin-based chemotherapy is the standard of care for all patients with advanced stage NSCLC and is also used as adjuvant treatment for patients with completely resected stage II and III NSCLC.[1,49–51] Cisplatin impedes DNA replication by establishing DNA-platinum adducts. Breaks in the DNA strand occur when the DNA unwinds in anticipation of initiation of replication. ERCC1 belongs to the nucleotide excision repair (NER) family of proteins and is involved in the repair of these DNA strand breaks.[52] The ERCC1 protein works with its partner protein xeroderma pigmentosum complementation group F (XPF) in the final step of the NER pathway that recognizes and removes cisplatin-induced DNA adducts, allowing the tumor DNA replication to continue.[53] The NER pathway-mediated removal of platinum DNA reverses the tumoral DNA damage induced by cisplatin, thereby leading to cisplatin resistance (Fig. 47.1). High expression of ERCC1 in the tumor thus predicts for cisplatin resistance and serves as a predictive molecular determinant for the efficacy of this chemotherapy agent.[54]

The nature-envisioned purpose of ERCC1 is to effect DNA repair when DNA damage occurs after exposure to natural DNA-damaging entities, such as ionizing radiation and mutagenic compounds. A relatively preserved DNA repair mechanism, as suggested by high nuclear ERCC1 expression, therefore preserves genomic integrity. High tumoral levels of ERCC1 have therefore been associated with better outcomes in patients with early-stage disease who have had curative resection, presumably because of more indolent tumor behavior secondary to a relatively preserved genomic integrity. ERCC1 thus functions as a prognostic marker in patients with early-stage NSCLC.

RRM1 is the regulatory component of ribonucleotide reductase and is a nonredundant component of DNA synthesis.[55] Its primary function is to generate nucleotides that can be used for DNA synthesis and repair.[56] It is also the principal target of the commonly used cytotoxic agent, gemcitabine, and hence, high RRM1 levels predict for resistance to gemcitabine.[10,57] Analogous to ERCC1, RRM1 has been associated with different survival outcomes in patients with NSCLC, with higher RRM1 levels predicting for a better prognosis and improved survival.[58] In preclinical trials, increased RRM1 expression was shown to be associated with decreased invasion and migration and with an overall more indolent behavior.[56] It is not entirely clear how RRM1 causes these effects, but it has been postulated that the effects are perhaps mediated through a direct correlation between RRM1 and expression of phosphatase and tensin homolog protein.[58] RRM1 therefore has both a predictive and prognostic function.[59,60]

The prognostic function of ERCC1 was first noted in a retrospective analysis of patients with NSCLC who had curative resection. ERCC1 was measured using reverse transcription (RT)-PCR, and its expression was normalized using 18SrRNA (a commonly used housekeeping gene) expression; therefore its levels were expressed as a unitless ratio. Using an ERCC1 value of 50 to dichotomize the cohort, researchers noted a significant difference in median survival for patients with ERCC1 expression of more than 50 in the tumor compared with patients with ERCC1 expression of less than 50 in the tumor (94.6 vs. 35.5 months; *p* = 0.01).[61] In multivariate analysis, high ERCC1 expression was found to be an independent predictor of better prognosis.

Olaussen et al.[62] further analyzed the prognostic value of ERCC1 in specimens obtained from the International Adjuvant Lung Trial (IALT). In the IALT study, patients with curatively resected NSCLC had been randomly assigned to receive adjuvant chemotherapy or no further therapy, as was the standard of care at that time. In the overall study population, adjuvant chemotherapy had improved 5-year survival by 4.1% (*p* < 0.03). Olaussen et al.[62] used IHC to analyze the tumor samples in that study for expression of ERCC1 (in addition to other markers) using an antibody that was then believed to stain for ERCC1 (murine antibody from clone 8F1; Neomarkers Inc, Fremont, CA, USA). Among patients with ERCC1-negative tumors, the 5-year overall survival rate was significantly longer for patients who received chemotherapy (47% vs. 39%; *p* = 0.002). However, among patients with ERCC1-positive tumors, overall survival did not differ between patients who received adjuvant chemotherapy and patients who did not. Of note, among patients who did not receive adjuvant chemotherapy, overall survival was significantly better for patients with ERCC1-positive tumors than for patients with ERCC1-negative tumors (adjusted HR for death, 0.66; 95% CI, 0.49–0.90; *p* = 0.009). This finding suggests an intrinsic prognostic function for ERCC1.

Given these results, the authors conducted a comprehensive analysis to compare various methods to measure ERCC1, as well as several antibodies used to measure ERCC1 by IHC.[63] They obtained 494 tumor specimens from two independent phase III trials (the National Cancer Institute of Canada Clinical Trials Group JBR.10 and the Cancer and Leukemia Group B 9633 trial from the Lung Adjuvant Cisplatin Evaluation Biology project). The researchers also repeated the staining of all 589 specimens in the original set of samples from the IALT study. They mapped the epitope recognized by 16 commercially available ERCC1 antibodies and investigated the capacity of the different ERCC1 isoforms to repair platinum-induced DNA damage. The investigators noted that ERCC1 was positive in 77% of the samples in the current study compared with 44% of the samples in the IALT study. Additionally, ERCC1 was no longer a predictive biomarker of the efficacy of chemotherapy (*p* = 0.53 for interaction). The 8F1 antibody used in the current study was different from that used in the initial analysis, and they concluded that there was a shift in the activity of the 8F1 antibody. Unfortunately the 8F1 antibody used in the IALT study had been totally consumed and was therefore not available for comparison.

Another significant finding was that each of the 16 antibodies tested could detect all of the four known isoforms of ERCC1. Because the epitopes are common in these four isoforms (201, 202, 203, and 204), none of the currently available antibodies could distinguish between them. For the purposes of RT-PCR, separate primers can be made for ERCC1 isomers 201 and 203;
Fig. 47.1. Molecular model for the incision stage of nucleotide excision repair (NER). In global genome NER (GG-NER), XPC-hHR23B senses DNA helix-distorting nuclear excision repair lesions, leading to conformational alterations of the DNA, whereas in transcription-coupled repair (TC-NER), lesions are detected by the elongating RNA Pol II. In GG-NER, XPC-hHR23B at lesion attracts TFIIH (and possibly XPG). In both GG-NER and TC-NER, TFIIH creates a 10- to 20-nucleotide opened DNA complex around the lesion by virtue of its helicases XPB and XPD; this step requires ATP. XPA and RPA stabilize the 10- to 20-nucleotide opening and position other factors. XPA binds to the damaged nucleotides, RPA to the undamaged DNA strand. XPG stabilizes the fully opened complex. XPG, positioned by TFIIH and RPA, makes the 3′ incision. ERCC1-XPF, positioned by RPA and XPA, makes the second incision 5′ of the lesion. Dual incision is followed by gap-filling DNA synthesis and ligation. Drawn contacts between molecules reflect reported protein–protein interactions. *(Reprinted with permission from de Laat WL, Jaspers NG, Hoeijmakers JH. Molecular mechanism of nucleotide excision repair. Genes Dev. 1999;13(7):768–785.)*

however, because of substantial homology, primers cannot be separately made against 202 and 204. Thus, these two polymorphisms were measured in unison and there was no detectable difference in ERCC1-positive or ERCC1-negative samples in terms of overall or progression-free survival. However, in cell line experiments only the ERCC1 202 polymorphism seemed to predict for resistance to cisplatin; thus, this polymorphism may be the functional one. The authors concluded that measuring the clinically relevant functional ERCC1 202 polymorphism may be the better predictor of benefit for cisplatin in patients with NSCLC. Measuring the specific ERCC1 202 polymorphism will, however, be challenging because the high percentage of sequence homology among the four protein isoforms makes the generation of an ERCC1 202-specific antibody technically difficult. Making ERCC1 202-specific primers is onerous for the same reason.[63] However, the ERCC1 202 polymorphism may be detectable by sequencing at the DNA level, which would convert this nondiscrete biomarker into a discrete one.

To study the association between ERCC1 and RRM1, Zheng et al.[12] estimated the expression of ERCC1 and RRM1 at the protein level by AQUA and at the RNA level by RT-PCR and correlated the findings with survival. RRM1 expression was directly correlated with ERCC1 expression. Furthermore, patients who had tumors with high expression of RRM1 also had superior survival compared with patients who had tumors with low expression of RRM1 (disease-free survival, more than 120 vs. 54.5 months; HR, 0.46; $p = 0.004$; and overall survival, more than 120 vs. 60.2 months; HR, 0.61; $p = 0.02$). Other investigators also showed that patients who had tumors with high expression of both biomarkers had superior overall survival compared with patients who had tumors with low expression of either one of the biomarkers or both.[12]

The Southwest Oncology Group conducted a trial to assess the feasibility of selecting treatment based on in situ tumor levels of ERCC1 and RRM1 in a cooperative group setting.[64] Patients with stage I lung cancer were enrolled. ERCC1 and RRM1 expression were determined at the protein level with use of AQUA (range of expression, 1–255), and the level was classified as high or low based on previously established cutoff values of 65.0 for ERCC1 and 40.0 for RRM1. The treatment regimen consisted of cisplatin and gemcitabine (80 mg/m^2 on day 1 and 1 g/m^2 on days 1 and 8) for patients who had tumors with a low level of ERCC1 or RRM1 or both. Patients who had tumors with a high level of ERCC1 or RRM1 were followed up with observation, which is essentially the standard of care. In the protocol, feasibility was defined as the assignment of treatment within 12 weeks after surgery in at least 75% of the enrolled patients. Eighty-five patients were accrued between March 2009 and April 2011. ERCC1 and RRM1 levels were successfully determined in 83 patients, and 72 patients (87%) were successfully assigned appropriate therapy within the 12-week time frame. Of the 83 patients, 64 (77%) were assigned to chemotherapy and 19 (23%) to observation. ERCC1 levels ranged from 4.3 to 211.2 (median, 44.7), and RRM1 levels ranged from 2.5 to 234.4 (median, 39.3). The authors therefore concluded that assignment of chemotherapy was feasible in a multi-institutional cooperative group setting.

In the advanced stage NSCLC setting, Rosell et al.[59] analyzed samples from 100 patients to evaluate the association between expression of ERCC1 and RRM1 and survival. Patients in the study were treated with either gemcitabine and cisplatin; gemcitabine, cisplatin, and vinorelbine; or gemcitabine and vinorelbine followed by vinorelbine and ifosfamide. ERCC1 and RRM1 expression at the mRNA level was determined by RT-PCR in FFPE samples that had been obtained bronchoscopically. Again, a strong correlation between the expression of ERCC1 and RRM1 was noted ($p < 0.001$). Among patients treated with gemcitabine and cisplatin, the median survival was significantly longer for patients who had tumors with low RRM1 mRNA expression than for patients who had tumors with high RRM1 mRNA expression

(13.7 vs. 3.6 months; $p = 0.009$). In addition, the median survival was significantly longer for patients who had tumors with low expression of RRM1 and ERCC1 than among patients who had high levels of both genes ($p = 0.016$). These results essentially corroborated the earlier findings by the same group in a smaller cohort of patients in which ERCC1 mRNA expression was significantly associated with response to cisplatin and gemcitabine in patients with advanced stage NSCLC.[65]

The Genomic International Lung Trial (GILT) was the first prospective randomized trial designed to show clinical benefit of customizing chemotherapy.[66] In this phase III trial, 444 patients with previously untreated advanced NSCLC were randomly assigned in a 1:2 ratio to either a control arm of docetaxel and cisplatin or a genotypic arm in which treatment was assigned based on the level of ERCC1 mRNA expression in the tumor, as measured by RT-PCR. In the genotypic arm, patients received docetaxel and cisplatin if their tumors expressed ERCC1 mRNA levels lower than the median or received docetaxel and gemcitabine if the tumors expressed ERCC1 mRNA levels higher than the median. The study reached its primary end point of response, with a significantly better response rate in the genotypic arm than in the control arm (51.2% vs. 39.3%; $p = 0.02$). In multivariate analysis, low ERCC1 expression was an independent predictor of tumor response to cisplatin. The study was not powered to show survival differences, but neither progression-free survival nor overall survival was significantly different between the control and genotypic arms; the median progression-free survival was 6.1 months for the genotypic arm compared with 5.2 months for the control arm (HR, 0.9; $p = 0.30$), and the median overall survival was 9.9 months compared with 9.8 months for the genotypic and control arms, respectively (HR, 0.9; $p = 0.59$). Within the genotypic arm, relatively similar response rates were noted for patients with ERCC1-negative tumors treated with docetaxel and cisplatin (53%) and patients with ERCC1-positive tumors treated with docetaxel and gemcitabine (47%), with a median progression-free survival of 6.7 and 4.7 months, respectively, and a median overall survival of 10.3 and 9.4 months, respectively. In retrospect, given that expression of ERCC1 and RRM1 correlates with each other, a fact that was not known to the investigators at the time GILT was designed, cisplatin and gemcitabine would have been optimal treatment for patients who had tumors with low ERCC1 expression, and docetaxel with vinorelbine (rather than gemcitabine) would possibly be more desirable for patients who had tumors with high ERCC1 expression (because the presence of high ERCC1 expression suggests concomitant high expression of RRM1 and high RRM1 expression predicts for resistance to gemcitabine). The reason for the strong correlation between high ERCC1 and RRM1 expression is not clear but it is postulated that a steady supply of nucleotides, which are generated by RRM1, is necessary for efficient repair, which is carried out by ERCC1.

