IASLC Thoracic Oncology

SECOND EDITION

Executive Editor:

Harvey I. Pass, MD

Stephen E. Banner Professor of Thoracic Oncology
Vice Chairman of Research
Department of Cardiothoracic Surgery
New York University Langone Medical Center
New York, New York

Editors:

David Ball, MD, FRANZCR

Director
Lung Cancer Stream
Victorian Comprehensive Cancer Centre
Parkville Professional Fellow
The Sir Peter MacCallum Department of Oncology
The University of Melbourne
Melbourne, Australia

Giorgio V. Scagliotti, MD, PhD

Professor of Medical Oncology
Head of Department of Oncology at San Luigi Hospital
University of Turin
Orbassano, Turin, Italy

Deborah Whippen
Managing Editor
Editorial Rx, Inc.

ELSEVIER

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Division of Pulmonary Allergy and
    Critical Care Medicine
University of Alabama at Birmingham
Birmingham, Alabama, USA

Raffit Hassan, MD
Senior Investigator
National Cancer Institute
National Institutes of Health
Bethesda, Maryland, USA

Christopher Hazzard, MD
Department of Thoracic Surgery
Icahn School of Medicine at Mount Sinai
New York, New York, USA

Fiona Hegi, MBBS, FRANZCR
Radiation Oncologist
Radiation Physics Laboratory
The University of Sydney
Sydney, Australia

Thomas Hensing, MD
Clinical Associate Professor
University of Chicago
NorthShore University HealthSystem
Kellogg Cancer Center
Evanston, Illinois, USA

Roy Herbst, MD, PhD
Ensign Professor of Medicine (Medical
    Oncology) and Professor of
    Pharmacology
Chief of Medical Oncology
Yale Cancer Center and Smilow Cancer
    Hospital
New Haven, Connecticut, USA

Fred R. Hirsch, MD, PhD
Professor
Professor of Medicine and Pathology
Department of Medicine
Department of Pathology
University of Colorado Cancer Center
Aurora, Colorado, USA

Nanda Horeweg, MD
Junior Researcher
Erasmus University Medical Center
Department of Public Health
Department of Pulmonary Diseases
Erasmus University Medical Center
Rotterdam, The Netherlands

David M. Jablons, MD
Professor and Chief Thoracic Surgery
UCSF Department of Surgery
Nan T. McEvoy Distinguished Professor
    of Thoracic Surgical Oncology
Ada Distinguished Professor of Thoracic
    Oncology
Program Leader Thoracic Oncology
UCSF Helen Diller Family
    Comprehensive Cancer Center
San Francisco, California, USA

James R. Jett, MD
Professor Emeritus
Department of Medicine
Division of Oncology
Cancer Center
National Jewish Medical Center
Denver, Colorado, USA

Andrew Kaufman, MD
Assistant Professor
Department of Thoracic Surgery
Mount Sinai Medical Center
New York, New York, USA

Paul Keall, PhD
Professor
Radiation Physics
The University of Sydney
Sydney, Australia

Karen Kelly, MD
Professor
Division of Hematology and Oncology
UC Davis Comprehensive Cancer Center
Sacramento, California, USA

Feng-Ming (Spring) Kong, MD, PhD
Professor of Radiation Oncology and
    Medical and Molecular Genetics
Director of Clinical Research/Clinical
    Trials
Radiation Oncology
Co-Leader of Thoracic Oncology
    Program
IU Simon Cancer Center
Indiana University School of Medicine
Indianapolis, Indiana, USA

Kaoru Kubota, MD
Department of Pulmonary Medicine and
    Oncology
Graduate School of Medicine
Nippon Medical School
Tokyo, Japan

Ite A. Laird-Offringa, PhD
Associate Professor
Department of Surgery
Department of Biochemistry and
    Molecular Biology
USC/Norris Cancer Center
Keck School of Medicine of USC
Los Angeles, California, USA

Primo N. Lara, Jr, MD
Professor of Medicine
University of California, Davis
School of Medicine
Acting Director
UC Davis Comprehensive Cancer Center
Sacramento, California, USA

Janessa Laskin, MD, FRCPC
Associate Professor
Department of Medicine
Division of Medical Oncology
British Columbia Cancer Agency
Vancouver, British Columbia, Canada

Quynh-Thu Le, MD, FACR, FASTRO
Professor and Chair
Department of Radiation Oncology
Stanford University
Stanford, California, USA

Cécile Le Péchoux, MD
Gustave Roussy, Hopital Universitaire
Radiation Oncology Department
Villejuif, France

Elvira L. Liclican, PhD
Scientific Officer
UCLA Clinical and Translational
    Science Institute
Los Angeles, California, USA

Yolande Lievens, MD, PhD
Associate Professor
Radiation Oncology Department
Ghent University Hospital
Ghent University
Ghent, Belgium

Chia-Chi (Josh) Lin, MD, PhD
Clinical Associate Professor
Department of Oncology
National Taiwan University Hospital
Taipei, Taiwan

Billy W. Loo, Jr., MD, PhD
Associate Professor
Radiation Oncology – Radiation Therapy
Stanford Cancer Institute
Stanford University
Stanford, California, USA

**Michael Mac Manus, MB, BCh, BAO,
MD, MRCP, FRANZCR**
Professor
The Sir Peter MacCallum Department of
    Oncology
Peter MacCallum Cancer Centre
The University of Melbourne
Melbourne, Australia

Homer A. Macapinlac, MD
Professor
Department of Nuclear Medicine
Division of Diagnostic Imaging
The University of Texas MD Anderson
    Cancer Center
Houston, Texas, USA

Nicholas Pastis, MD, FCCP
Associate Professor of Medicine
Fellowship Program Director
Division of Pulmonary and Critical Care
Medical University of South Carolina
Charleston, South Carolina, USA

Luis Paz-Ares, MD, PhD
Head of Medical Oncology Department
University Hospital Doce de Octubre
Professor
Complutense University, Medicine
    Campus
Madrid, Spain

Nathan Pennell, MD, PhD
Associate Professor
Department of Hematology and Medical
    Oncology
Cleveland Clinic Taussig Cancer
    Institute
Cleveland, Ohio, USA

Maurice Perol
Centre Leon Berard
Department of Medical Oncology
Lyon, France

Rathi N. Pillai, MD
Assistant Professor
Department of Hematology and
    Oncology
Winship Cancer Institute
Emory University
Atlanta, Georgia, USA

Pieter E. Postmus, MD
Professor of Thoracic Oncology
Clatterbridge Cancer Centre
Liverpool Heart and Chest Hospital
University of Liverpool, United Kingdom

Suresh S. Ramalingham, MD
Professor of Hematology and Medical
    Oncology
Roberto C. Goizueta Chair for Cancer
    Research
Deputy Director
Winship Cancer Institute
Emory University School of Medicine
Atlanta, Georgia, USA

Sara Ramella, MD
Associate Professor
Radiation Oncology Department
Campus Bio-Medico University
Rome, Italy