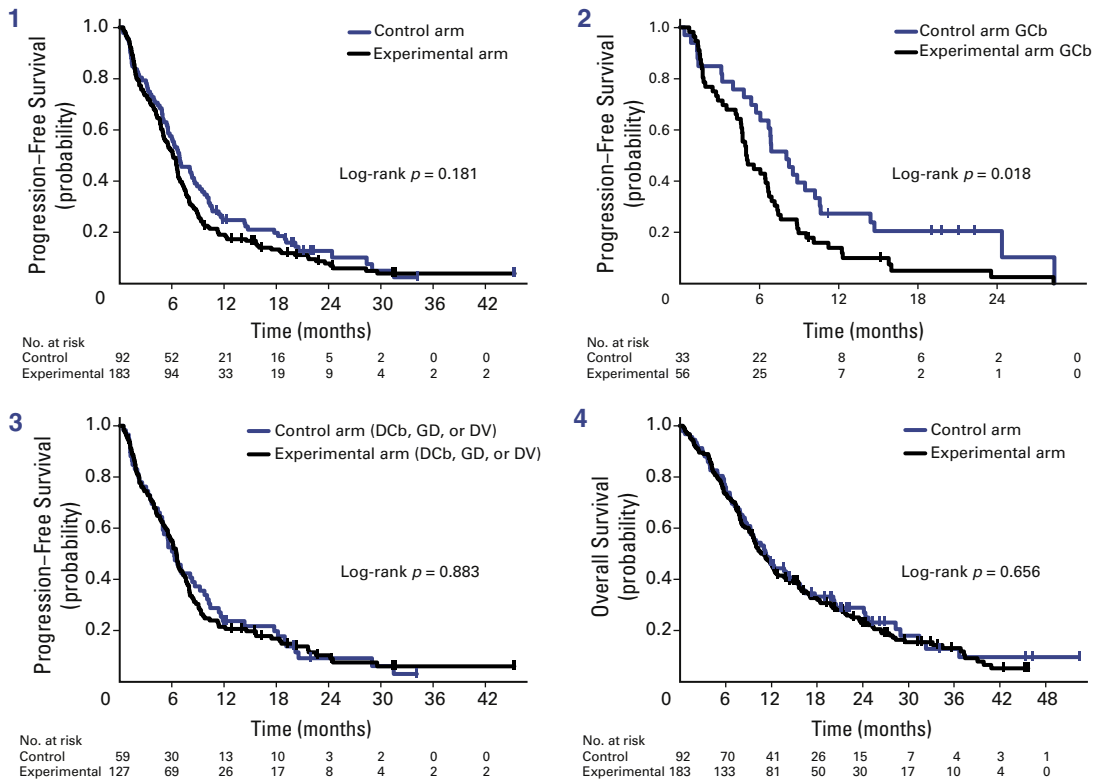
In an attempt to accelerate the application of this research to clinical practice, a prospective phase II trial, Molecular Analysis-Directed Individualized Therapy (MADe IT), assigned combination chemotherapy according to expression of ERCC1 and RRM1 (as measured by RT-PCR), with a primary end point of feasibility.[67] Patients who had tumors with low ERCC1 expression were treated with carboplatin, and patients who had tumors with low RRM1 expression were treated with gemcitabine; patients who had tumors with high expression of either marker were treated with docetaxel. Therefore, based on the expression of ERCC1 and RRM1, patients could be assigned to one of four treatment groups: gemcitabine and carboplatin (low expression of both RRM1 and ERCC); gemcitabine and docetaxel (low RRM1 expression and high ERCC1 expression); docetaxel and carboplatin (high RRM1 expression and low ERCC1 expression); or docetaxel and vinorelbine (high expression of both RRM1 and ERCC1). The response rate was 44%, with an overall survival of 13.3 months and a progression-free survival of 6.6 months (Fig. 47.2).[67]


Fig. 47.2. (A) Overall survival (OS) and progression-free survival (PFS) for 53 patients with advanced nonsmall cell lung cancer treated with chemotherapy based on expression of the ribonucleotide reductase subunit 1 (*RRM1*) and excision repair cross-complementing group 1 (*ERCC1*) genes. ERCC1 and RRM1 were measured by reverse transcription polymerase chain reaction in this trial.[34] (B) Comparison of survival according to ERCC1 and RRM1 expression. ERCC1 and RRM1 in situ protein levels were used for dichotomization, with in situ protein expression measured with use of the automated quantitative analysis (AQUA) technique. (1) Progression-free survival. (2) Comparison of progression-free survival between the experimental and control arms for patients with low expression of both ERCC1 and RRM1 levels who received identical therapy (gemcitabine and carboplatin [GCb]). (3) Comparison of progression-free survival between the experimental and control arms for patients with high expression of RRM1 and low expression of ERCC1; low expression of RRM1 and high expression of ERCC1; and high expression of both RRM1 and ERCC1; patients in the experimental arm received either docetaxel and carboplatin (DCb), gemcitabine and docetaxel (GD), or docetaxel and vinorelbine (DV), and patients in the control arm received GCb. (4) Overall survival.
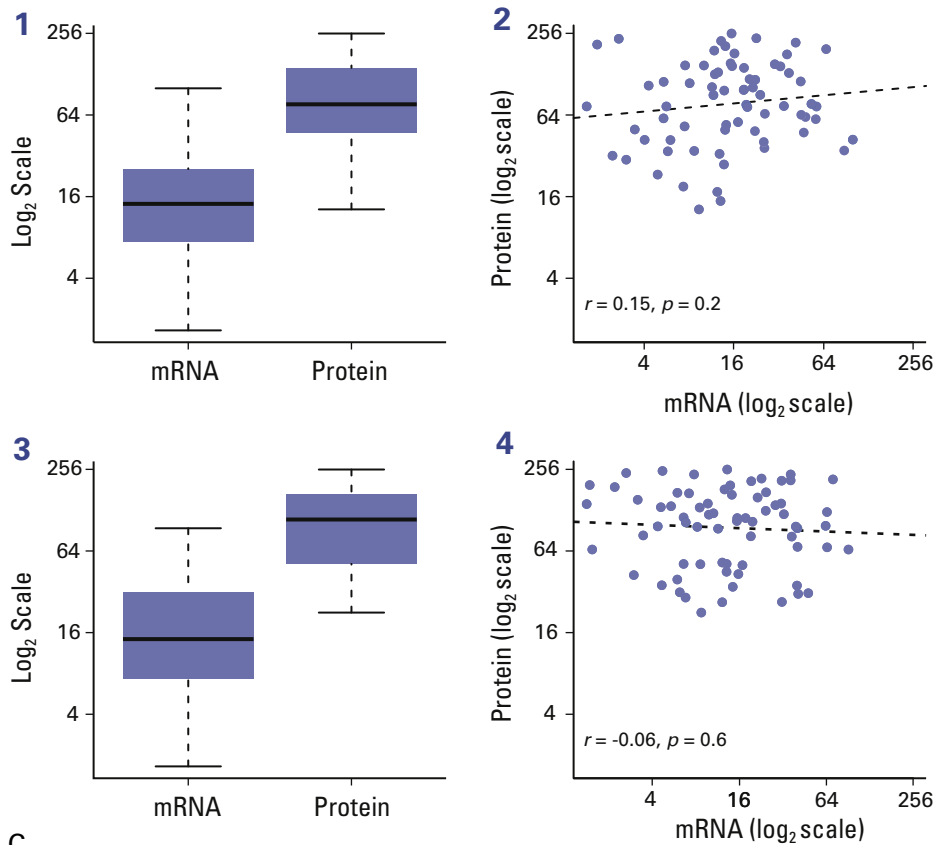

Fig. 47.2. con'd (C) No correlations were found in the expression of ERCC1 (1 and 2) and RRM1 (3 and 4). *(A. Reprinted with permission from Simon G, Sharma A, Li X, et al. Feasibility and efficacy of molecular analysis-directed individualized therapy in advanced non-small-cell lung cancer.* J Clin Oncol. *2007;25(19):2741–2746; B. and C. Modified with permission from Bepler G, Williams C, Schell MJ, et al. Randomized international phase III trial of ERCC1 and RRM1 expression-based chemotherapy versus gemcitabine/carboplatin in advanced non-small-cell lung cancer.* J Clin Oncol. *2013;31(19):2404–2412.)*

To further analyze the effect of treatment customization, three other trials were conducted in the same institution using similar eligibility criteria; however, all patients were treated with a similar regimen and the results were compared with the findings of the phase II MADe IT trial. The data were allowed to mature before these comparisons were made. Encouraged by the promising results of these studies,[68] a prospective randomized phase III trial (phase III MADe IT trial) was launched. In this trial, 275 eligible patients were randomly assigned in a 2:1 ratio to the experimental arm or the control arm. In the control arm, treatment was with gemcitabine and carboplatin. In the experimental arm, treatment was given according to ERCC1 and RRM1 expression as in the phase II trial. Progression-free survival was the primary end point and the trial was powered to show a 32% improvement in progression-free survival at 6 months.[69] In both arms, a median of four cycles of chemotherapy were given. There were no significant differences between the experimental and control arms in terms of progression-free survival (6.1 vs. 6.9 months) or overall survival (11.0 vs. 11.3 months). Of interest, a subset analysis demonstrated that, among patients who had tumors with low levels of both ERCC1 and RRM1 expression and received the same treatment (carboplatin and gemcitabine), progression-free survival was significantly better in the control arm than in the experimental arm (8.1 vs. 5.0 months; *p* = 0.02; Fig. 47.2B). The reason for this finding is not clear. A key difference between the phase II and phase III trials was that ERCC1 and RRM1 expression was measured at the mRNA level by RT-PCR in the phase II trial, whereas, for dichotomization purposes, it was measured at the protein level using AQUA and the 8F1 antibody. Hence, the estimations of ERCC1 may have not been entirely accurate. Indeed, no correlation between ERCC1 mRNA and protein levels (*r* = –0.06) was noted in this trial. There were also no correlations between RRM1 mRNA levels and in situ protein levels measured by AQUA; this finding was thought to be due to different fixation and processing techniques used in these investigations.

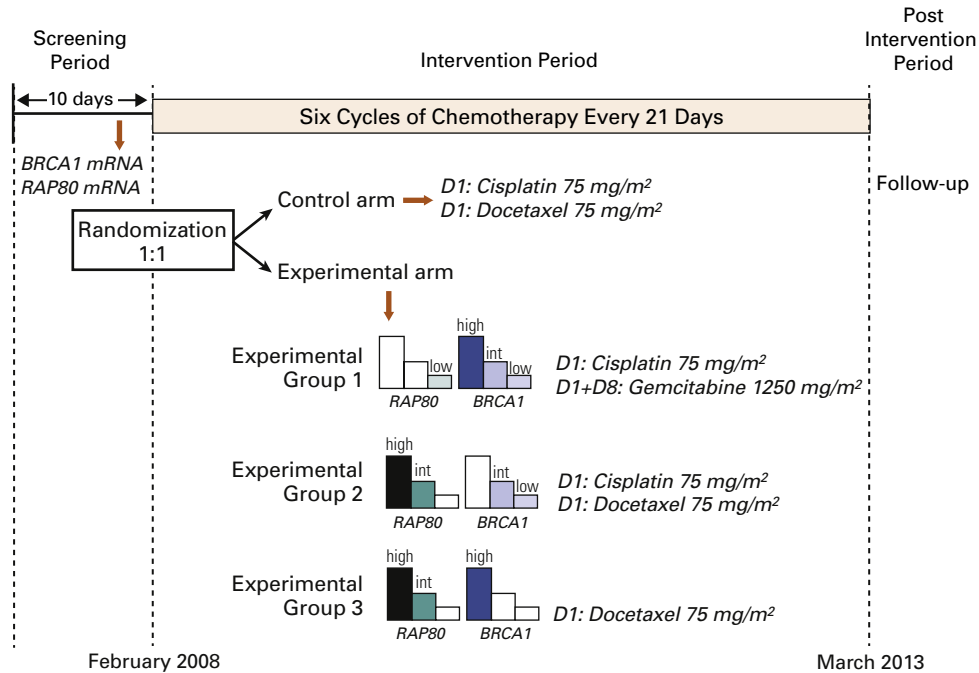
Significant batch effects were also noted; that is, ERCC1 and RRM1 expression levels were higher or lower in batches. The expression levels also tended to vary according to when and where the tests were performed (personal communication, Michael Schell). Hence, it is quite likely that the fallacies in measurement may have led to the differences in efficacy with carboplatin and gemcitabine in the experimental arm and the control arm. It should be noted that these studies were done before the Centers for Medicare and Medicaid Services mandate that all molecular testing of tissue on which clinical decisions are made must be performed in Clinical Laboratory Improvement Amendments–certified laboratories.[69] Thus, the clinical uses of markers such as ERCC1 and RRM1 remain to be elucidated; however, exploring


Fig. 47.3. Study design and intervention period for the Spanish Lung Cancer Group phase III randomized trial. During the 10-day screening period, BRCA1 and RAP80 mRNA expression was analyzed, and if the analysis was successful, patients were randomly assigned in a 1:1 ratio to either the control or experimental arm. The screening and intervention periods were similar for the Chinese phase II randomized trial, but patients were randomized in a 1:3 ratio to either the control or one of three experimental arms.

specific isoforms may provide further opportunities for additional investigation.

BRCA1

BRCA1 belongs to the mismatch repair pathway of genes and is typically instrumental in repairing single-strand breaks. It also functions as a differential regulator of chemotherapy-induced apoptosis.[70] In preclinical models, BRCA1 has been shown to be a sensitizer to apoptosis induced by antimicrotubulin agents, such as taxanes and vinca alkaloids, and also abrogates the apoptosis induced by a range of DNA-damaging agents, including cisplatin and etoposide.[71] BRCA1 mRNA expression has been shown to correlate with ERCC1 mRNA expression, and low expression of BRCA1 has been shown to predict for a more favorable outcome in patients with resected NSCLC who have received adjuvant cisplatin and gemcitabine.[72,73]

In a feasibility study, the Spanish Customized Adjuvant Trial and the Spanish Lung Cancer Group (SLCG) customized adjuvant chemotherapy based on BRCA1 mRNA levels in 84 patients with completely resected NSCLC.[74] Docetaxel was used to treat tumors with high levels of BRCA; docetaxel and cisplatin were used to treat tumors with intermediate levels; and cisplatin and gemcitabine were used to treat tumors with low levels. The median survival had not been reached for patients with high or intermediate BRCA1 levels at the time of the report and was 25.6 months for patients with low levels ($p = 0.04$). Interim analyses showed that single-agent docetaxel was not inferior to cisplatin and docetaxel in terms of survival for patients with high BRCA1 levels. Based on these results, the SLCG designed a phase III open multicenter randomized study of customized adjuvant chemotherapy, based on BRCA1 mRNA levels, for completely resected early-stage (II–IIIA) NSCLC. In this study, patients were randomly assigned to the control or experimental arms in a 1:3 ratio. In the control arm, patients received docetaxel plus cisplatin, and in the experimental arms, patients who had tumors

with higher BRCA1 transcriptional levels were treated with single-agent docetaxel and patients who had tumors with intermediate and low BRCA1 expression received cisplatin-based doublets. Postoperative radiotherapy was mandatory for patients with N2 disease. According to the preliminary results of the study,[75] differences in the safety profile of the treatment schedules were noted, with customized treatment requiring fewer dose reductions; the efficacy results had not been reported by the time of publication. Therefore, high BRCA1 levels predict resistance to cisplatin and possibly sensitivity to docetaxel.

In the SLCG phase II customized chemotherapy trial, BRCA1 and RAP80 expression had a combined effect on outcome for patients with advanced NSCLC. Based on this finding, the SLCG conducted a randomized phase III trial to compare nonselected cisplatin-based chemotherapy with therapy customized according to BRCA1 and RAP80 levels (the BREC study).[76] A parallel randomized phase II trial was carried out in China under the auspices of the SLCG (Fig. 47.3). Patients were randomly assigned to the control or experimental arm in a 1:1 ratio in the SLCG trial and in a 1:3 ratio in the Chinese trial. The primary end point was progression-free survival. The results of the two studies indicated a poor predictive capacity of RAP80 for customization. Indeed, the prespecified interim analysis showed a detrimental effect in the experimental arm (HR for disease progression, 1.35; $p = 0.03$) and, based on these results, the study was prematurely closed. However, a significant interaction between performance status and treatment arm was found; in the experimental arm, a favorable, although nonsignificant, effect was found for patients with a performance status of 0, whereas there was a negative effect for patients with performance status of 1, including a significantly increased risk of death. Despite previous findings showing a predictive capacity for RAP80, the results of the BREC study indicate that other molecular factors may also influence the BRCA1-RAP80 predictive model.[76,77] For instance, a preclinical model published in 2012 showed that BRCA1 protein, p53 binding protein 1 (53BP1), and RAD51

may assemble at double-strand breaks in RAP80-depleted cells, whereas RAP80 and 53BP1, but not RAD51, may assemble at double-strand breaks in BRCA1-depleted cells.[78] Therefore, the results of the BREC study may provide the groundwork for research to define better predictive models for chemotherapy outcomes. The benefit obtained from biomarker-directed treatment in patients with a performance status of 0, while not significant, may pave the way for further investigation in this subgroup of patients.

Class β-Tubulin

Increased expression of class III β-tubulin has been shown to correlate with resistance to antimicrotubule agents such as taxanes and vinorelbine in patients with advanced NSCLC.[79] However, interest in β-tubulin faded after the findings of a retrospective analysis of data from the JBR.10 trial were reported. The JBR.10 trial compared adjuvant cisplatin and vinorelbine with observation alone after curative-intent surgical resection of stage IB–II NSCLC. β-tubulin expression measured by semiquantitative IHC demonstrated that high expression of β-tubulin was associated with poorer recurrence-free and overall survival among patients treated with surgery alone, but not among patients treated with adjuvant chemotherapy.[80] Further study of β-tubulin as a predictor of taxane sensitivity has been halted.

Thymidylate Synthase

Thymidylate synthase is essential for purine synthesis required for DNA replication. 5-Fluorouracil is a prototypic drug known to inhibit thymidylate synthase. However, thymidylate synthase has also been proposed as a target for pemetrexed, which has become a cornerstone drug for patients with nonsquamous NSCLC. Levels of thymidylate synthase have been high in small cell lung carcinoma; among NSCLCs, thymidylate synthase expression has been higher in squamous cell carcinoma than in adenocarcinomas.[81] Preclinical studies suggest that low expression of thymidylate synthase, dihydrofolate reductase, glycinamide ribonucleotide formyl transferase, and *MRP4* gene expression correlate with response to pemetrexed.[82] In animal studies, overexpression of thymidylate synthase correlated with decreased sensitivity to pemetrexed.[83] Taken together, these data suggest that high expression of thymidylate synthase predicts resistance to pemetrexed.

High levels of thymidylate synthase in squamous cell lung cancer provide an explanation for the decreased activity of pemetrexed in patients with this histologic subtype of NSCLC. A randomized phase III trial compared pemetrexed with docetaxel in the second-line treatment of patients with advanced stage NSCLC. Overall, there was no difference in efficacy between pemetrexed and docetaxel. Pemetrexed, however, was significantly less toxic than docetaxel.[84] Among patients with nonsquamous carcinoma, pemetrexed led to better overall survival than docetaxel (9.3 vs. 8.0 months), whereas docetaxel appeared to yield better overall survival for patients with squamous cell carcinoma (7.4 vs. 6.2 months).

This differential benefit of chemotherapy according to histology was also evident in a phase III trial comparing cisplatin and gemcitabine (863 patients) with cisplatin and pemetrexed (862 patients) in advanced NSCLC, with a prespecified subset analysis based on histology.[85] Although there was noninferiority for the pemetrexed-containing regimen compared with the gemcitabine-containing regimen in an unselected cohort of patients (median survival, 10.3 vs. 10.3 months; HR, 0.94; 95% CI, 0.84–1.05), overall survival was significantly superior for pemetrexed compared with gemcitabine among 847 patients with adenocarcinoma (12.6 vs. 10.9 months) and 153 patients with large cell carcinoma (10.4 vs. 6.7 months). For 473

patients with squamous cell carcinoma, however, the reverse was true, with gemcitabine providing additional benefit (10.8 vs. 9.4 months).

Similarly, in a randomized double-blind study of 663 patients with stage IIIB or IV disease who did not have disease progression after four cycles of platinum-based chemotherapy, the authors postulated a differential expression of thymidylate synthase between squamous and nonsquamous histology as a possible mechanism for the histology-specific benefit for pemetrexed. In this study, patients were assigned to receive pemetrexed (500 mg/m^2, day 1) or best supportive care until disease progression.[86] Although maintenance therapy with pemetrexed was of benefit for the entire cohort of patients (overall survival, 13.4 vs. 10.6 months; HR, 0.79, $p = 0.012$) compared with best supportive care, the overall survival was significantly better for patients with nonsquamous histology (15.3 vs. 10.3 months; HR, 0.70; $p = 0.002$).

Given the findings of these studies, investigators have attempted to tailor chemotherapy based on ERCC1 and thymidylate synthase in the International Tailored Chemotherapy Adjuvant Trial. This ongoing phase III multicenter randomized trial is comparing adjuvant pharmacogenomic-driven chemotherapy with standard adjuvant chemotherapy for patients with completely resected stage II to stage IIIA NSCLC. ERCC1 and thymidylate synthase are assessed by quantitative RT-PCR on FFPE tumor specimens in a central laboratory. The primary end point is overall survival; secondary end points include disease-free survival, toxicity profile of the treatment regimen in relation to ERCC1, and thymidylate synthase mRNA quantification versus protein quantification. The total anticipated patient accrual is 700. Patients in each genomic category will be randomly assigned to receive either a standard chemotherapy selected by the investigator (cisplatin and vinorelbine, cisplatin and docetaxel, or cisplatin and gemcitabine) or an experimental treatment chosen according to the following algorithm: high expression of ERCC1 and thymidylate synthase: single-agent paclitaxel; high expression of ERCC1 and low level of thymidylate synthase: single-agent pemetrexed; low ERCC1 expression and high level of thymidylate synthase: cisplatin and gemcitabine; and low expression of ERCC1 and thymidylate synthase: cisplatin and pemetrexed. Four cycles of the selected chemotherapy will be administered in both the standard and experimental arms. Enrollment on this trial was ongoing at the time of publication.

Gene Expression Profiling

With the advent of high-throughput technologies, investigators have attempted to develop oligonucleotide array–based gene signatures that can be used as both a prognostic and predictive tool. Although multiple genes can be analyzed at one time with gene expression microarrays, the technique itself is complex and necessitates specialized techniques and complex bioinformatics. This complexity has precluded its wider application in community centers. Several private and for-profit entities have offered to analyze samples and provide the results on a fee-for-service basis.

Among the first gene expression signatures to be studied was a multivariate model that included p53, KRAS, and HRAS, which was used to determine prognosis in stage I resected NSCLC.[87] Chen et al.[88] reported on a five-gene signature that may provide prognostic value for patients with NSCLC. These authors first identified a 16-gene panel, utilizing oligonucleotide microarrays, which correlated with survival. From this panel of 16 genes, five genes (*DUSP6*, *MMD*, *STAT1*, *ERBB3*, and *LCK*) were selected for further studies by RT-PCR and decision-tree analysis. This gene profile dichotomized patients into two groups: high risk (59 patients) and low risk (42 patients). For patients in the high-risk

group, the median overall survival was significantly shorter than for patients in the low-risk group (20 vs. 40 months; $p < 0.001$). The median progression-free survival was also significantly shorter in the high-risk group (13 vs. 29 months; $p = 0.002$).

Several other chemotherapy predictive or prognostic gene signatures have also been developed and are moving toward validation.[89–95] Gene-expression profile signatures are now used in clinical practice for breast cancer,[96–99] but have not been used widely in clinical practice, most likely because of the complexity of the technology itself and cost. In addition, the lack of clear understanding of the genes that constitute the panel raises questions about its validity and lack of validation in large data sets consisting of hundreds of patients.

HOST-RELATED FACTORS

In theory, specific chemotherapy regimens may be selected or avoided based on genetic factors within the host. These germline genetic factors typically predict for the risk of toxicity rather than efficacy. Single-nucleotide polymorphisms (SNPs) and substitutions of a single base in a DNA sequence account for approximately 90% of genetic variation in humans. SNPs are estimated to occur as frequently as every 100 to 300 bases, and, by definition, must be present in at least 1% of the population. SNPs are found in both coding and noncoding sequences and may alter DNA transcription rates, RNA splicing, translation efficiency, and protein function.

UGT1A1*28

Chemotherapy metabolism and detoxification are influenced by a large number of SNPs. As a key example, polymorphisms in the uridine diphosphate glucuronosyltransferase 1A1 (*UGT1A1*) gene have a substantial effect on gastrointestinal and myelosuppressive toxicity in patients treated with irinotecan. Gilbert syndrome has often been diagnosed in patients with the *UGT1A1* gene, and people with this syndrome have a predominantly unconjugated hyperbilirubinemia that is asymptomatic.[100–103]

Irinotecan is activated to SN-38, which then exerts antitumor activity.[104] SN-38 is then detoxified to the pharmacologically inactive SN-38 glucuronide (SN-38G). UGT1A1 is the principal enzyme responsible for the glucuronidation of SN-38. The in vitro glucuronidation of SN-38 is strongly correlated with the *UGT1A1* gene promoter polymorphism UGT1A1*28, which contains an additional TA repeat in the TATA sequence of the *UGT1A1* promoter; i.e., the sequence is (TA)7TAA instead of (TA)6TAA.[104] Among patients with the (TA)7TAA sequence, the rate of SN-38 glucuronidation has been reported to be significantly slower than among patients with the normal allele ($p = 0.001$) and the rates of grade 4 toxicities, especially diarrhea and myelosuppression, have been significantly higher. These results suggest that screening for UGT1A1*28 polymorphism may identify patients with lower SN-38 glucuronidation rates and greater susceptibility to irinotecan-induced gastrointestinal and bone marrow toxicity.[103,105] Use of the UGT1A1 polymorphism to predict for toxicity to irinotecan is approved by the United States Food and Drug Administration (FDA) for use in clinical practice.

CYP3A

Polymorphic variants in cytochrome P450 (CYP) proteins are also recognized as determinants of chemotherapy activity and toxicity. This large and diverse family of enzymes catalyzes the metabolism of xenobiotics, including many anticancer agents.[106] CYP3A members are the most abundant type of CYP in the small intestine and liver, with substantial interindividual and interracial variation in expression attributed to SNPs.[107,108] CYP3A expression affects the pharmacokinetic disposition of multiple drugs

and may have an impact on the metabolism of environmental procarcinogens, thus influencing an individual's predisposition toward cancer. The role of SNPs in drug metabolism and disposition is complex, and efforts to define their utility for personalized medicine are ongoing.[109,110] Interindividual differences in host DNA repair capacity may also affect the response to chemotherapy. Multiple SNPs have been identified in genes involved in nucleotide excision repair, double-strand DNA break repair, nucleotide synthesis, and other DNA repair processes.[111,112] Decreased DNA repair capacity resulting from SNPs appears to contribute to lung cancer risk, particularly in patients who are young, female, and light smokers or nonsmokers.[113]

Although such host-related differences are typically considered on an individual patient basis, in a broader sense, genotyping studies may help to explain differences in patients' outcomes based on ethnic or racial background (i.e., population-related pharmacogenomics). For example, variations in taxane metabolism between Japanese and white populations have been reported and purported to account for differences in outcomes of taxane-based chemotherapy.[114] To address this question, joint studies between Japanese and United States investigators have been designed to identify population-related differences in drug pharmacogenomics using a so-called common-arm approach.[115] In such studies, separate phase III trials evaluating paclitaxel and carboplatin for advanced-stage NSCLC incorporated similar study criteria for patient eligibility and treatment. In a preliminary report, differences in allelic distribution for genes involved in paclitaxel disposition or DNA repair were found between patients in Japan and the United States. Genotype-associated correlations with clinical outcomes were observed for progression-free survival with CYP3A4*1B and for response with ERCC2 K751Q. This research strategy may assist in determining whether the significant differences in efficacy and toxicity that have been reported in these two populations are attributable to population-related genetic variance.[115]

CONCLUSION

Sensitizing EGFR mutations and the ALK fusion oncogene are now recognized as predictive biomarkers in lung cancer. KRAS mutational status is predictive of lack of therapeutic efficacy with EGFR tyrosine kinase inhibitors. MET and ROS1 genomic alterations are more rare driver mutations that, when detected, may enable more precision treatment for patients with lung cancer. Conversely, the use of molecular biomarkers such as ERCC1, RRM1, BRCA1, thymidylate synthase, and others remains investigational. The pharmacogenomic research community must come to an agreement on optimal ways of measuring these biomarkers. Because these biomarkers are discrete—measured at the DNA level with a clear and unambiguous answer (positive or negative)—they are most likely to have wide clinical application. With regard to host-related factors, one biomarker is FDA-approved for use in clinical practice: estimation of the UGT1A1 polymorphism to predict for toxicity to irinotecan. However, this biomarker also has not found wide application because of the limited use of irinotecan to treat lung cancer in the United States. Asymptomatic predominantly unconjugated hyperbilirubinemia is a hallmark of Gilbert syndrome, which in turn is caused by the UGT1A1*28 polymorphism. Thus, in the clinical setting, hyperbilirubinemia according to routinely performed metabolic or liver panels would provide a clue to the possibility of increased toxicity with irinotecan and may prompt formal testing for the UGT1A1*28 polymorphism.

The field of lung cancer pharmacogenomics has advanced exponentially since the early 2000s and yet is essentially still in its initial stages. The pace of development is expected to continue over the coming years, and research has highlighted several important lessons that will serve us well going forward.