Ramón Rami-Porta, MD, PhD, FETCS
Attending Thoracic Surgeon
Department of Thoracic Surgery
Hospital Universitari Mutua Terrassa
University of Barcelona and CIBERES
    Lung Cancer Group
Terrassa, Barcelona, Spain

Martin Reck, MD, PhD
Professor
Department of Thoracic Oncology and
    Department of Clinical Trials
Lungen Clinic Grosshansdorf
Grosshansdorf, Germany

Mary W. Redman, PhD
Associate Member
Clinical Biostatistics
Clinical Research Division
Lead Statistician
SWOG Lung Committee
Fred Hutchinson Cancer Research Center
Seattle, Washington, USA

Niels Reinmuth, MD, PhD
Professor
Department of Thoracic Oncology
Lungen Clinic Grosshansdorf
Member of German Center for Lung
    Research (DZL)
Grosshansdorf, Germany

Umberto Ricardi, MD
Full Professor Radiation Oncology
Department of Oncology
University of Turin
Turin, Italy

David Rice, MD
Professor
Department of Thoracic and
    Cardiovascular Surgery
The University of Texas MD Anderson
    Cancer Center
Houston, Texas, USA

Carole A. Ridge, FFRRCSI
Consultant Radiologist
Department of Radiology
Mater Misericordiae University Hospital
Dublin, Ireland

William N. Rom, MD, MPH
Professor
Division of Pulmonary, Critical Care,
    and Sleep Medicine
Department of Medicine
Department of Environmental Medicine
New York University School of Medicine
New York University College of Global
    Public Health
New York, New York, USA

Kenneth E. Rosenzweig, MD, FASTRO, FACR
Professor and Chairman
Department of Radiation Oncology
Icahn School of Medicine at Mount Sinai
New York, New York, USA

Enrico Ruffini, MD
Associate Professor
Section of Thoracic Surgery
Department of Surgery
University of Turin
Turin, Italy

Valerie W. Rusch, MD, FACS
Attending Surgeon
Thoracic Service
Vice Chair
Clinical Research
Department of Surgery
Miner Family Chair in Intrathoracic
    Cancers
Memorial Sloan Kettering Cancer Center
New York, New York, USA

Ravi Salgia, MD, PhD
Professor and Chair
Associate Director for Clinical Sciences
Department of Medical Oncology and
    Therapeutics Research
City of Hope Comprehensive Cancer
    Center
Duarte, California, USA

Montse Sanchez-Cespedes, PhD
Head of the Genes and Cancer
    Laboratory
Cancer Epigenetics and Biology Program
Bellvitge Biomedical Research Institute-
    IDIBELL
Hospital Duran i Reynals
Barcelona, Spain

Anjali Saqi, MD, MBA
Professor
Department of Pathology and Cell
    Biology
Columbia University Medical Center
New York, New York, USA

Giorgio V. Scagliotti, MD, PhD
Professor of Medical Oncology
Head of Department of Oncology at
    San Luigi Hospital
University of Turin
Orbassano, Turin, Italy

Selma Schimmel[†]
Founder
Vital Options International, Inc
Studio City, California, USA

Ann G. Schwartz, PhD, MPH
Deputy Center Director and Professor
Department of Oncology
Karmanos Cancer Institute
Wayne State University
Detroit, Michigan, USA

Suresh Senan, MRCP, FRCR, PhD
Professor of Clinical Experimental
    Radiotherapy
Department of Radiation Oncology
VU University Medical Center
Amsterdam, The Netherlands

Professor of Medicine
University of Toronto
Scott Taylor Chair in Lung Cancer
    Research
Department of Medical Oncology and
    Hematology
University Health Network
Princess Margaret Cancer Centre
Toronto, Ontario, Canada

Jill M. Siegfried, PhD
Professor and Head
Department of Pharmacology
Frederick and Alice Stark Endowed Chair
Associate Director for Translation
Masonic Cancer Center
University of Minnesota
Minneapolis, Minnesota, USA

Gerard A. Silvestri, MD, MS, FCCP
Professor
Vice Chair of Medicine for Faculty
    Development
Division of Pulmonary and Critical Care
Medical University of South Carolina
Charleston, South Carolina, USA

George R. Simon, MD
Professor
Department of Thoracic/Head and Neck
    Medical Oncology
The University of Texas MD Anderson
    Cancer Center
Houston, Texas, USA

Egbert F. Smit, MD, PhD
Professor
Department of Pulmonary Diseases
Vrije Universiteit VU Medical Centre
    and Department of Thoracic Oncology
Netherlands Cancer Institute
Amsterdam, The Netherlands

Stephen B. Solomon, MD
Chief
Interventional Radiology Service
Department of Radiology
Memorial Sloan Kettering Cancer Center
New York, New York, USA

Laura P. Stabile, PhD
Research Associate Professor
Department of Pharmacology and
    Chemical Biology
University of Pittsburgh
Pittsburgh, Pennsylvania, USA

Matthew A. Steliga, MD
Associate Professor of Surgery
Division of Cardiothoracic Surgery
University of Arkansas for Medical
    Sciences
Little Rock, Arkansas, USA

Thomas E. Stinchcombe, MD
Duke Cancer Institute
Durham, North Carolina, USA

Nicholas S. Stollenwerk, MD
Associate Clinical Professor
UC Davis Comprehensive Cancer Center
VA Northern California Health Care
    System
Sacramento, California, USA

Jong-Mu Sun, MD, PhD
Clinical Assistant Professor
Division of Hematology/Oncology
Samsung Medical Center
Sungkyunkwan University School of
    Medicine
Seoul, Korea

Anish Thomas, MD
Developmental Therapeutics Branch
National Cancer Institute
National Institutes of Health
Bethesda, Maryland, USA

Ming-Sound Tsao, MD, FRCPC
Professor
Department of Laboratory Medicine and
    Pathobiology
Department of Medical Biophysics
University of Toronto
Consultant Pathologist
University Health Network
Princess Margaret Cancer Centre
Toronto, Ontario, Canada

Jun-Chieh J. Tsay, MD, MSc
Assistant Professor
Division of Pulmonary, Critical Care,
    and Sleep Medicine
Department of Medicine
New York University School of Medicine
New York, New York, USA

Paul Van Houtte, MD, PhD
Professor Emeritus
Department of Radiation Oncology
Institut Jules Bordet
Université Libre Bruxelles
Brussels, Belgium

Paul E. Van Schil, MD, PhD
Chair
Department of Thoracic and Vascular
    Surgery
Antwerp University Hospital
Edegem, Belgium

Nico van Zandwijk, MD, PhD, FRACP
Professor University of Sydney
Director Asbestos Diseases Research
    Institute
Rhodes, Australia

J. F. Vansteenkiste, MD, PhD
Professor Internal Medicine
Respiratory Oncology Unit (Department
    of Respiratory Medicine)
University Hospital KU Leuven
Leuven, Belgium

Marileila Varella-Garcia, PhD
Professor
Department of Medicine
Division of Medical Oncology
University of Colorado Anschutz Medical
    Campus
Aurora, Colorado, USA

Giulia Veronesi, MD
Division of Thoracic Surgery
Director of Robotic Thoracic Surgery
Humanitas Research Hospital
Rozzano, Italy

Shalini K. Vinod, MBBS, MD, FRANZCR
Associate Professor
Cancer Therapy Centre
Liverpool Hospital
Sydney, Australia

Everett E. Vokes, MD
John E. Ultmann Professor
Chairman
Department of Medicine
Physician-in-Chief
University of Chicago Medicine and
    Biologic Sciences
Chicago, Illinois, USA

[†] Deceased.