48 New Targets for Therapy in Lung Cancer

Aaron S. Mansfield, Grace K. Dy, Mjung-Ju Ahn, and Alex A. Adjei

SUMMARY OF KEY POINTS

- Treatment of lung cancer is rapidly evolving. Large cell carcinomas as a group have therapeutically relevant driver mutations in nearly 40% of cases.
- Despite the recent failures of some agents, in 2015 the US Food and Drug Administration issued seven approvals of agents for the treatment of lung cancer.
- Many additional promising agents that target several aberrant signaling pathways are under development.
- A large proportion of genomic alterations are not considered directly druggable targets, such as mutant p53 or amplified SOX2; this obstacle may be surmounted by identifying synthetically lethal changes amenable to drug therapy.
- Targeted therapy requires simultaneous development of the targeted agent along with biomarker assay platforms for patient selection to optimize therapeutic benefit.
- To avoid misinterpretation of clinical trial data, thorough understanding of drug activity and characterization of pharmacologic activity, particularly of small-molecule inhibitors, is necessary, particularly when an anticipated clinical benefit is not found.

Major advances in the therapy of cancer have occurred since the beginning of the new millennium. These advances were spurred by increased knowledge of the biologic hallmarks of cancer coupled with breakthroughs in genomic and pharmaceutical technologies. In the field of lung cancer, researchers discovered the oncogenic role of so-called druggable proteins arising from somatic mutations in the epidermal growth factor receptor (*EGFR*) gene and chromosomal rearrangements in the anaplastic lymphoma kinase (*ALK*) gene. These findings led to therapies resulting in substantially higher response rates and survival in patients with lung cancer being treated with EGFR and ALK inhibitors, respectively, compared with conventional chemotherapy.[1–3] Recognizing the integral role played by the tumor microenvironment in the initiation and maintenance of the malignant phenotype has also resulted in the development of antiangiogenesis agents with clinical relevance in various malignancies, such as the use of the monoclonal antibody bevacizumab in the nonsquamous subtype of nonsmall cell lung cancer (NSCLC).[4] Modulation of immune checkpoints is another highly promising approach. In this chapter, we review promising therapeutic drug targets for the treatment of NSCLC as of 2016.

Although the relevance of each target and its role in each signaling pathway is presented in a linear fashion to facilitate discussion, individual targets do not function in isolation because cells possess a complex architecture of signaling networks that are highly interconnected. Moreover, negative feedback loops and concurrent activation of multiple substrates involved in a number of important pathways can lead to paradoxical effects depending on the cellular context. Thus, the presence of a drug inhibitor can result in pathway activation that leads to cell survival or proliferation rather than cell death, resulting in ineffective therapies. This is a challenge in the therapy of malignancies such as lung cancer, which tend to harbor multiple molecular aberrations. Additionally, targeted therapies may also affect signaling networks within nonmalignant cells and modulate antitumor immunity or the tumor microenvironment.[5]

KEY SIGNAL TRANSDUCTION PATHWAYS

The two major signaling cascades that are triggered upon activation of growth factor receptors are the RAS/RAF/MAPK and the PI3K/AKT/mTOR pathways. Multiple relevant targets for drug therapy in NSCLC can be illustrated as they transduce signals through these two interconnected pathways (Fig. 48.1).

The RAS/RAF/MAPK pathway plays a major role in the signaling cascades of various growth factor receptors, such as EGFR, human epidermal growth factor receptor type 2 (HER2), fibroblast growth factor receptor (FGFR), and others. Upon activation of receptor kinase signaling, recruitment of adaptor proteins (e.g., Grb2, Shc, and others) triggers key downstream steps involving RAS activation. After this event, the serine/threonine kinase RAF (a member of the MAPK kinase or MAPKKK group of protein kinases), represented by the members ARAF, BRAF, and CRAF, phosphorylates two distinct serine residues on the MAPKs (also known as MEK) MEK1 and MEK2. MEK1/2 subsequently phosphorylates both serine/threonine and tyrosine residues in the final p44 and p42 MAPK (also known as ERK1/2) in the cascade, which then phosphorylates downstream substrates, resulting in proliferation and survival.[6,7]

Similarly, lipid phosphorylation via phosphoinositide 3-kinase (PI3K) signaling regulates various cellular functions such as proliferation, survival, metabolism, and metastasis. This pathway is normally regulated by receptor tyrosine kinases (RTKs), particularly signals generated by insulin and insulin-like growth factor 1 (IGF-1) receptors (IGF-1Rs).[8] The PI3K pathway is also frequently involved in the development and maintenance of the malignant phenotype arising from oncogenically driven RTK activation of the pathway. The class I PI3Ks are primarily involved in the generation of phospholipid messengers in response to RTK activation.[9] Termination of PI3K signaling in turn is mediated by phosphatases such as the tumor suppressor phosphatase and tensin homolog (PTEN) on chromosome 10.[10]

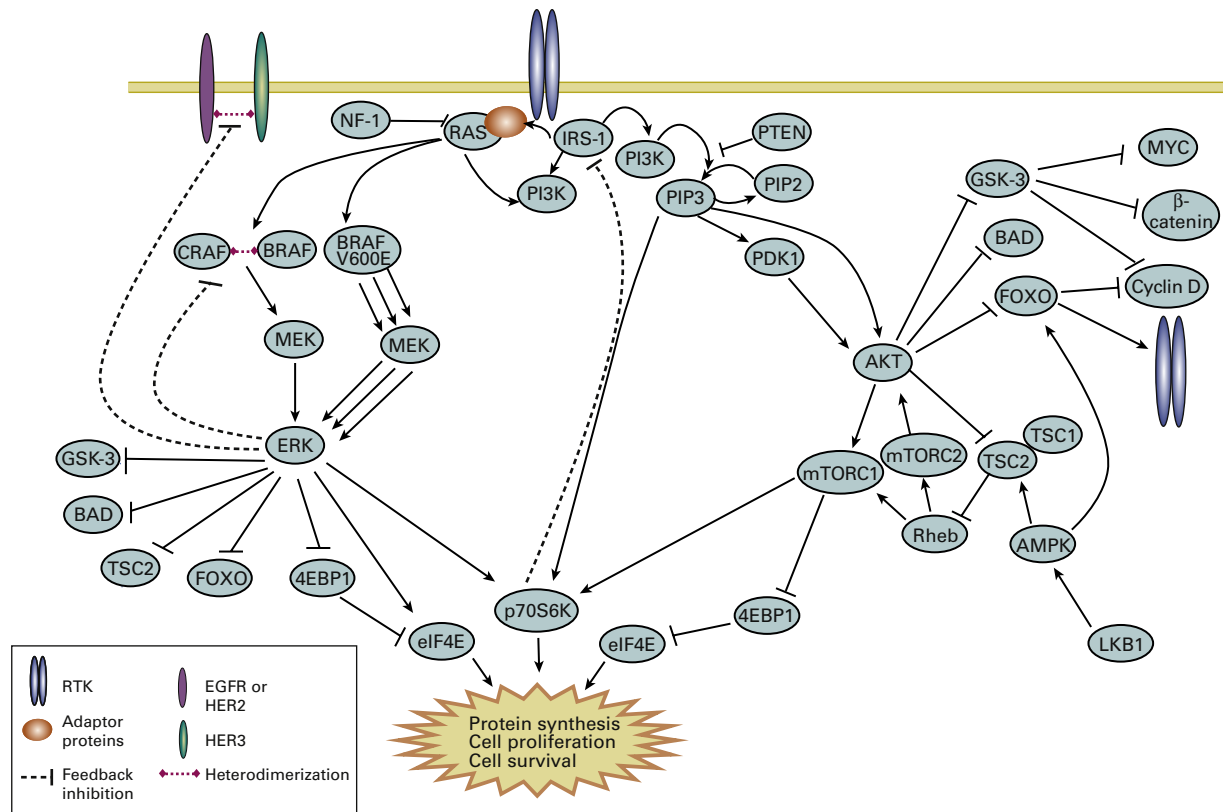
Phospholipid messengers generated upon PI3K activation bind to phosphoinositide-dependent kinase 1 (PDK1) and, downstream to it, protein kinase B (AKT) and other effector proteins through specific pleckstrin homology or other lipid-binding domains. PDK1 is the principal kinase responsible for phosphorylation and activation of the serine/threonine kinase AKT. AKT itself is also phosphorylated by downstream substrates, an example of nonlinear interactions that exist in signaling pathways. Activated AKT phosphorylates various substrates that mediate diverse functions, such as degradation of the Forkhead (FOXO) transcription factors and inhibition of BAD and BAX, resulting in reduced apoptosis and cell survival. AKT also activates mammalian target of rapamycin (mTOR) by direct phosphorylation as well as by phosphorylating the tumor suppressor tuberin (also known as TSC2), thus inhibiting the repressor function of the tuberin–hamartin (also known as TSC1) complex on mTOR.[11,12] mTOR kinase, a highly conserved serine/threonine kinase,


Fig. 48.1. Simplified signaling output mediated through relevant drug targets in nonsmall cell lung cancer.

subsequently regulates cellular metabolism and protein synthesis through downstream effectors such as p70S6K and 4EBP1. MEK/ERK signaling also activates mTOR by inactivating TSC2 upon phosphorylation by ERK1/2, one of the several links between the RAS/RAF/MAPK and PI3K/AKT/mTOR pathways.[13]

THERAPEUTIC TARGETS

This chapter provides a review of the frequency of genomic alterations found in relevant selected targets for two major histologic subtypes of NSCLC, squamous cell carcinoma and adenocarcinoma (Table 48.1). Large cell carcinomas as a group have therapeutically relevant driver mutations in nearly 40% of cases. The distribution of these mutations has been described and mirrors the classification of squamous and nonsquamous subtypes of NSCLC as defined by immunohistochemistry (IHC),[14] and thus is not categorized separately. Many drugs are in clinical use or in development for each corresponding drug target.

Receptor Tyrosine Kinases
Human Epidermal Growth Factor Receptor Type 2

HER2 (also known as ERBB2) belongs to the same family of HER RTKs as EGFR.[15] In contrast to EGFR, HER2 does not interact with any ligand directly but serves as the preferred dimerization partner of EGFR and other ErbB family members, such as HER3 and HER4, to trigger autophosphorylation and downstream signaling through both the MAPK and PI3K pathways described earlier.[16] *HER2* gene amplification (defined as HER2/CEP17 ratio per cell of 2 or greater, and absolute *HER2* signals in more than 4; or more than 15 copies in more than 10% of cells using fluorescence in situ hybridization [FISH] assay) is found in approximately 1% to 3% of lung cancers.[17,18] *HER2* exon 20

insertions are found in approximately 3% of adenocarcinomas.[19] *HER2* amplification is correlated with histologic subtype and tumor grade, such that high-level amplification appears to be concentrated in the subgroup of high-grade adenocarcinomas.[17] Intratumor heterogeneity in the level of *HER2* amplification also appears frequently.[17] This latter feature may partly account for the negative results of clinical trials conducted a decade ago using trastuzumab in combination with chemotherapy for patients with NSCLC. In addition to patients with tumor heterogeneity, these studies included patients with potentially low-to-absent *HER2* amplification (e.g., inclusion of patients with 2+ HER2 protein expression as determined by IHC).[20–22]

Afatinib, an oral pan-HER inhibitor, has been used as monotherapy in genotypically selected solid tumors (lung cancers excluded) with either *EGFR* or *HER2* amplification but showed limited activity, with an objective response rate of 5%.[23] Lapatinib, an oral dual EGFR/HER2 inhibitor, demonstrated limited activity as monotherapy in a molecularly unselected population of NSCLC tumors. Of interest is that one of two patients with *HER2* amplification (determined retrospectively) had a partial response, although this result was not confirmed.[24] Dacomitinib is another oral pan-HER inhibitor with demonstrated in vitro activity in selected *HER2*-amplified cell lines resistant to trastuzumab and lapatinib,[25,26] which resulted in a 12% response rate in patients with *HER2* exon 20 insertions, but no responses in patients with *HER2* amplification.[27]

HER2 amplification is also implicated in acquired resistance to therapy with EGFR tyrosine kinase inhibitors (TKIs) in laboratory models and in the clinical setting.[18,28] *HER2* amplification is found in 12% to 13% of cases of acquired resistance to EGFR-TKIs wherein it is mutually exclusive with the EGFR T790M mutation among tumors with acquired EGFR-TKI resistance. In contrast, no *HER2* exon 20 mutations were identified in patients who developed resistance to the irreversible EGFR-TKI

TABLE 48.1 Genetic Abnormalities in Squamous Cell Carcinoma and Adenocarcinoma of Lung[a]

Genetic Abnormality	Gene Location	Frequency (%)	
		Squamous Cell Carcinoma	Adenocarcinoma
HER2 overexpression	17q11.2–q12, 17q21	3–5	5–9
*HER2 amplification	17q11.2–q12, 17q21		
EGFR-TKI naïve		<1	1–4
Acquired EGFR-TKI resistance		—[b]	12–13
*FGFR1 amplification	8p12	22	1–3
PIK3CA amplification	3q26.3	33	6
c-MET amplification	7q31.1	3–21	3–21
HER2 mutation	17q11.2–q12, 17q21	1	2
*HER3 mutation	12q13	1	1
c-MET mutation	7q31.1	1	2
*FGFR2 mutation	10q26.13	3	1–2
*FGFR3 mutation	4p16.3	3	<1
DDR2 mutation	1q23.3	4	1
KRAS mutation	12p12.1	6	21
*NRAS mutation	1p13.2	—	<1
*BRAF mutation	7q34	<1–2	3–5
*MAP2K1 mutation	15q21	—	<1
*PIK3CA mutation	3q26.3	3–9	2–3
PTEN mutation	10q23.3	10	2
PTEN loss	10q23.3	8–20	8–20
AKT1 mutation	14q32.32	1	Very rare
LKB1 mutation	19p13.3	5	23
*LKB1/KRAS dual mutations	19p13.3/12p12.1	—	5–10
*PIK3CA/KRAS dual mutations	3q26.3/12p12.1	—	<1
*NRG1 fusion	8p12	—	<4[c]
*ROS1 fusion	6q22	0–1	1–3
*RET fusion	10q11.2	<1	1–2
*FGFR fusion	(FGFR1) 8p12 (FGFR2) 10q26.13 (FGFR3) 4p16.3	<1–2	<1
*BRAF fusion	7q34	—	3[c]

[a]Table adapted with permission from the American Association for Cancer: Perez-Moreno P, et al. Squamous cell carcinoma of the lung: molecular subtypes and therapeutic opportunities. *Clin Cancer Res.* 2012;18(9):2443–2451. Genetic abnormalities with an asterisk (*) pertain to data updated or not found in the original table.

[b]Denotes that no data have been published to date.

[c]Prevalence in never-smokers.

EGFR-TKI, epidermal growth factor receptor-tyrosine kinase inhibitor; *HER2,* human epidermal growth factor receptor type 2.

afatinib.[29] *HER2* amplification is also a putative mechanism of acquired resistance to ALK inhibitors in EML4–ALK-translocated lung cancer cells in vitro, although clinical studies have not confirmed this possibility to date.[30]

In comparison, mutations in *HER2* occur in 2% to 4% of NSCLC tumors, largely in high-grade and moderately to poorly differentiated adenocarcinomas.[19,31–33] More than 95% of the mutations described to date are small insertions in exon 20, mostly represented by an in-frame insertion of 12 base pairs that causes duplication of the amino acids YVMA.[31] Functional studies of this insertion mutation show that it confers greater

transforming and antiapoptotic potential, in addition to its stronger catalytic activity, compared with wild-type *HER2*.[34] It can also trigger EGFR activation in the absence of cognate ligands and EGFR kinase activity.[34] *HER2* mutations appear to occur in greater proportions among women and never-smokers and are generally mutually exclusive with *EGFR* and Kirsten rat sarcoma (*KRAS*) mutations as well as *HER2* amplification, with rare exceptions.[35–37] An activating *HER2* V659E mutation sensitive to lapatinib was described in a specimen of lung adenocarcinoma from a patient with Li-Fraumeni syndrome.[38] It is anticipated that secondary *HER2* mutations, such as L755S, T862A, and the gatekeeper T798M mutation, can arise as a mechanism of acquired drug resistance similar to what is seen in *HER2*-amplified breast cancers after chronic therapy with lapatinib.[39,40]

Afatinib has been reported to induce tumor response or disease stabilization when used as monotherapy in *HER2*-mutant lung adenocarcinomas.[36] Similarly, trastuzumab-based combinations have induced partial responses.[36,37,41] Although lapatinib demonstrated preclinical activity against cells expressing the *HER2* insertion mutation,[34] tumor response has not been documented with monotherapy in the very limited number of patients reported on thus far.[36] Clinical activity has been documented, however, when lapatinib is used in combination with either chemotherapy or trastuzumab-based regimens in patients with NSCLC who have either a *HER2* exon 20 insertion or the *HER2* V659E mutation.[38,41] As per above, dacomitinib resulted in a 12% response rate in patients with *HER2* exon 20 insertions.[27] *HER2* exon 20 mutations, especially HER2YVMA, appear to be a promising target in lung cancer but needs to be validated.

Human Epidermal Growth Factor Receptor Type 3

HER3 (also known as ERBB3) is another representative of the four-member group in the HER RTK family. HER3 is generally considered to have functionally weaker kinase activity compared with EGFR.[42,43] Heterodimerization with other HER members, such as with HER2 upon binding of the ligand neuregulin, triggers autophosphorylation and recruitment of downstream signaling molecules. *HER3* mutations have been reported in approximately 1% of lung adenocarcinomas and 1% of squamous cell lung cancers.[44] Most of the *HER3* mutations identified to date are clustered in the extracellular domain (ECD), although some are mapped to the kinase domain.[44] The functional characteristics of most specific mutants described in NSCLC are yet to be verified; however, several *HER3* mutations in either the ECD or kinase domain have been shown to promote oncogenesis in a ligand-independent manner, although this effect required the presence of kinase-active HER2. Recently, an activating *HER3* V855A mutation that is homologous to *EGFR* L858R was identified in a patient with chemotherapy resistant NSCLC.[45] This mutation was transforming in murine and human cell line studies in the presence of wild-type *HER2*. Various small-molecule inhibitors and monoclonal antibodies against HER2 and HER3, as well as PI3K inhibitors, have demonstrated variable effectiveness depending on the specific *HER3* mutation.[44]

The recurrent fusion gene CD74-NRG1 found in mucinous lung adenocarcinomas of never-smokers appears to correlate with increased HER3 phosphorylation in tumor tissue.[46] This chimeric transcript results in the expression of the EGF-like domain in tumor tissue that is otherwise negative for neuregulin. Functional characterization of this fusion protein in vitro showed activation of the PI3K-AKT pathway.[46] Indeed, HER3 plays an integral role in activation of the PI3K survival pathway upon its heterodimerization with EGFR or HER2 in malignant cell lines.[47] EGFR-TKI-sensitive NSCLC cancer cell lines rely on HER3 signaling to activate the PI3K/AKT pathway.[48]

HER3 signaling is also implicated in acquired resistance to EGFR-TKIs. Persistent HER3-activated PI3K signaling is

uncoupled from EGFR and is mediated instead through its interaction with MET, which is amplified in this setting.[49] Another mechanism that can sustain HER3-activated PI3K signaling is disruption of negative feedback networks. ERK signaling leads to feedback phosphorylation of the conserved T669 residue within the juxtamembrane domain of EGFR, HER2, and HER4, and this prevents transphosphorylation of HER3 (Fig. 48.1).[50] The loss of this dominant negative feedback suppression of HER3 by intact MEK/ERK signaling is thought to account for the increased AKT phosphorylation found with MEK inhibitors in EGFR- and HER2-driven malignant tumors.[50]

Blockade of HER3 signaling, through monoclonal antibody therapies or antisense oligonucleotides, improves the antitumor activity of EGFR and HER2 TKIs in preclinical models, including cell lines with acquired resistance to EGFR-TKIs.[51–53] Another proposed approach for reducing HER3-mediated activation to enhance EGFR-TKI activity involves modulation of circulating neuregulin ligands via inhibition of ADAM17, a membrane-associated metalloprotease that cleaves and releases HER ligands from cells to enable receptor binding.[54] Afatinib and dacomitinib are both oral irreversible pan-HER TKIs that have produced marked tumor regression in xenograft models that contained *EGFR* mutations, including the T790M mutation, which is associated with acquired resistance to EGFR-TKIs.[55,56] However, subsequent modeling showed that cytotoxicity against T790M can be accomplished only at clinically unachievable concentrations, thus accounting for the limited efficacy seen for this patient subset in the clinic.[57] Nonetheless, these agents can block HER2 heterodimerization with EGFR or HER3,[58] thus explaining the potential to overcome acquired resistance mediated by HER3. In a randomized phase II study comparing dacomitinib and erlotinib, dacomitinib demonstrated significantly improved progression-free survival in KRAS wild-type NSCLC with or without EGFR mutation.[59] A phase III study comparing first-line dacomitinib with gefitinib for patients who have NSCLC with EGFR-activating mutations was ongoing at the time of publication. Another phase III study comparing second- or third-line dacomitinib and erlotinib in patients with KRAS wild-type NSCLC has completed enrollment at the time of the publication of this chapter (ClinicalTrials.gov identifier: NCT01360554). A phase III clinical trial recently demonstrated statistically significant but modest improvements in progression-free and overall survival with afatinib compared with erlotinib in patients receiving second-line therapy for squamous cell NSCLC;[60] however, enthusiasm for these results has been muted by the advances seen with immunotherapy for this patient population. Various monoclonal antibodies against HER3 are being investigated in clinical trials, combining them with other inhibitors of the EGFR or HER2 pathway.

Hepatocyte Growth Factor Receptor

Binding of the ligand hepatocyte growth factor (HGF, also known as scatter factor), a paracrine factor secreted by stromal cells, to its cognate receptor MET facilitates receptor phosphorylation, leading to the activation of downstream signaling through the MAPK and PI3K pathways, which promote epithelial-to-mesenchymal transition (EMT), invasion, and metastasis.[61] Ubiquitin-mediated receptor degradation is regulated at the Cbl E3-ligase RTK binding domain, similar to what has been described for EGFR and HER2.[62] Mechanisms of aberrant activation of MET described in NSCLC include receptor overexpression (with or without HGF), *c-MET* gene amplification, or exon 14 skipping abnormalities. Levels of *MET* expression as high as 60% have been reported in various studies of NSCLC.[63] Both the *EGFR* and *c-MET* genes are located on chromosome 7, and an increased copy number of the *c-MET* gene as determined by FISH is associated with an increased copy number of the *EGFR* gene and confers a

worse prognosis.[64] Coamplification of *c-MET* and *EGFR* is also described in up to 8.5% of NSCLCs not previously treated with EGFR-TKIs.[65] Amplification of *c-MET* also occurs infrequently with an incidence of 3% to 7% among patients not treated with EGFR-TKIs, but this incidence increases to 10% to 22% among patients with acquired resistance to EGFR-TKIs.[49,66] Exon 14 skipping mutations occur in about 3% of patients with NSCLC.[67] Patients with sarcomatoid pulmonary carcinomas are enriched for *MET* exon 14 skipping mutations, and one study identified that 22% of patients with this relatively rare form of lung cancer have this mutation.[68] MET can be transactivated through a variety of protein interactions and can heterodimerize with other RTKs, such as EGFR, HER2, HER3, and ret proto-oncogene (RET), in cells with *c-MET* amplification, representing an escape or bypass mechanism mediating resistance to inhibitors of these RTK-activated signaling pathways.[49,69,70] In a preclinical model, MET activation through paracrine secretion of HGF also served as a mechanism for resistance to second-generation selective ALK inhibitors such as ceritinib (LDK378), but not to the MET/ALK inhibitor crizotinib.[71]

Somatic intronic mutations of *c-MET* that lead to an alternatively spliced transcript, encoding a deletion of the exon-14 juxtamembrane domain spanning the amino acids 964 through 1010, result in loss of the Cbl binding site at Y1003.[62] This skipping mutation in exon 14 yields a functional MET protein with decreased ubiquitination and consequently sustained activation of the MAPK pathway through altered receptor downregulation.[62] This mutation variant appears to be mutually exclusive with mutations of other genes involved in the MAPK pathway (e.g., *EGFR*, *RAS*, and *RAF*).[62] Additional mutations have been described in both the ECD and juxtamembrane domains, some of which have transforming potential.[63,72,73] No reports have indicated nonsynonymous mutations in the kinase domain to date. Of note is that most of these other mutations reported are in fact germline.[74] The germline mutation N375S, which occurred at the highest frequency, appears to be associated with smoking and squamous histology. The *MET*-N375S mutation seems to confer resistance to the small-molecule MET kinase inhibitor SU11274.[74]

Various approaches for inhibiting the MET pathway have been tested or are in clinical development. These strategies include anti-HGF and anti-MET monoclonal antibodies, or small-molecule MET kinase inhibitors. The MET/ALK/ROS1 inhibitor crizotinib was reported anecdotally to induce a rapid and durable response in a patient with de novo *c-MET* amplification without ALK rearrangement.[75] Models of resistance to MET inhibitors predict the emergence of either secondary mutations or activation of EGFR signaling through increased expression of transforming growth factor-α.[76] A randomized phase III study in previously treated patients with NSCLC of erlotinib with or without tivantinib, initially thought to be a selective nonadenosine triphosphate (non-ATP) competitive MET inhibitor, was halted because of an increased incidence of interstitial lung disease; regardless, there was no improvement in overall survival.[77] Similarly, a separate phase III clinical trial conducted throughout Europe and the United States failed to show an overall survival benefit of erlotinib and tivantinib compared with erlotinib and placebo.[78] Nonetheless, preclinical data generated from two different groups suggest that although tivantinib can mitigate HGF-dependent MET activation, this is not its major mechanism of action.[79,80] Tivantinib (in contrast to crizotinib) did not inhibit MET autophosphorylation at doses that induced apoptosis. Instead, it exhibited cytotoxicity regardless of activation status of the MET pathway or the presence or absence of a functional MET kinase. In fact, growth inhibition and cytotoxicity reported with tivantinib may be mainly due to its effect on microtubule dynamics,[81] which is not found with other MET inhibitors.[79,80]

Onartuzumab (MetMAb), a monoclonal antibody that binds to the ECD of MET to prevent ligand binding, was evaluated in a randomized phase III study in combination with erlotinib as compared with placebo plus erlotinib in patients with NSCLC and MET-positive status as determined by IHC. The rationale for the study was based on promising results for progression-free survival (2.9 vs. 1.5 months; hazard ratio [HR], 0.53; $p = 0.04$) and overall survival (12.6 vs. 3.8 months; HR, 0.37; $p = 0.002$) noted in patients with MET-positive NSCLC who received the onartuzumab plus erlotinib combination compared with the placebo plus erlotinib treatment in the preceding randomized phase II study.[82] In contrast, patients with MET-negative NSCLC who received the combination had worse progression-free survival (1.4 vs. 2.7 months; HR, 1.82; $p = 0.05$) and overall survival (8.1 vs. 15.3 months; HR, 1.78; $p = 0.16$) compared with patients who received placebo plus erlotinib.[82] Unfortunately, the phase III clinical trial was stopped early due to futility as the experimental arm did not improve overall survival (OS), progression free survival (PFS), or overall response rate (ORR) compared with erlotinib alone.[83]

Whereas targeting MET based on protein expression has had challenges, *MET* amplification and *MET* exon 14 skipping mutations are emerging as promising targets. The interim analysis of a small study demonstrated that 4 of 12 patients with intermediate (2.2–5) or high (>5) ratios of MET to CEP7 responded to crizotinib.[84] An even more impressive response rate was observed in an interim analysis of a trial of the safety and efficacy of crizotinib for patients with *MET* exon 14 skipping mutations where 10 of 15 patients had confirmed or unconfirmed partial responses.[85] One case report showed that a patient with a *MET* exon 14 skipping mutation who demonstrated a response to crizotonib acquired a mutation in the *MET* kinase domain, D1228N, at the time of progression.[86] Responses have also been observed in patients with *MET* exon 14 skipping mutations treated with cabozantinib.[87] Other MET inhibitors in development include AMG337 and capmatinib (INC280). These ongoing trials will help clarify which MET abnormalities are potentially targetable in NSCLC, but *MET* exon 14 skipping mutations and amplification seem to be better predictors of response than MET expression by IHC at this time.