Heather Wakelee, MD
Associate Professor of Medicine
Division of Oncology
Stanford Cancer Institute
Stanford, California, USA

Tonya C. Walser, PhD
Assistant Professor
Division of Pulmonary and Critical Care
  Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California, USA

Shun-ichi Watanabe, MD
Department of Thoracic Surgery
National Cancer Center Hospital
Tokyo, Japan

Walter Weder, MD
Professor
Department of Thoracic Surgery
University Hospital
Zurich, Switzerland

Benjamin Wei, MD
Assistant Professor
Section of Thoracic Surgery
Division of Cardiothoracic Surgery
Department of Surgery
University of Alabama-Birmingham

Preface

Reference texts for the management of cancer are only as good as their information, and the information must be relevant to clinical practice and must be current. Moreover, lung cancer and other thoracic malignancies remain an international problem. Lung cancer is not only the greatest cause of cancer death but also a major cause of disability and suffering.

For the past 40 years the **International Association for the Study of Lung Cancer** has remained the only society totally dedicated to the study and treatment of lung cancer and other thoracic malignancies. These cancers are notoriously complicated, as was recently pointed out by their mutational burdens and histologic heterogeneity. New discoveries, novel trials, and changes in the standard of care are happening at an extraordinary rate, and medical, surgical, and radiation oncologists, as well as respiratory physicians, nurses, physician's assistants, and social workers, need reliable and up-to-date sources of information filtered by experts in the field. The IASLC represents international and multidisciplinary expertise at every level: basic science, epidemiology, respiratory medicine, medical and radiation oncology, surgery, and palliative care, as well as nursing and advocacy. The IASLC, however, has recognized that this expertise must be channeled toward a mission of education. At the foundational level of education is a reference text that is thorough, timely, and readily available to all practitioners who are confronted with patients with thoracic malignancy.

That is why the organization published the first edition of *The IASLC Multidisciplinary Approach to Thoracic Oncology* in 2014 with the hope that this would be the first step in consolidating this information in one comprehensive source. The plan was always to be able to update, amend, and incorporate new ideas in later editions so that the basics were retained but new discoveries were discussed by the "discoverers" themselves. That is the reason why we now have a new edition of the reference text, *IASLC Thoracic Oncology*. However, we never imagined the explosion of information that would happen over a 2-year period that would need to be presented to the reader. The genomic phenotyping of lung cancer has expanded remarkably, necessitating the discovery and validation with new trials of third-generation targeted agents. The staging system for the disease has been modified and externally validated. Histologic classification of the disease has helped to define high-risk patients in early-stage disease. Radiation techniques are being expanded with greater implementation in oligometastatic disease as well as for early-stage patients, and, most dramatically, immunotherapeutic strategies, not limited solely to check point inhibition, now dominate many of the novel trials for metastatic disease as well as for neoadjuvant and adjuvant therapy.

Can you cover everything and be "au courant" with a textbook? It's a formidable task; however, the editors, along with our previous dedicated group of chapter writers, have been extraordinarily fortunate to add new experts and the most recent data from meetings in the fourth-quarter of 2016. The textbook remains a "work in progress" with online capabilities, which the IASLC and its publishing partner, Elsevier, hope to use to get information to the "treaters" in the future as early as "real time." Future updates available for selected chapters online will give readers access to the latest news as well as innovations for many of the disciplines. Just as the IASLC has matured and is growing, it is hoped that these chapters will mature so that the reader will alter his or her practice quickly due to a more rapid delivery of timely evidence-based information.

But for now, this second edition, which represents updated material for more than 50 percent of the book, will help manage the wealth of new data so that the word gets out in a comprehensive multispecialty coordinated fashion. Novel findings are presented "hot off the press" in a way that academics and nonacademics alike can keep up with thoracic cancer diagnostics and therapeutics so that the ultimate beneficiary is the patient. This endeavor calls for one international society and one book or information source that is born and keeps on growing, just like the society

As with the first edition, there is absolutely no way that this project would have been completed essentially in less than 2 years without our managing editor, Deborah Whippen. Deb has always been the binding glue for this book, as well as every single IASLC publication, and without her, every page would have scattered to the wind. Physicians are notoriously unorganized, and physician editors fall right into that category. Therefore the momentum for getting this task accomplished, from keeping updates about the status of the chapters to copyediting to indexing to even organizing what the cover would look like, fell to Deb and her cadre of book-producing experts at Elsevier including Taylor Ball and Sharon Corell. We are the luckiest editors in the world to be able to work with and listen to these dedicated manuscript aficionados.

The editors are also indebted to the Board of the IASLC for allowing us to expand this portion of the IASLC educational portfolio. Although the IASLC has been extraordinarily successful with conferences, webinars, consensus meetings, and publications, including the *IASLC Staging Manual in Thoracic Oncology* and the *IASLC Atlas of ALK and ROS1 Testing in Lung Cancer,* the updating of this 62-chapter textbook has proceeded on schedule for many reasons. We felt that our authors are dedicated to the mission, and this devotion is very different from the usual heartaches that come with editing a book. The commitment of the authors to write the most informative chapters was obvious from the beginning to the end of the task.

IASLC Thoracic Oncology is meant to provide both the practitioner and the fellow with an updated reference source that will be useful in dealing with lung cancer. It is also meant to further unify the international community through recognition that wars are won by forming allies, and in the battle against lung and other thoracic cancers, the IASLC stands for such an alliance. The battle is not only fought in the clinics and the hospitals but also on the educational front in order to supply the troops with successful plans for therapy. The editors' most profound wish is that the knowledge available in the book and all of its associated future ventures will help to move the survival curves upward and toward the right.

1   Classic Epidemiology of Lung Cancer

Paolo Boffetta

SUMMARY OF KEY POINTS

- Lung cancer incidence and mortality has declined among men in many countries, following a decline in the prevalence and level of smoking. Among women, lung cancer incidence and mortality is still increasing in many countries and has become the main cause of cancer death.
- Despite important advances in lung cancer screening, primary prevention through tobacco control remains the main approach in the fight against lung cancer, especially in low-income countries.
- Occupational factors, passive smoking and other indoor pollutants, including radon, and air pollution are other important modifiable causes of lung cancer; nutritional factors and infectious agents are additional potential risk factors. Control of exposure to lung carcinogens other than tobacco, in both the general and the occupational environment, has had a substantial impact in several high-risk populations.
- Lung cancer in never-smokers is not an uncommon disease. While there is an interaction between tobacco smoking and other lung carcinogens, several agents have been shown to cause lung cancer also in never-smokers.
- Lung cancer was the most important epidemic of the 20th century, and it is likely to remain a major public health problem in the 21st century. It is also a paradigm of the importance of primary prevention and a reminder that scientific knowledge is not sufficient per se to ensure human health.