Fibroblast Growth Factor Receptor

The fibroblast growth factor receptor (FGFR) signaling module plays an important role in various cellular processes, such as vascular and skeletal development during embryogenesis, as well as regulation of angiogenesis and wound healing in adults. The FGF family of ligands, with more than 20 members, is sequestered to the extracellular matrix by heparin sulfate proteoglycans. Five FGFRs exist, of which *FGFR*s 1–4 are highly conserved and contain the classic tyrosine kinase motifs in their split kinase domain.[88] Moreover, *FGFR*s 1–3 are subject to alternate splicing, which results in variants with tissue-specific expression and varying ligand affinity. Dimerization of the ternary complex consisting of FGF, FGFR, and heparin sulfate proteoglycan activates downstream signaling, which ultimately leads to pathway activation of the RAS/MAPK and PI3K/AKT signaling cascades.[88]

Various mechanisms of oncogenic FGFR signaling have been described in NSCLC. Focal amplification of *FGFR1* is reportedly found in 22% of squamous-type NSCLCs.[89] *FGFR1* amplification appears to result in ligand-independent signaling and confers sensitivity to treatment using small molecule FGFR-TKIs.[89] Somatic gain-of-function mutations in *FGFR2* and *FGFR3*, a subset of which have transforming ability, have also been described in up to 6% of squamous NSCLCs.[90] These mutations are commonly coincident with mutations in *TP53* and *PIK3CA* and are mostly sensitive to inhibition by FGFR-TKIs.[90] Mutations in

FGFR2 or *FGFR3* can occur in either the kinase domain, causing constitutive activation, or in the ECD, which results in constitutive dimerization.[90] Cell models (i.e., fibroblasts) expressing the ECD mutations and exposed to a low concentration of multikinase inhibitors with anti-FGFR activity exhibited enhanced growth. This growth-promoting phenomenon was not seen with higher drug concentrations or with the use of selective FGFR inhibitors.[90]

Various chromosomal rearrangements involving *FGFR1–3* result in fusion products that also exhibit ligand-independent oligomerization capability, activation of the MAPK pathway, and sensitivity to FGFR-TKIs. Several of these reported in NSCLC include BAG4–FGFR1, FGFR2–CIT, FGFR2–KIAA1967, and FGFR3–TACC3. The FGFR3–TACC3 fusion, found in approximately 2% of squamous cell NSCLCs and rarely in adenocarcinoma, is the most frequently reported to date.[91–94] Other potential fusion partners that mediate oligomerization in other tumor types include BICC1, CCDC6, BAIAP2L1, CASP7, and OFD1.[94]

Similar to other TKIs, an anticipated mechanism of acquired resistance to FGFR inhibitors is the emergence of secondary mutations, such as the V555M alteration in *FGFR3*.[95] Oncogenic switch or constitutive activation of other pathways leading to activation of the MAPK or PI3K pathway, such as through MET,[96] may also underlie acquired or intrinsic resistance to FGFR inhibition, thus providing a rationale for investigations on combination therapy. Likewise, oncogenic switch to FGFR signaling has been suggested to mediate resistance to EGFR-TKIs,[97,98] as well as to HER2, MET, and angiogenesis inhibitors.[96,99–101]

Because of the high degree of homology between the vascular endothelial growth factor receptor 2 (VEGFR2) and FGFR tyrosine kinase domains, various oral multikinase inhibitors that are approved by the US Food and Drug Administration (FDA) or in clinical development (e.g., sorafenib, pazopanib, axitinib, regorafenib, ponatinib, cediranib, nintedanib) are able to inhibit FGFR1 in nanomolar concentrations. Several of these agents, such as dovitinib and brivanib, were in fact developed to have relatively greater selectivity for FGFR kinase than for VEGFR2. Nonetheless, hypertension is a common toxic effect of these agents, which suggests that inhibition of the VEGF pathway remains a major effect of these agents.[102–104] More selective FGFR inhibitors in early phase clinical testing include AZD4547 and BGJ398. On-target adverse effects, such as hyperphosphatemia and retinal detachment, have been reported.[105,106]

The results of the Lung Cancer Master Protocol, which includes the FGFR inhibitor AZD4547 in patients with squamous cell carcinoma of the lung, are eagerly awaited (NCT02154490).

c-Ros Oncogene 1

c-Ros oncogene 1 (ROS1) is a proto-oncogene that encodes an RTK closely related to ALK. Notably, ROS1 is expressed only transiently in the lung during murine development and is not found in healthy adult human lung tissue.[107,108] Its ligand has yet to be identified. A phosphoproteomic analysis of TK signaling demonstrated that ROS1 ranked among the top 10 RTKs activated in NSCLC.[109] Further analysis demonstrated that constitutive activation of ROS1 arose from the presence of SLC34A2–ROS1 fusion in an NSCLC cell line. Multiple other fusion partners have since been reported in NSCLC, such as CD74–, TPM3–, SDC4–, EZR–, LRIG3–, KDELR2–, CCDC6–, and FIG–ROS1.[110] The transforming potential of many of these fusions has been well established. Although localization to the Golgi apparatus of the FIG–ROS1 fusion appears to be crucial for its transforming ability, no discernible pattern of distribution has been found for the other variants.[110] ALK inhibitors have demonstrated preclinical and clinical activity against ROS1-rearranged NSCLCs.[111] This is not surprising

given the close homology between ALK and ROS1. However, unlike FGFR, ALK, and RET fusions, in which the mechanism of constitutive kinase activation is attributed to the dimerization domain of the partner protein, the mechanism of activation of most ROS1 fusion proteins remains unclear because most partner proteins lack the dimerization domains.

In an unselected population of patients with NSCLC, the frequency of ROS1 rearrangement is 0.9% to 1.7%, with most cases found in adenocarcinomas.[110] This prevalence can increase to approximately 6% of EGFR/KRAS/ALK wild-type lung adenocarcinomas in East Asian never-smokers.[111,112] For patients who have lung cancer with ROS1 rearrangement, the objective response rate to pemetrexed appears to be higher and the median progression-free survival longer than in lung cancer patients without the ROS1 or ALK rearrangement.[112] One mechanism of acquired resistance to crizotinib is the acquisition of a secondary mutation in the ROS1 kinase domain that interfered with drug binding in a patient with CD74–ROS1 rearrangement.[113] Cabozantinib is one agent that may overcome resistance mutations in this setting.[114] Aside from crizotinib, other oral agents with anticipated or demonstrated activity against oncogenic ROS1 fusions as well as crizotinib-resistant ALK translocations in NSCLC include the selective ALK inhibitors ceritinib (LDK398), lorlatinib, the dual ALK/EGFR inhibitor brigatinib, and the ROS1/ALK/NTRK inhibitor entrectinib. Crizotinib is a more potent inhibitor than ceritinib. The expansion cohort of a phase I clinical trial with 50 patients with ROS1 mutations treated with crizotinib demonstrated a response rate of 72% with a median duration of 17.6 months.[115] A separate retrospective study of off-label use crizotinib for ROS1-rearranged NSCLC similarly reported an overall response rate of 80% with a median PFS of 9.1 months.[116] Crizotinib has since been approved by the US FDA for the treatment of ROS-1 rearranged NSCLC.

Rearranged During Transfection–RET

The primary mechanism of RET activation in NSCLC occurs through chromosomal rearrangements. Various oncogenic RET fusions have been described by separate investigators since the first publication in late 2011.[117] Fusion partners reported include KIF5B, CCDC6, TRIM33, and NCOA4, all of which contain coiled–coil domains that have oligomerization potential to induce constitutive TK activation.[118] Functional studies indicate that these RET fusions have oncogenic potential.[119]

RET rearrangements, similar to ROS1 and ALK, are observed primarily in lung adenocarcinomas from never-smokers and are also associated with poorly differentiated tumors.[120] Although the overall prevalence is only 1% to 2% in adenocarcinomas, the prevalence can be as high as 16% among never-smokers with nonsquamous histology negative for driver mutations in other oncogenes (*EGFR*, *KRAS*, *NRAS*, *BRAF*, *HER2*, *PIK3CA*, *MEK1*, *AKT*, *ALK*, and *ROS1*).[121] Vandetanib and cabozantinib are small-molecule inhibitors of multiple kinases, including VEGFR2 and RET, that are currently approved for treatment of metastatic medullary thyroid cancer. Other FDA-approved agents that demonstrate in vitro inhibition of RET include axitinib, sunitinib, regorafenib, sorafenib, and ponatinib (which exhibits the highest potency). Preliminary findings from a phase II study of cabozantinib in patients with NSCLC and RET rearrangements demonstrated objective tumor responses in two of three patients treated.[121] Clinical activity has also been reported with vandetanib.[122] Alectinib also has potent antitumor activity against RET rearrangements, including those with gatekeeper mutations (V804L and V804M).[123] In fact, in one report two of four patients responded to alectinib after failure of other RET inhibitors.[124] Mechanisms of acquired resistance are yet to be

established in the clinical setting. Preclinical modeling predicted the emergence of the gatekeeper V804L/M mutation, which is resistant to vandetanib but remained sensitive to ponatinib.[125,126]

Discoidin Domain Receptors

The members of the discoidin domain family of receptors, DDR1 and DDR2, are unusual RTKs that have as their ligand different types of collagen rather than a typical growth factor.[127] Both DDRs are activated by fibrillar collagens, but only DDR1 can be activated by nonfibrillar collagen.[127] DDR1 is mainly expressed in epithelial cells, whereas DDR2 is found in mesenchymal cells.[127] Novel somatic mutations in lung cancer of both DDR1 and DDR2 were first described in 2005.[128] Mutations are found in both the kinase domain and other regions. Functional characterization of *DDR2* mutations, identified in approximately 3% to 4% of squamous cell lung cancers,[129] later established their oncogenic potential.[130]

DDR2-transformed cells appear to require the coordinated activity of both DDR2 and the Src family of kinases for maximal proliferation, which explains their exquisite sensitivity to dasatinib, a dual Src and DDR2 inhibitor, compared with either a DDR2- or Src kinase-specific inhibitor as a single agent.[130] Of the commercially available kinase inhibitors, dasatinib has the most potent activity against DDR2 (Kd value 5.4 nM) compared with other kinase inhibitors such as ponatinib (9 nM), imatinib (71 nM), nilotinib (35–55 nM), sorafenib (55 nM), and pazopanib (474 nM).[130–132] Clinical responses to dasatinib among patients with DDR2 mutation have been reported.[130,133] However, its therapeutic index is narrow because of its multiple off-target effects, particularly pleural effusion, and thus DDR2-selective agents are needed.

Tyrosine-Protein Kinase Receptor UFO (AXL) and Proto-Oncogene Tyrosine-Protein Kinase (MER)

The primary ligand for AXL and MER, both members of the TAM (representing the three members: Tyro-3, Axl, and Mer) receptor family of RTKs, is the vitamin K–dependent ligand growth arrest-specific protein 6 (Gas6).[134,135] Ligand binding induces dimerization that results in stimulation of proliferative and antiapoptotic signaling through the MAPK/ERK and PI3K/AKT pathways.[134,135] AXL is ubiquitously expressed, whereas MER is expressed in hematopoietic-derived cells, epithelium, and reproductive tissues.[135] Both are involved in regulation of the actin cytoskeleton and tumor cell migration and invasion. They exhibit transforming potential and have complementary roles in promoting tumor cell survival and resistance to chemotherapy in NSCLC.[134] Conversely, either knockdown or pharmacologic inhibition of AXL or MER using sulfasalazine reduces growth, suppresses invasiveness, and restores sensitivity to various cytotoxic agents.[134,136]

Overexpression of AXL and MER is reported in 93% and 50% to 69% of NSCLCs, respectively.[134,135] The Gas6 ligand is also frequently expressed in NSCLC, thus providing continuous signaling through autocrine and/or paracrine mechanisms. Overexpression of AXL, which can be upregulated during activation of EMT, appears to mediate resistance to targeted therapies as well as to EGFR and HER2 TKIs.[137,138] Inhibition of AXL restores sensitivity to EGFR-TKI therapy. A potentially oncogenic AXL fusion product that carries the tyrosine kinase domain and dimerization units (AXL–MBIP) was identified by transcriptome analysis of lung adenocarcinomas.[92] Taken together, these findings highlight the therapeutic potential of targeting AXL and MER. A caveat in drug development against these targets is that both proteins have an essential function in limiting inflammation. Increased inflammation seen in knockout mice lacking both

receptors paradoxically fosters a tumor-promoting microenvironment in colitis-associated colon cancer.[139]

Tropomysin Receptor Kinase

The genes *NTRK1–3* encode the tropomyosin receptor kinase (Trk) proteins Trk A, B, and C, respectively. The Trk receptors are transmembrane proteins critical for the development of both the central and peripheral nervous systems. Rearrangements of *NTRK* genes are the most common oncogenic mutations of these genes that result in constitutive activation of fusion proteins. *NTRK* gene rearrangements have been discovered in NSCLC and other malignancies such as colorectal cancer, papillary thyroid carcinoma, glioblastoma, and human secretory breast cancer. One patient with a soft-tissue sarcoma that harbored a LMNA–NTRK1 rearrangement had a dramatic response to the TRK inhibitor LOXO-101.[140] Similarly, a patient with metastatic colorectal cancer with a LMNA–NTRK1 rearrangement experienced a partial response to the pan-TRK inhibitor entrectinib.[141] In NSCLC, MPRIP–NTRK1 and CD74–NTRK1 rearrangments were the first to be reported and were found to be oncogenic.[142] This same study suggested that *NTRK1* gene rearrangements are present in 3% to 4% of patients without other known oncogenic alterations, but this may represent fewer than 1% of all patients with NSCLC. Regardless, the responses observed in other malignancies to the TRK inhibitors in development are similarly encouraging for NSCLC.

Nonreceptor Targets

RAS

The RAS superfamily of guanosine triphosphatases (GTPases) consists of three highly related proteins: KRAS, HRAS, and NRAS. These proteins interface with a large number of effectors, including RAF and PI3K. Although they share similar properties, each isoform may have preferential signaling. For example, KRAS is more potent than HRAS in RAF activation, and the opposite is true for PI3K activation.[143,144] Mutations in NSCLC resulting in constitutive activation of RAS proteins occur predominantly at codons 12, 13, and 61 of KRAS, particularly in smoking-related adenocarcinomas, of which approximately 30% harbor these mutations. Mutant *KRAS* alleles are also often amplified at higher levels in NSCLC compared with the wild-type allele, similar to observations seen with EGFR and suggesting that the preferential amplification of the mutant copy of the gene has functional significance.[145,146]

RAC1b, an isoform of the RAC1 GTPase that includes one additional exon, is found to be preferentially upregulated in lung cancer via splice–site mutations.[147] RAC1b appears to promote KRAS-induced lung tumorigenesis, and its expression appears to be associated with sensitivity to MEK inhibition.[148] Inactivating mutations in the tumor suppressor gene *NF1* are found in approximately 7% of lung adenocarcinomas.[145] Because *NF1* suppresses the activity of GTPase-activating proteins that stimulate the catalytic activity of RAS, its inactivation mimics a hyperactivated RAS phenotype even in the absence of *RAS* mutations.

Intact signaling through the PI3K pathway, specifically the binding of RAS to PI3K, is also required for tumorigenesis in mouse models of *KRAS*-driven lung tumors.[149] Other mouse models indicate that nuclear factor-κB and cell-cycle targets such as PLK1 and cyclin-dependent kinase (CDK) signaling, particularly CDK4 are essential for proliferation of *KRAS*-mutant lung adenocarcinoma, with lethal effects seen upon pharmacologic inhibition of these implicated pathways.[150–154] Additional observations also indicated that inhibition of proteasome function and of transcription factor pathways impaired the growth and increased the apoptosis of KRAS-mutant NSCLC.[153,155] Of

interest is that GATA2 dependency is also found in other similar oncogenically driven NSCLC tumors, such as those mediated by *EGFR*, *NRAS*, *NF1*, and EML4–ALK.[155]

Data based on *KRAS*-knockdown experiments showed variable effects on cell viability among *KRAS*-mutant cell lines, with some *KRAS*-mutant cell lines appearing not to be dependent on this pathway.[156,157] The same *KRAS*-knockdown experiments showed dependency on RAS signaling in various *KRAS* wild-type cell lines.[156] Based on this finding, a *KRAS*-dependency gene expression signature was developed that was more predictive of sensitivity or resistance to targeted therapies, such as MEK inhibitors, than was *KRAS* mutation status itself.[156] Presence of the *KRAS*-dependency gene expression signature in *KRAS*-mutant cell lines is associated with a well-differentiated tumor phenotype, whereas induction of EMT results in *KRAS* independence.[157] A potentially druggable target protein identified from integrated global transcriptome, proteome, and phosphoproteome analysis of a panel of NSCLC cell lines using this *KRAS*-dependency stratification is lymphocyte-specific tyrosine kinase (LCK).[158] Indeed, *KRAS*-dependent cell lines were sensitive to LCK inhibition, whereas *KRAS*-independent cell lines were not. MET inhibition also selectively impaired the growth of *KRAS*-dependent cell lines, as predicted based on this stratification.[158]

NRAS mutations are present in less than 1% of lung cancers and have been described predominantly in adenocarcinomas.[159] These mutations appear to be more common in current or former smokers. The nucleotide transversion mutations typically associated with smoking appear to be found less frequently in *NRAS*-mutant NSCLC (13%) than in *KRAS*-mutant NSCLC (66%).[159] In vitro studies showed that, similar to *KRAS* mutants, many of the NRAS-mutant cell lines were sensitive to MEK inhibition alone. In one MEK-resistant cell line that displayed high levels of IGF-1R, combination treatment with an IGF-1R and MEK inhibitor showed a greater antiproliferative effect compared with either drug used alone. These results parallel those seen with this combination in *KRAS*-mutant NSCLC, which exhibits increased dependence on IGF-1R signaling compared with *KRAS* wild-type cells.[160]

No direct RAS inhibitors have been successfully developed in the clinic as yet. Strategies explored have mainly sought to prevent plasma membrane localization of RAS, such as with the use of farnesyl transferase inhibitors, with disappointing results.[161] More recently, disruption of the interaction with phosphodiesterase δ, which facilitates plasma membrane localization, has been proposed as a novel approach.[162] Biochemical screening identified the derivative deltarasin, which inhibited RAS signaling and suppressed proliferation of *KRAS*-mutant pancreatic cancer cell lines in vitro and in vivo.[162] Inhibition of the mTOR pathway as monotherapy demonstrates only modest activity in *KRAS*-mutant NSCLC.[163] MEK inhibitors represented a promising approach for *KRAS*-mutant NSCLC. In a randomized second-line study of *KRAS*-mutant NSCLC, the combination of docetaxel and selumetinib (a MEK inhibitor) improved progression-free survival compared with placebo plus docetaxel (5.3 months vs. 2.1 months; HR, 0.58), with objective responses seen only in the selumetinib group (37% vs. 0%).[164] Adverse events were increased in the selumetinib group, such as febrile neutropenia (18% vs. 0%) and asthenia (9% vs. 0%). Recently it was reported in a press release that the SELECT-1 phase III clinical trial that randomized 510 patients to selumetinib or placebo in combination with docetaxel failed to improve progression-free survival.[165]

v-Raf Murine Sarcoma Viral Oncogene Homolog B–BRAF

Mutations in the RAF family most commonly occur in *BRAF*, whereas mutations in *CRAF* and *ARAF* are rare, found in less than 1% of human cancers.[166,167] Among patients with NSCLC, *BRAF* mutations are found in both squamous and nonsquamous

histologies and tend to occur in smokers.[168,169] These mutations appear to promote constitutive BRAF–CRAF dimerization, resulting in RAS-independent activation of the MEK/ERK cascade.[170] Dimerization appears to be needed for downstream signaling for either wild-type or mutant *BRAF*, except for those characterized by high catalytic activity, such as the V600E and G469A mutations, wherein dimerization is not required for biologic function.[171] Oncogenic alterations in *BRAF* may also arise from chimeric fusion proteins. The SND1–BRAF fusion transcript has been described in 3% of lung adenocarcinomas among never-smokers. A few of these fusion transcripts are present concurrently in specimens with either *EGFR* or *HER2* mutations.[172]

The constitutively activated V600E mutation represents nearly 50% to 60% of the *BRAF* mutations found in NSCLC. It is associated with micropapillary features, female gender, and poor prognosis.[168,169] In contrast to RTK-activated cells, which show feedback downregulation of RAF/MEK signaling upon ERK activation (Fig. 48.1), this physiologic feedback inhibition is missing in V600E *BRAF*-mutant tumors and is accompanied by high levels of MEK kinase activity.[173,174] The efficacy of MEK inhibitors in *BRAF* V600E mutants is attributed to this dependency on MEK activity for proliferation and survival. Non-V600E mutations, such as G469A, T599_V600insT, and V600_K601delinsE, demonstrate increased kinase activity relative to wild-type *BRAF*.[175] However, other non-V600E mutations are known to be kinase-impaired or inactivating (e.g., D594, G466, G496del, and Y472). Nonetheless, ERK activation can still be achieved through heterodimerization with CRAF,[176] thus predicting resistance to selective *BRAF* inhibitors (BRAFi). These kinase-impaired *BRAF* mutations, which have weak oncogenic potential,[176] appear to be sensitive to dasatinib.[177]

Tumor responses have been reported among patients with *BRAF* V600E-mutant NSCLC treated with vemurafenib and dabrafenib.[178–180] A recently published phase II clinical trial demonstrated a 63.2% overall response rate in patients with *BRAF* V600E mutations receiving dabrafenib and trametinib in the second line.[181] Despite the clinical success of BRAFi, resistance may develop due to the emergence of *KRAS* mutations.[180] Other anticipated mechanisms of acquired resistance to BRAFi, based on models of melanoma, include emergence of activating somatic mutations in *NRAS* or *MAP2K1/MAP2K2*, bypass signaling (e.g., other RTK-mediated pathways such as FGFR), *BRAF* amplification, or alternative *BRAF* splice isoforms.[182–184] MAPK-independent mechanisms also occur, with the PI3K pathway frequently implicated.[185] In contrast to the experience with various TKIs, secondary mutations in the target oncoprotein itself (i.e., *BRAF* or *CRAF*) are yet to be described in clinical samples, although several *CRAF* mutations generated from random mutagenesis experiments have been identified that can promote *CRAF* dimerization and confer resistance to RAF inhibitors.[186] The selective advantage from the relief of RAF autoinhibition due to the presence of RAF inhibitors (RAFi) may also paradoxically foster drug dependence for growth.[187,188]

Mitogen Activated Protein Kinase Kinase–MEK

A somatic activating mutation in the nonkinase region of the kinase in exon 2 of MEK1/2 (*MAP2K1/MAP2K2*), a dual-specificity serine/threonine and tyrosine kinase, has been reported in approximately 1% of lung adenocarcinomas and renders the cells sensitive to MEK inhibitors.[189] This G to T transversion mutation is known to be related to smoking and is found in specimens from former smokers. Because MEK1/2 activation represents the penultimate step of signaling in the canonical MAPK pathway, its inhibition has potential activity against tumors dependent on MAPK signaling, regardless of *MEK* mutation status. However, despite high basal ERK phosphorylation in EGFR mutant cells, these cells are uniformly resistant to MEK inhibition because of

the feedback mechanism discussed earlier.[173,174,190] In addition, MEK inhibition induces positive feedback of PI3K/AKT signaling as well in EGFR- and HER2-driven cancers through an increase in HER3 activation.[50]

MEKi demonstrate heterogeneous effects in *KRAS*-mutant tumors, which are in part attributed to the presence of activated parallel pathways such as PI3K/AKT/mTOR in *KRAS*-driven tumors.[191] Thus, synergistic effects have been documented with the combination of MEKi and PI3K inhibitors (PI3Ki),[192] although clinical development is challenging because of the serious toxicities encountered with combination therapy.[193] Results of a preclinical study suggest that an intermittent dosing regimen is effective and may be successful in mitigating toxicity with PI3Ki and MEKi combinations.[194] The effects of MEK inhibition in *KRAS*-mutant cancer cell lines also tend to be cytostatic, and xenograft models typically show reduction in tumor growth but not tumor regression with MEK inhibition alone.[195,196] These preclinical features predict the clinical experience thus far with MEK inhibitors used as monotherapy; that is, objective tumor responses are rarely seen.[197,198] In one pooled shRNA drug-screening approach to identify synthetically lethal combinations with MEKi in *KRAS*-mutant cancer cells independent of sensitivity to MEK/PI3K inhibition, the antiapoptotic member of the BH3 family of proteins BCL-XL was identified as a promising target.[195] MEK inhibition increases levels of the proapoptotic protein BIM, which, however, is bound and inhibited by antiapoptotic proteins such as BCL-XL. Indeed, the combination of MEKi and inhibitors of BCL-XL (BCL-XLi) caused marked tumor regression in vivo in *KRAS*-mutant xenografts and in a genetically engineered mouse model of *KRAS*-driven lung cancer.[195] Nonetheless, this strategy was not universally effective. *KRAS*-mutant cells exhibiting EMT demonstrated less sensitivity to this combination. Moreover, acquired resistance ultimately emerges.[195]

Phosphoinositide 3-Kinase

Class I PI3Ks are heterodimeric proteins composed of a regulatory and a catalytic p110 subunit that has four isoforms: α, β, δ, and γ. Tissue distribution and function vary according to the isoform, with cell proliferation and growth principally regulated by p110α. Amplification or activating mutations in *PIK3CA*, which encodes the p110α catalytic subunit, have both been described in NSCLC. Amplification of *PIK3CA* and mutation of *PIK3CA* appear to be mutually exclusive.[199] Somatic gain-of-function mutations in *PIK3CA* can be found in up to 9% of squamous NSCLCs.[200] These mutations most commonly occur either in the helical domain encoded by exon 9 (E542K, E545K), and therefore interfere with binding of the p85α regulatory subunit, or in the kinase domain encoded by exon 20 (H1047R, H1047L). Somatic mutations in the gene encoding p85α, *PIK3R1*, occur in approximately 40% of endometrial carcinomas and in approximately 1% of NSCLCs.[201,202] Although several mutants described in endometrial cancer have increased AKT signaling, others show no appreciable biologic effect. The functional consequences of *PIK3R1* mutations in NSCLC are still unknown.

Loss of PTEN, the negative regulator of PI3K, results in a hyperactivated AKT phenotype.[203] Mechanisms implicated in the loss of PTEN include epigenetic silencing (e.g., promoter methylation), posttranslational modification, increased degradation, and mutations or homozygous deletions.[204] Genetic changes in PI3K (amplification or mutation) and mutation of *PTEN* appear to be more common in squamous cell carcinomas than in adenocarcinoma (9.8% vs. 1.6%, respectively), particularly within the Asian population.[205] Although both activating *PIK3CA* mutations and inactivating *PTEN* mutations augment AKT signaling in experimental systems, they do not appear to be functionally redundant in vivo because they can be found

concurrently, such as in endometrial cancers.[206] Indeed, in contrast to the *PTEN* null setting, cell lines with *PIK3CA* mutations have variable degrees of AKT phosphorylation and often show diminished AKT signaling.[206]

Despite experimental preclinical data suggesting that these mutants can be exquisitely sensitive to PI3K or AKT inhibitors, clinical experience to date suggests that the mutation status alone is not a good predictive marker for tumor response because most patients with tumors harboring either a *PIK3CA* mutation or *PTEN* loss appear to have stable disease rather than objective response when treated with these agents.[207,208] Resistance to PI3K inhibitors is unlikely to arise from mutations at the gatekeeper residue alone, as indicated by modeling experiments showing that the mutated kinase has severely reduced catalytic activity and thus cannot be viable.[209] In a large phase II trial that screened over 1200 patients for *PI3K* mutations, the 12-week progression-free survival rates in response to buparlisib (BKM120) were 23.3% and 20.0% in squamous (*n* = 30) and nonsquamous groups (*n* = 33), respectively. Since the prespecified rate of 50% was not met by either group, this trial was halted.[210] Some PI3K inhibitors still in development include the PI3Kα inhibitors BYL719 and taselisib, and the dual PI3K/mTOR inhibitors SF1126 and PQR309.