The history of lung cancer epidemiology parallels the history of modern chronic disease epidemiology. In the 19th century, an excess of lung cancer was observed among miners and some other occupational groups, but otherwise the disease was very rare. An epidemic increase in lung cancer began in the first half of the 20th century, with much speculation and controversy about its possible environmental causes.

Among both women and men, the incidence of lung cancer is low in persons under 40 years of age, it increases up to age 70 or 75 years (Fig. 1.1), and it declines thereafter. The decline in incidence in the older-age groups can be explained, at least in part, by incomplete diagnosis or by a generation (birth cohort) effect.

Methodologically, epidemiologic studies of lung cancer have been straightforward because the site of origin is well defined, progressive symptoms prompt diagnostic activity, and the predominant causes are comparatively easy to ascertain. Novel approaches to the classification of lung cancer based on molecular techniques will likely bring new insights into its etiology, especially among nonsmokers.

DESCRIPTIVE EPIDEMIOLOGY

Lung cancer, a rare disease until the beginning of the 20th century, has become the most frequent malignant neoplasm among men in most countries and the main neoplastic cause of death in both men and women. In 2012, lung cancer accounted for an estimated 1,242,000 new cancer cases among men, which is 17% of all cancers excluding nonmelanoma skin cancer, and 583,000, or 9%, of new cancers among women. After nonmelanocytic skin cancer, lung cancer is the most frequent malignant neoplasm in humans and the most important cause of neoplastic death. Approximately 58% of all cancers occur in developing countries.[1]

The geographic and temporal patterns of lung cancer incidence are determined chiefly by consumption of tobacco. An increase in tobacco consumption is paralleled a few decades later by an increase in the incidence of lung cancer, and a decrease in consumption is followed by a decrease in incidence. Other factors, such as genetic susceptibility, poor diet, and indoor air pollution, may act in concert with tobacco smoking in shaping the descriptive epidemiology of lung cancer.

The pattern found today in men (Fig. 1.2) is composed of populations at high risk, in which consumption of tobacco has been persistently high for decades, and populations at low risk, either because tobacco consumption has not been increasing for long (e.g., China, Africa) or because a decrease in consumption has been present for several decades (e.g., Sweden).

In countries with populations made up of different ethnic groups, differences in lung cancer rates are frequently observed. For example, in the United States, the rates are higher among black men than among other ethnic groups (Table 1.1).

Over the past 25 years, the distribution of histologic types of lung cancer has been changing. In the United States, squamous cell carcinoma, which was formerly the predominant type, is decreasing, whereas adenocarcinoma has increased in both genders.[2] In Europe, similar changes are occurring in men, whereas in women, both squamous cell carcinoma and adenocarcinoma are increasing.[3] Although the increase in the incidence of adenocarcinoma may be due, at least in part, to improved diagnostic techniques, changes in composition and patterns of tobacco consumption (deeper inhalation of low-nicotine and tar tobacco smoke) are additional explanations.[4]

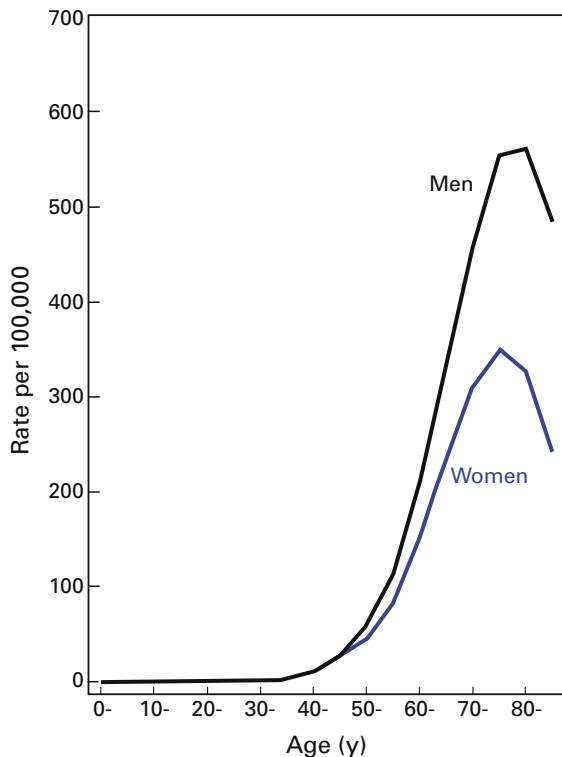
RISK FACTORS

Tobacco Smoking

The evidence is very strong that tobacco smoking causes all major histologic types of lung cancer. A carcinogenic effect of tobacco smoke on the lung has been demonstrated in epidemiologic studies conducted since the early 1950s and has been recognized by public health and regulatory authorities since the mid-1960s. Tobacco smoking is the main cause of lung cancer in most populations, and the geographic and temporal patterns of the disease largely reflect tobacco consumption during the previous decades. Because of the high carcinogenic potency of tobacco smoke, a major reduction in tobacco consumption would result in the prevention of a large fraction of human cancers.[5,6]

The excess risk among continuous smokers relative to the risk among never-smokers is on the order of 10-fold to 20-fold. The overall relative risk reflects the contribution of the different aspects

of tobacco smoking: average consumption, duration of smoking, time since quitting, age at start, type of tobacco product, and inhalation pattern, as well as the absolute risk in never-smokers.

Several large cohort and case–control studies have provided detailed information on the relative contributions of duration and amount of cigarette smoking to excess lung cancer risk. Doll and Peto[7] analyzed data from a large cohort of British doctors and concluded that the excess lung cancer risk rises in proportion to the square of the number of cigarettes smoked per day but to the fourth power of the duration of smoking. Therefore duration of smoking should be considered the strongest determinant of lung cancer risk in smokers. Analysis of the same cohort after 50 years of follow-up confirmed these results.[8]


An important aspect of tobacco-related lung carcinogenesis is the effect of cessation of smoking. The excess risk sharply decreases in ex-smokers, starting approximately 5 years after quitting, and an effect is apparent even for cessation late in life. However, an excess risk throughout life likely persists even in long-term quitters.[6]

The risk of lung cancer is lower among smokers of low-tar cigarettes than among smokers of high-tar cigarettes and lower among smokers of filtered cigarettes than among smokers of unfiltered cigarettes. Smokers of black (air-cured) tobacco cigarettes are at twofold to threefold higher risk of lung cancer than smokers of blond (flue-cured) tobacco cigarettes.[6] Tar content, the presence or absence of a filter, and the type of tobacco are not independent, however. High-tar cigarettes tend to be unfiltered, and in countries where both black and blond tobacco are used, cigarettes are more frequently made from black tobacco.