Concurrent mutations in genes of the MAPK signaling pathway are common in lung adenocarcinomas with *PIK3CA* mutations.[211] Coexisting mutations that activate MAPK signaling render cells resilient to the effects of inhibiting a single pathway because of built-in redundancy from integration of both pathways to a final common effector, such as 4EBP1 phosphorylation.[196] Combined inhibition of ERK and AKT signaling is thus necessary to suppress tumor growth in such conditions. However, parallel pathway inhibition, although potentially efficacious, may cause greater clinical toxicity as a tradeoff.[212]

Protein Kinase B–AKT

The AKT family of kinases includes three isoforms—AKT1, AKT2, and AKT3—which belong to the protein kinase B family of serine/threonine kinases. Each isoform shows relative specificity, albeit considerable overlap, in its regulation of cellular processes and tissue distribution. These activities include antiapoptosis and cell survival for the ubiquitously expressed *AKT1*; maintenance of glucose homeostasis for *AKT2* in insulin-responsive tissues including liver, adipose tissue, and skeletal muscle; and brain development for *AKT3*.[213,214] The oncogenic E17K mutation in exon 4 of the pleckstrin homology domain of *AKT1* is uncommon in NSCLC, occurs primarily in the subset with squamous histology, and is generally mutually exclusive with the presence of *PIK3CA* mutations.[215,216] This mutation is associated with increased membrane localization, which results in elevated autophosphorylation of AKT1, increased levels of cyclin D1, and reduced sensitivity to an allosteric Akt kinase inhibitor.[216,217] In contrast, amplification of either *AKT1* or *AKT2* has been reported collectively in 7% of lung cancers but coamplification of these genes has not been found.[200,213] Although the reported cases involved small cell and large cell carcinomas as well, most cases appear to involve squamous histology rather than adenocarcinoma.[200,213]

The PI3K/AKT/mTOR signaling pathway is subject to feedback regulation similar to that of other pathways. Moreover, AKT activates multiple processes besides mTOR. Indeed, inhibition of AKT results in greater than a threefold increase in RTKs, such as HER3, RET, FGFR, and IGF-1R, across several cell lines, supporting the view that activation of AKT causes feedback inhibition of RTK expression.[218] This feedback regulation/inhibition of RTK expression effect appears to be independent of mTOR activity. Induction of HER3 phosphorylation appears to be the most prominent effect of AKT inhibition, particularly in HER2-driven tumors. These findings may provide an explanation for the

modest objective responses seen to date with these agents even in patients with an activated PI3K pathway signature.[219,220]

Mammalian Target of Rapamycin

mTOR interacts with a number of proteins to form two distinct complexes: mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2).[221] mTORC2 is characterized by its association with the rapamycin-insensitive Rictor, and the interaction between Rictor and mTOR is mutually exclusive with that of Raptor, the binding partner in mTORC1. Physiologic activation of PI3K/AKT/mTOR signaling results in feedback downregulation of the pathway, with loss of expression of insulin receptor substrate-1 (IRS-1) (Fig. 48.1), which is the major substrate of IGF-1R and insulin receptors. The indolent behavior of several tumor types with an activated mTOR pathway has been ascribed to this negative feedback loop.[222] Inhibition of mTORC1 by rapamycin and its analogs paradoxically increases AKT activity through induction of IGF-1 signaling via inhibition of p70S6K-mediated IRS-1 downregulation.[223]

Unlike mTORC1, which is inhibited by rapamycin and its analogs, mTORC2 is generally insensitive to rapamycin, although prolonged treatment in several models can block mTORC2 assembly to cause its degradation.[221] Because mTORC2 plays an important role in AKT activation, this differential effect of rapamycin on the mTOR complexes also explains the phenomenon of feedback activation that probably underlies the modest responses seen in the clinic with rapalogues. This phenomenon also provided the impetus for the development of small-molecule inhibitors that can inhibit the catalytic activity of both mTORC1 and mTORC2 to avoid or mitigate the feedback AKT activation. In addition, a consequence of mTOR inhibition is feedback activation of RTKs as well as activation of ERK signaling through loss of p70S6K-mediated inhibition of PI3K.[218,222] These findings provide further evidence supporting the development of dual PI3K/mTOR inhibitors as well as the combination of MAPK and PI3K/AKT/mTOR pathway inhibitors described previously.

LKB1/STK11 is a serine/threonine kinase whose major phosphorylation target, AMP-activated protein kinase (AMPK), upon activation regulates various targets, including the TSC2 gene product tuberin, resulting in mTOR suppression.[224] LKB1/STK11 also phosphorylates related AMPK subfamily members (e.g., BRSK, MARK, NUAK), which have additional functions including regulation of cell polarity and cytoskeletal organization.[225] *LKB1/STK11* is the second most commonly mutated tumor suppressor after *p53* found in NSCLCs, particularly in adenocarcinomas, accounting for 20% to 30% of cases in the Western hemisphere.[145,205] Most *LKB1* mutations in lung tumors result in the generation of truncated and inactive LKB1 proteins.[226,227] *LKB1*-deficient cells exhibit aberrant upregulation of mTOR signaling with an attenuated AKT activation phenotype (similar to TSC2-deficient models) because of the previously mentioned negative feedback phenomenon in PI3K/AKT/mTOR signaling.[224,228] However, *LKB1*-deficient cells are paradoxically hypersensitive to apoptosis, relative to wild-type cells, during conditions of low-nutrient energy stress (e.g., glucose deprivation) or exposure to AMPK agonists (e.g., AICAR) because of an inability to restore metabolic homeostasis.[229] *LKB1*-deficient cells also exhibit alterations in dTTP metabolism and are sensitized to DNA damage and disruption of intracellular dTTP synthesis compared with *LKB1* wild-type cells; this finding suggests that deoxythymidylate kinase is a putative synthetic lethal target.[230]

Inactivating mutations of *LKB1* appear to be more frequent in patients with a history of smoking, and the higher frequency of these mutations among white compared with Asian populations is thought to be due in part to the higher prevalence of smokers in the West.[231] *LKB1* mutations often occur concurrently

with *KRAS* mutations (up to 20% of *KRAS* mutants) or *BRAF* mutations (up to 25% of *BRAF* mutants, particularly non-V600 types).[231,232] Expression of the glucose transporter GLUT1 is elevated in *LKB1* mutant tumors, which results in increased glycolysis and the clinical observation of increased avidity on fluorodeoxyglucose-positron emission tomography scanning.[233]

In a meta-analysis of published data on individual and coincident mutations in NSCLC, *LKB1/KRAS* double mutants were found in approximately 5% of adenocarcinomas in the western world and thus represent a distinct subset of NSCLC with epidemiologic and therapeutic relevance.[205] The degree of activation of the MAPK pathway in the *LKB1/KRAS* double mutants in vivo appeared to be decreased compared with *KRAS* mutants with wild-type *LKB1* status, and signaling was shown to occur primarily through the AKT, FAK, and SRC pathways.[233,234] That the signaling circuitry is shunted away from MAPK in *KRAS* and *BRAF* mutants when *LKB1* is inactivated explains why preclinical models of *LKB1/KRAS* double mutants were resistant to the combination of docetaxel and the MEK inhibitor selumetinib, which otherwise showed synergism in *KRAS* mutants with wild-type *LKB1*. It has been reported that dual *LKB1/KRAS* mutants exhibited a vigorous apoptotic response to phenformin, a mitochondrial inhibitor as an analog of metformin, regardless of the presence of other additional unique mutations (e.g., P53 loss or *PIK3CA* mutation).[235] However, efficacy is not sustained beyond 4 weeks, which suggests that the emergence of resistance and/or cellular adaptation will render monotherapy ineffective.

Heat Shock Protein 90

Heat shock protein 90 (HSP90) is one of the most abundant cellular proteins even under nonstress conditions, and at baseline it constitutes 1% to 2% of the total cellular protein content. HSP90 is named after its characteristic upregulation in response to temperature stress (to 4% to 6% of the total cellular protein content) as well as its molecular weight of about 90 kd.[236,237] This housekeeping protein is an evolutionarily conserved, specialized molecular chaperone with an intrinsic ATPase activity that, along with the assistance of various cochaperones such as the kinase-specific cochaperone Cdc37, ensures the proper folding of nascent polypeptides and the proper assembly of multimeric proteins to prevent aggregation of immature proteins.[238] HSP90 stabilizes and activates more than 200 client proteins, which fall into three main categories: protein kinases (including various mutant oncoproteins discussed previously), steroid hormone receptors, and proteins not involved in signal transduction, such as the transcription factor hypoxia-inducible factor-1alpha.[237,239] Research suggests some functional selectivity of HSP90 toward regulating most tyrosine kinases and tyrosine-like kinases, in contrast to other protein kinase families wherein nonclient proteins may be found in higher proportions.[240] In addition, members of the PI3K/AKT pathway are subject to regulation by HSP90 throughout the pathway, in contrast to the MAPK pathway (i.e., ERK is not a client protein).[240] Conversely, HSP90 itself is subject to posttranslational modification from client protein kinases such as BRAF and WEE1; this phenomenon is thought to represent a positive feedback loop ensuring chaperone function.[241]

HSP90 is often overexpressed in cancer cells;[242] their reliance on this protein stems from the fact that mutant oncoproteins are often less stable and that additional cellular stresses are often incurred to maintain the malignant phenotype.[236] Inhibition of HSP90 can preferentially affect the mutant oncoproteins compared with their wild-type forms, such as EGFR, HER2, and BRAF, particularly since in some cases, the wild-type form (such as EGFR) may not be a client protein itself and is resistant to degradation induced by the HSP90 inhibitor.[243–245] This

differential protein stability and reliance on HSP90 function of mutant oncoproteins in NSCLC provides a rationale for investigating the role of HSP90 inhibition in this disease, particularly in combination approaches to overcome or prevent the oncogenic switch that is often seen as a mechanism of acquired resistance to kinase inhibitors used in the clinic. Moreover, inhibition of HSP90 has activity against tumor cells with gatekeeper or multiple other secondary mutations mediating acquired resistance to various kinase inhibitors.[246] HSP90 inhibitor monotherapy, such as with AUY992 or retaspimycin, has shown clinical activity in patients with ALK gene rearrangement, including patients with acquired resistance to crizotinib.[246,247]

Intrinsic resistance to HSP90 inhibitors may occur when specific mutant oncoproteins are innately not sensitive to these agents.[243] Various tumor suppressors are also subject to HSP90 regulation, and their inhibition may adversely spur the proliferation of clones harboring low-penetrant tumor suppressors.[248] WEE1 phosphorylation of HSP90 positively affects HSP90 function, but negatively affects binding of HSP90 inhibitors.[249] Pharmacologic inhibition of WEE1 sensitizes cancer cells to HSP90 inhibitors and thus provides a rationale for this combination. One mechanism of acquired resistance to HSP90 inhibition may arise through feedback activation of the heat shock transcription factor HSF1, a predictable response to currently available HSP90 inhibitors, which results in the induction of other heat shock proteins such as HSP70, HSP27, and HSP90 itself.[250] Lastly, an in vitro model showed that acquired resistance may arise by mutations that increase ATPase activity of HSP90.[251]

HSP90 as a drug target had eluded successful clinical development, largely because of issues regarding drug formulation, toxicities, and modest clinical responses seen with early-generation compounds, such as geldanamycin and its derivatives (17AAG/tanespimycin, 17-DMAG/alvespimycin).[252] The hepatotoxic effects were thought to be related to the nucleophilic reactions arising from the quinone component in the geldanamycin chemotype.[253] Next-generation compounds such as ganetespib, with different structural backbones, were thus developed. A randomized phase II study of docetaxel with or without ganetespib in patients with advanced lung adenocarcinoma showed improved overall survival among patients who received the drug combination, regardless of *EGFR* or *KRAS* mutation status. The incidence of febrile neutropenia was higher in the combination group, but no treatment-related deaths were seen.[254] The phase III trial of this combination in the treatment of patients with adenocarcinoma of the lung in the second line was terminated early for futility.[255]

Cyclin-Dependent Kinase

Cyclin-dependent kinases (CDKs) are serine/threonine kinases that, along with their associated cyclins, mediate cell cycle progression and transcription events. According to the classic model, CDK4 or CDK6 and D-type cyclins regulate events in the early G1 phase of the cycle; CDK2–cyclin E triggers the S phase; CDK2 or CDK1–cyclin A regulates the completion of the S phase; and CDK1–cyclin B is responsible for mitosis.[256–258] Although recurrent mutations of CDKs are rare, gene amplification or protein overexpression of the cyclin partners such as cyclin D1 is frequently encountered in various malignancies, including lung cancer.[259] In turn, the tumor suppressor that negatively regulates the cyclin D1–CDK4 complex, *p16INK4*, is often inactivated in lung cancer, most commonly by homozygous deletion, followed by promoter-region methylation, and rarely by point mutations.[260,261] Cyclin D-dependent kinases (CDK4 and CDK6) phosphorylate retinoblastoma, thereby inhibiting its growth-repressive effects that occur during its hypophosphorylated state.[262] Thus, cells

with endogenous expression of functional p16 or mutant retinoblastoma are thought to be mechanistically insensitive to CDK4/6 inhibitors.

Although early-generation pan-CDK inhibitors failed in clinical development because of toxicity, dramatic clinical results and a favorable toxicity profile have been reported in breast cancer using the small-molecule CDK4/6 inhibitor palbociclib (PD0332991), was approved by the US FDA in combination with letrozole for first-line treatment of estrogen receptor positive, HER2-negative advanced breast cancer.[263] These results have renewed interest in this class of agents. As discussed earlier, CDK signaling, particularly of CDK4, appears to be essential for proliferation of *KRAS*-mutant lung adenocarcinoma.[154] Inhibition of CDK4/6 also appears to be synergistic with trastuzumab in *HER2*-amplified breast cancer cell lines, suggesting the potential for similar activity in NSCLC cells with activated HER2 signaling.[264] A single-arm phase II study of palbociclib in patients with previously treated NSCLC with wild-type retinoblastoma and inactive p16 was closed to accrual after no responses were observed in 16 evaluable patients.[265] The Lung Cancer Master Protocol for patients with squamous cell carcinoma of the lung includes an arm with palbociclib.

CONCLUSION

Advances in our understanding of lung cancer biology and improvements in technology, especially genomic studies, have led to the identification of recurrent functional oncogenic events that represent potential targets for therapy. A large proportion of these genomic alterations are not considered directly druggable targets, such as mutant p53 or amplified SOX2. Nonetheless, this obstacle may be surmounted by identifying synthetically lethal changes amenable to drug therapy. Understanding of both forward signaling and feedback loops in physiologic as well as aberrant activation of oncogenic pathways facilitates the development of novel compounds and aids in the choice of drug combinations for clinical development. A multipronged approach entails the incorporation of immunotherapeutic and epigenetic approaches in future studies. Moreover, although tumor responses to certain targeted therapies in NSCLC can be dramatic, clinical benefit is always limited by the emergence of drug resistance, which commonly occurs through either secondary mutations in the drug target or activation of bypass alternative pathways. Other models of resistance, such as the counterintuitive phenomenon of tumor regression upon drug cessation because of acquired drug dependence for continued proliferation, provide a rationale for testing intermittent treatment strategies rather than the conventional approach of continuous dosing. The intermittent approach may also be necessary to mitigate toxicities incurred in the clinical setting, such as with PI3Ki and MEKi combinations, particularly when preclinical studies support this approach.

Targeted therapy requires simultaneous development of the targeted agent along with biomarker assay platforms for patient selection to optimize therapeutic benefit. Pertinent issues regarding standardization of assays and rigorous validation of biomarkers should be considered. Moreover, intratumor heterogeneity can contribute to suboptimal treatment outcomes even in the selected population. Coincident mutations also abrogate the therapeutic efficacy of monotherapy approaches, and these tumor subsets should be considered separately in prospective studies, although this approach inevitably introduces complexity and logistic challenges to the design and analysis of therapeutic trials. A thorough understanding of the spectrum of drug activity and characterization of pharmacologic activity, particularly of small-molecule inhibitors, is necessary to avoid misinterpretation of clinical trial data, particularly when an anticipated clinical benefit is not found.