Although cigarettes are the main tobacco product smoked in Western countries, an exposure–response relationship with lung cancer risk has also been shown for cigars, cigarillos, and pipes, indicating a carcinogenic effect of these products as well.[6] An increased risk of lung cancer has also been shown after consumption of local tobacco products, such as bidi and hookah in India, khii yoo in Thailand, and water pipe in China.[6] Limited data suggest an increased lung cancer risk after consumption of other tobacco products, such as narghile in western Asia and northern Africa and toombak in Sudan.

Differences in the Effect of Tobacco Smoking According to Histology, Gender, and Race

Although the evidence is abundant that tobacco smoking causes all major histologic types of lung cancer, the associations appear to be stronger for squamous cell and small cell carcinoma and weaker for adenocarcinoma. The incidence of adenocarcinoma has greatly increased during the past decades. Some of the increase may be attributable to improved diagnostic techniques,

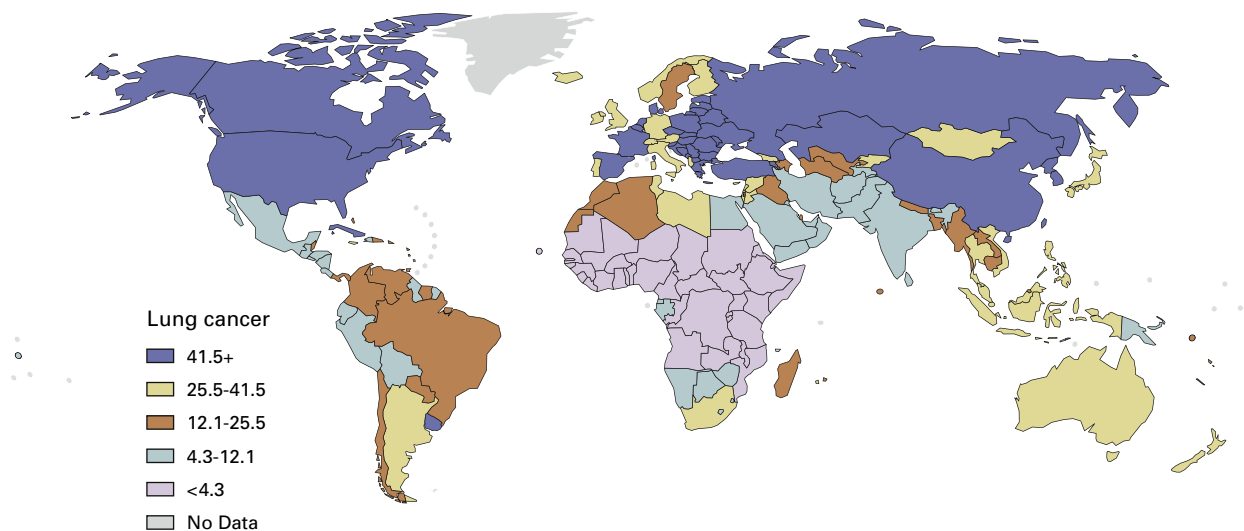
Fig. 1.1. Age-specific incidence rate of lung cancer per 100,000, by gender, according to the US Surveillance, Epidemiology End-Result (SEER) database for 2003–2007.[1]


Fig. 1.2. Estimated age-standardized rate (ASR) of lung cancer in men per 100,000 men, by country, 2012
Ferlay J1, Steliarova-Foucher E., Lortet-Tieulent J., et al. Cancer incidence and mortality patterns in Europe: estimates for 40 countries in 2012. Eur J Cancer. 2013 Apr;49(6):1374–1403. http://dx.doi.org/10.1016/j.ejca.2012.12.027. Epub 2013 Feb 26. (Reprinted from International Agency for Research on Cancer. GLOBOCAN 2012. Estimated Cancer Incidence, Mortality, and Prevalence Worldwide in 2012. http://globocan.iarc.fr/Default.aspsx. 2012.)

but aspects of tobacco smoking may also have played a role; it is unclear, however, which aspects of smoking might explain these changes.

A few studies have suggested a difference in the risk of lung cancer between men and women who have smoked a comparable amount of tobacco,[9] but most of the available evidence does not support this gender difference.[6]

The higher rate of lung cancer among the black population compared with the rates in other ethnic groups in the United States is probably explained by the higher tobacco consumption in that population.[10] The lower risk of lung cancer among smokers in China and Japan compared with the risks among smokers in Europe and North America may be due to the relatively recent beginning of regular heavy smoking in Asia, although differences in the composition of traditional smoking products and in genetic susceptibility may also play a role.[11]

Secondhand Tobacco Smoke

The epidemiologic evidence and biologic plausibility support a causal association between secondhand exposure to cigarette smoke and lung cancer risk in nonsmokers.[12] The evidence of a high relative risk in the original studies[13,14] has been challenged on the basis of both possible confounding by active smoking, diet, or other factors and possible reporting bias. However, when these factors were taken into account, the association was confirmed, and the excess risk was on the order of 20% to 25%.[12,15]

The effect of involuntary smoking appears to be present for both household exposure, mainly from the spouse, and workplace exposure.[16,17] By contrast, little evidence has been found for an effect of childhood involuntary smoking exposure.[18]

Confounding Effects of Tobacco Smoking

The importance of tobacco smoking in the causation of lung cancer complicates the investigation of the other causes of this disease because tobacco smoking may act as a powerful confounder. For example, a population of industrial workers exposed to a suspected carcinogen may smoke more than the unexposed comparison population. An excessive lung cancer risk in the exposed group, especially if small, might be due to the difference in smoking rather than to the effect of the occupational agent. One solution is to restrict the investigation to lifetime nonsmokers. However, they may represent a selected group, with low prevalence of exposure to many agents of interest. An alternative is to collect detailed information on smoking habits and to compare the effect of the suspected carcinogens across different groups of smokers. This approach has shown that tobacco smoking as a confounder rarely completely explains excess risks larger than about 50%.[19]

Interaction Between Tobacco Smoke and Other Lung Carcinogens

Other carcinogens may interact with tobacco smoke in the determination of their carcinogenic action on the lung. In other words, the absolute or relative risk from exposure to another agent may be greater (or smaller) among heavy smokers compared with the corresponding risk among light smokers and nonsmokers. The interaction may take place at the stage of exposure; that is, the other agent has to be absorbed on the tobacco particles to penetrate the lung. Or it may take place at some stage of the carcinogenic process, for example, on induction of common metabolic enzymes or activation of common molecular targets. The empirical evidence for an interaction between tobacco smoking and other agents is scanty, mainly because of lack of data among light smokers and nonsmokers.[20] The interaction between asbestos exposure and tobacco smoking falls between the additive and the multiplicative model.[21] The interaction between radon exposure and tobacco smoking best fits a submultiplicative model; data for other agents are too sparse to allow conclusions.

Use of Smokeless Tobacco Products

Few studies have investigated the risk of lung cancer among users of smokeless tobacco products. In two large cohorts of US volunteers, the relative risk of lung cancer associated with spit tobacco use among nonsmokers was 1.08 (95% confidence interval [CI], 0.64–1.83) and 2.00 (95% CI, 1.23–3.24).[22] In a Swedish cohort, the relative risk of lung cancer for every use of snus was 0.80 (95% CI, 0.61–1.05).[23] In a large case–control study from India, the relative risk of lung cancer for every use of tobacco-containing chewing products was 0.74 (95% CI, 0.57–0.96).[24] Overall, the evidence of an increased risk of lung cancer from use of smokeless tobacco products is weak; the apparent protective effect detected in studies including smokers may be due to uncontrolled negative confounding.

Dietary Factors
Vegetables and Fruits

There is some evidence that a diet rich in vegetables and fruits probably exerts a protective effect against lung cancer.[25] Although a protective effect of high vegetable and fruit intake was found in most case–control studies, results of prospective studies with detailed information on dietary intake are less consistent in showing a similar effect. Possible reasons for the inconsistent results include bias from retrospective dietary assessment, misclassification and limited heterogeneity of exposure in cohort studies, residual confounding by smoking, and variability in food composition. Among specific types of fruits and vegetables, the evidence is stronger for cruciferous vegetables,[26] but even in this case it is unlikely that this group of foods represents a strong protective factor against lung cancer.

Meat and Other Foods

It has been suggested that high intake of meat, in particular fried or well-done red meat, increases the risk of lung cancer,[27] although the available evidence does not support this hypothesis.[25] If real, the association may be explained by the formation of nitrosamines during cooking of the meat,[28] as well as by the saturated fat content of meat (as discussed later). Although risk estimates for the intake of other foods, such as cereals, pulses, eggs, milk, and dairy products, have been specified in some studies, these results are inadequate for a judgment of the evidence of an effect.[25]

Coffee and Tea

In a few studies, high consumption of coffee has been associated with an increased risk of lung cancer.[29] However, residual confounding by tobacco smoking is a distinct possibility, and no conclusion can be drawn at present.[25] There is some evidence of a chemopreventive effect of tea, notably green tea, in smokers.[30] The overall evidence, however, is not consistent.

TABLE 1.1 Age-Standardized Incidence Rates of Lung Cancer per 100,000 by Gender and Ethnic Group[a]

Ethnic Group	Men	Women
Asian and Pacific Islander	31.6	17.5
Black	66.8	35.5
Hispanic white	25.0	16.5
Non-Hispanic white	51.2	38.1

[a]Combined with selenium (50 µg) and alpha-tocopherol (30 mg).
[b]Follow-up for cancer incidence.
[c]50 mg on alternate days.
CI, confidence interval; *NA*, not available; *RR*, relative risk.

Lipids

In several ecologic studies, a positive association was found between total lipid intake and lung cancer risk that appears to be independent of the risk of tobacco consumption.[31] The analytic studies that have addressed this association, however, have produced mixed results. Although no study has provided evidence of a protective effect of total lipid intake, an increased risk was shown only in case–control studies, whereas a pooled analysis of eight cohort studies provided no evidence of an increased risk of lung cancer for high intake of either total fat or saturated fat.[32]

Carotenoids

Many studies have addressed the risk of lung cancer in relation to estimated intake of either beta-carotene or total carotenoids (which in most cases correspond to the sum of alpha- and beta-carotene).[33] Five cohort and 18 case–control studies published up to 1994 provided 28 risk estimates in different populations; with one notable exception,[34,35] 25 of these estimates indicated a protective effect of high beta-carotene intake. The protective effect provided a 30% to 80% reduction in the risk of lung cancer between the highest and lowest intake categories.[31] The risk decreased for all major histologic types of lung cancer in many countries, in both genders, and in both smokers and nonsmokers. Similar results have been obtained in studies based on measurement of beta-carotene in prospectively collected sera.[36] The evidence of a protective effect from most observational studies has been refuted by the results of randomized intervention trials based on beta-carotene supplementation (Table 1.2). In two of these trials, which included smokers or workers exposed to asbestos, a significant increase in the incidence of lung cancer was observed in the treated groups; in the remaining studies, no effect was ascertained. The difference in results between observational studies and preventive trials can be explained by confounding by cancer-protective factors in fruits and vegetables other than beta-carotene or by the possibility that high, nonphysiologic doses of beta-carotene may cause oxidative damage, especially among smokers.[37]

Other Micronutrients

For none of the antioxidant vitamins or the other micronutrients is there conclusive evidence of a protective effect against lung cancer. The data for selenium, vitamin A, lutein, and lycopene, in particular, are inconclusive.[25,38] The results of studies of serum level of these micronutrients are insufficient for an evaluation. There is evidence from observational studies that low levels of vitamin D are associated with lung cancer risk;[39] results of randomized trials, however, do not provide supportive evidence, arguing for caution in drawing conclusions.

Isothiocyanates

Isothiocyanates are a group of chemicals with cancer-preventive activity in experimental systems and may be responsible for the
Fig. 1.3. Interaction between high intake of isothiocyanates and polymorphism in glutathione S-transferase mu 1 (GSTM1) and glutathione S-transferase theta 1 (GSTT1) in four case–control studies of lung cancer.

possibly reduced risk of lung cancer associated with high intake of cruciferous vegetables. The enzymes glutathione S-transferase M1 and T1 are involved in their metabolism. As indicated, these enzymes are polymorphic, with 5% to 10% of Europeans and 30% to 40% of Asians being carriers of a deletion in both. In four studies it has been shown that the protective effect of a high intake of isothiocyanates is stronger in carriers of both deletions than in other noncarriers (Fig. 1.3).[40–43] No final conclusions can be drawn, but this effect is an example of a possible gene–environment interaction in lung carcinogenesis.

Alcohol

Given the strong correlation between alcohol drinking and tobacco smoking in many populations, it is difficult to disentangle the contribution of alcohol to lung carcinogenesis while properly controlling for the potential confounding effect of tobacco. Meta-analyses have demonstrated that the increased risk of lung cancer observed among alcoholics is mainly attributable to such residual confounding, but some evidence of a smoking-adjusted association with high alcohol consumption was found.[44,45] This conclusion was confirmed by a pooled analysis of seven cohort studies.[46] Overall, it may be premature to conclude that an association between alcohol drinking and lung cancer has been confirmed by the available data. If the association is causal, alcohol may act as a solvent for carcinogens such as the ones in tobacco smoke. In addition, alcohol can induce metabolic enzymes or act through direct DNA damage via the active metabolite acetaldehyde.[47]

Hormones

Estrogen and progesterone receptors are expressed in the normal lung and in lung cancer cell lines, and estradiol has a proliferative effect on lung cancer cells. Although an effect of estrogens on lung carcinogenesis has not been demonstrated, estrogens may act via formation of DNA adducts and activation of growth factors.[48] Data on risk of lung cancer after the use of hormone

replacement therapy have been reported from five case–control studies, two cohort studies, and one randomized trial.[49–56] A small increased risk of lung cancer has been found in the early studies, whereas a decreased risk was detected in the more recent studies. No effect was observed in the only randomized trial.[53] Although the different results may be explained by changes in the formulations used for replacement therapy, the lack of an effect in the only study with an experimental design argues against an effect of this type of exposure on lung cancer.

Three cohort studies and one case–control study were included in a meta-analysis of serum insulin-like growth factor 1 level and lung cancer. The overall relative risk was 1.01 (95% CI, 0.49–2.11).[57] The results for insulin-like growth factor–binding protein 3 level were also negative (summary relative risk, 0.83; 95% CI, 0.38–1.84), although exclusion of a deviant study resulted in a decreased risk of lung cancer for a high level of insulin-like growth factor–binding protein 3 (relative risk, 0.53; 95% CI, 0.34–0.83).

Anthropometric Measures

There is some evidence for association between a reduced body mass index and an increased risk of lung cancer.

However, this inverse association can be explained, at least in part, by negative confounding by smoking,[58] and no clear association has been demonstrated among never-smokers. Subsequent studies have supported this conclusion that the apparent association is due to confounding.[59]

Evidence suggests a direct association between height and lung cancer risk.[60] Subsequent studies have supported this finding,[61,62] although the evidence is not fully consistent.[63,64]

Infections

People with pulmonary tuberculosis have been found to be at increased risk of lung cancer.[65] A similar association was reported from community-based studies among smoking and nonsmoking women.[49,66–68] In the most informative study, involving a large cohort of people with tuberculosis from Shanghai, China,[69] the relative risk of lung cancer in the whole cohort was 1.5 and it was 2.0 20 years after the diagnosis of tuberculosis; a correlation was also seen with the location of the tuberculosis lesions. Whether the excess risk is caused by the chronic inflammatory status of the lung parenchyma or by the specific action of the *Mycobacterium* is not clear. A role of isoniazid, a widely used tuberculosis drug that causes lung tumors in experimental animals, was excluded in one large study.[70]

Chlamydia pneumoniae is a cause of acute respiratory infection. Six studies have been published on the risk of lung cancer among individuals with markers of *C. pneumoniae* infection. A positive association was detected in all six studies.[71] However, studies based on prediagnostic samples had lower risk estimates than studies based on postdiagnostic samples. An association between infection with human papilloma virus and lung cancer, in particular the adenocarcinoma type, has been suggested by the results of an analysis of series of cases and by the growing evidence of an increased risk among workers potentially exposed to this agent, such as butchers.[72] The results are insufficient to draw a conclusion about the presence or absence of a causal association. Other biologic agents that have been suggested as playing a role in lung carcinogenesis include simian virus 40 and the fungus *Microsporum canis*.[73,74]

Ionizing Radiation

There is conclusive evidence that high exposure to ionizing radiation increases the risk of lung cancer.[75] Atomic bomb survivors and patients treated with radiotherapy for ankylosing spondylitis or breast cancer are at moderately increased risk of lung cancer (relative risk, 1.5–2.0 for cumulative exposure in excess of 100 rad).[76] The association with high doses of ionizing radiation was stronger for small cell carcinoma than for other histologic types of lung cancer. Studies of nuclear industry workers exposed to relatively low levels of ionizing radiation, however, provided no evidence of an increased risk of lung cancer.[75]

Underground miners exposed to radioactive radon and its decay products, which emit alpha particles, have been consistently found to be at increased risk of lung cancer.[77] The risk increased with estimated cumulative exposure and decreased with attained age and time since cessation of exposure.[78] In a pooled analysis of 11 cohorts, an apparently linear, approximately 6% risk increase per working-level year of exposure was estimated.[78] Evidence was also found that for comparable cumulative exposure, the risk is greater for lower rates over a longer period and that smoking modifies the carcinogenic effect of radon.[78,79] Today the main concern about lung cancer risk from radon and its decay products comes from residential rather than occupational exposure. In a pooled analysis of 13 European case–control studies, a relative risk of 1.084 (95% CI, 1.030–1.158) per 100 Bq/m^3 increase in measured indoor radon was found.[80] After correction for the dilution caused by measurement error, the relative risk was 1.16 (95% CI, 1.05–1.31). The exposure–response relationship was linear with no evidence of a threshold. The same conclusion was reached from a similar analysis of North American studies.[81] These results suggest that indoor radon exposure may be an important cause of lung cancer, in particular among nonsmokers unexposed to occupational carcinogens.

Occupational Exposures

The important role of specific occupational exposures in lung cancer etiology has been well established in reports dating back to the 1950s. The risk of lung cancer is increased among workers employed in a number of industries and occupations (Table 1.3).[82,83] The responsible agents have been identified for several, but not all, of these high-risk workplaces. Evidence for the carcinogenicity of many occupational agents has been reviewed.[19] Estimates of the proportion of lung cancer cases attributable to occupational agents in France (12.5% in men and 6.5% in women) and the United Kingdom (14.5% overall) have been reported in two studies, published in 2010 and 2012, respectively.[84,85] Although asbestos remains the most important occupational lung carcinogen, the precise role of silica, radon, heavy metals, and polycyclic aromatic hydrocarbons (PAHs) in the burden of occupational cancer is uncertain. The remaining occupational lung carcinogens are likely to play a lesser role in terms of disease burden.

Asbestos

The first evidence of increased risk of lung cancer after inhalation of asbestos fibers dates back to the 1950s.[86] All forms of asbestos—chrysotile and amphiboles, including crocidolite, amosite, and tremolite—are carcinogenic to the human lung, although chrysotile's potency may be lower than that of other types.[87] Although asbestos has been banned in many countries, a substantial number of workers are still exposed, mainly in the construction industry. In many low-resource and medium-resource countries, occupational exposure is widespread. Asbestos is responsible for a large number of occupationally related lung cancers in many countries.

Metals

Exposure to inorganic arsenic, known as a lung carcinogen since the late 1960s, occurs mainly among workers employed in hot smelting; other groups at increased risk are fur handlers,

TABLE 1.3 Occupational Agents, Groups of Agents, Mixtures, and Occupations Classified as Human Carcinogens (Group 1) by the IARC Monographs Program, Volumes 1–100, Which Have the Lung as Target Organ (Cogliano et al.[82])[a]

Agents, Mixtures, Occupations	Main Industry, Use
AGENTS AND GROUPS OF AGENTS	
Arsenic and inorganic arsenic compounds	Glass, metals, pesticides
Asbestos	Insulation, filters, textiles
Beryllium and beryllium compounds	Aerospace
Bis(chloromethyl)ether and chloromethyl methyl ether	Chemical intermediate
Cadmium and cadmium compounds	Dye/pigment
Chromium-b compounds	Metal plating, dye/pigment
Involuntary tobacco smoking	Hospitality
Nickel compounds	Metallurgy, alloy, catalyst
Plutonium	Defense
X-ray radiation and gamma radiation	Medical
Radon-222 and its decay products	Mining
Silica, crystalline	Stone cutting, mining, glass, paper
MIXTURES	
Coal-tar pitch	Construction, electrodes
Soot	Pigments
OCCUPATIONS	
Aluminum production	NA
Coal gasification	NA
Coke production	NA
Hematite mining (underground)	NA
Iron and steel founding	NA
Painting	NA
Rubber production industry	NA

[a]Since the publication of this source, diesel engine exhausts (mainly used in mining and transportation) have been added to the list (Benbrahim-Tallaa et al.[83]).

IARC, International Agency for Research on Cancer; *NA,* not available.

manufacturers of sheep-dip compounds and pesticides, and vineyard workers.[88] Chromium VI compounds increase the risk of lung cancer among chromate-production workers, chromate-pigment manufacturers, chromium platers, and ferrochromium producers. No such risk has been detected among workers exposed only to chromium III compounds. An increased risk of lung cancer has been found in studies of nickel miners, smelters, electrolysis workers, and high nickel alloy manufacturers.[88] Agreement is lacking on whether all nickel compounds are carcinogenic for humans; the available evidence does not allow a clear separation of the effects of the different nickel salts to which workers are exposed. An increased risk of lung cancer has been demonstrated among workers in cadmium-based battery manufacturing industries, copper–cadmium alloy industries, and cadmium smelters. The increased risk does not seem to be attributable to concomitant exposure to nickel or arsenic. In US studies, an excess risk of lung cancer has been found among workers exposed to beryllium in the early technologic phase of the industry,[89] although the relevance of these results to the current exposure situation has been debated.[90]

Silica

An increased risk of lung cancer has been consistently reported in cohorts of people with silicosis.[91] Many authors have investigated workers exposed to crystalline silica in foundries, pottery making, ceramics, diatomaceous earth mining, brick making, and stone cutting, in some of whom silicosis may have developed. An increased risk of lung cancer was found in some, but not all, studies, and in the positive studies the increase was small, with evidence of an exposure–response relationship.[92]

Polycyclic Aromatic Hydrocarbons

PAHs are a complex and important group of chemicals formed during combustion of organic material. They are widespread in the human environment; for most people, diet and tobacco smoke are the main sources of exposure to PAHs. A number of occupational settings entail exposure to high levels of PAHs. These chemicals, however, occur inevitably as complex mixtures of variable composition; an assessment of the risk from individual PAHs is therefore difficult. An increased risk of lung cancer has been demonstrated in several industries and occupations entailing exposure to PAHs, such as aluminum production, coal gasification, coke production, iron and steel founding, tar distillation, roofing, and chimney sweeping.[93] An increase has also been suggested in a few other industries, including shale oil extraction, wood impregnation, road paving, carbon black production, and carbon electrode manufacture, with an exposure–response relationship found in the studies with detailed exposure information. Motor vehicle and other engine exhausts represent an important group of mixtures of PAHs because they contribute significantly to air pollution. The available epidemiologic evidence shows an excess risk among workers with high occupational exposure to diesel engine exhaust.[94]

Medical Conditions and Treatment

In addition to tuberculosis and lung fibrosis from chronic exposure to high levels of fibers and dusts (both discussed in earlier sections), chronic respiratory diseases have been associated with lung cancer risk. People with chronic bronchitis and emphysema are at moderately increased risk, and after adjustment for tobacco smoking, this risk is greater for squamous cell carcinoma than for other cancers.[66,94,95] The roles of shared exposures, namely, tobacco smoking and chronic inflammation, have not been fully elucidated. A meta-analysis of studies of lung cancer and asthma in never-smokers showed a summary relative risk of 1.8 (95% CI, 1.3–2.3);[96] the results were similar when the analysis was restricted to studies that controlled for smoking. However, because the evidence is based mainly on case–control studies, selection and recall bias cannot be fully excluded.[97]

The risk of lung cancer is increased in individuals surviving other tobacco-related and lifestyle-related cancers.[98] Commonality of risk factors, long-term effects of radiotherapy, and increased susceptibility probably interact in the causation of second primary cancers. The effect of chemotherapy and radiotherapy on the risk of a second primary lung cancer has been extensively investigated among long-term survivors of breast cancer; lung cancer develops in 2% to 9% of this group.[99] The increased risk is restricted to patients receiving radiotherapy. Among them, a clear exposure–response relationship has been shown, together with an interactive effect of tobacco smoking.

Several studies have assessed lung cancer risk among regular users of aspirin and other nonsteroidal anti-inflammatory drugs. A meta-analysis of 15 studies resulted in a pooled relative risk of 0.86 (95% CI, 0.76–0.98).[100] However, there was heterogeneity among the different studies, likely owing in part to differences in the definition of the exposure. The protective effect was stronger for case–control studies (relative risk, 0.74; 95% CI, 0.57–0.99) than for cohort studies (relative risk, 0.97; 95% CI, 0.87–1.08), suggesting a role for recall bias. In particular, in a large cohort study of 1 million US volunteers, a reduction in risk was not found.[101] However, in a meta-analysis of eight aspirin trials, the risk of lung cancer was reduced during the first 10 years after the end of the trial (relative risk, 0.68; 95% CI, 0.50–0.92).[102]

Indoor Air Pollution

Indoor air pollution is thought to be the main determinant of the elevated risk of lung cancer among nonsmoking women living in

TABLE 1.4   Results of Selected Cohort Studies on Fine Particle Exposure and Risk of Lung Cancer

Study; Population; Reference	No. and Sex	RR	95% CI	Exposure Contrast[a]	Basis for Exposure Assessment	Range or Mean (SD) or Both, µg/m³
Seventh-Day Adventists; USA, 1977–1992 (McDonnell et al., 2000)[102a]	6338, M	2.23	0.56–8.94	per 24.3 µg/m³ $PM_{2.5}$	Residential history 1966–1992 and local monthly pollutant estimates based on airport visibility data 1966–1992	Mean (SD) $PM_{2.5}$, 59.2 (16.8)
ASC/CPS-II; USA, 1982–1998 (Pope et al., 2002)[102b]	500,000, M + F	1.08	1.01–1.16	per 10 µg/m³ $PM_{2.5}$	City of residence in 1982. Pollutant average of 1979–1983	Mean (SD) $PM_{2.5}$, 21.1 (4.6); range, roughly 5–30 µg/m³
Six Cities; USA, 1975–1998 (Laden et al., 2006)[102c]	8111, M + F	1.27	0.96–1.69	per 10 µg/m³ $PM_{2.5}$	City of residence in 1975. Pollutant average 1979–1985	Range $PM_{2.5}$, 34.1–89.9 µg/m³
ESCAPE; Europe; 1990s–2000s[a] (Raaschou-Nielsen, 2013)[102d]	273,838, M + F	1.18	0.96–1.46	per 5 µg/m³ $PM_{2.5}$	Place of residence at enrollment. Pollutant average 2008–2011	Range of cohort-specific mean $PM_{2.5}$, 6.6–31.0 µg/m³

[a]Pooled analysis of 14 cohorts, enrollment mainly in the 1990s, follow-up until late 2000s.

several regions of China and other Asian countries. The evidence is stronger for coal burning in poorly ventilated houses, but evidence also exists for burning of wood and other solid fuels, as well as for the fumes from high-temperature cooking using unrefined vegetable oils, such as rapeseed oil.[103] A positive association between various indicators of indoor air pollution and lung cancer risk has also been reported in populations exposed to less extreme conditions than the ones encountered by some Chinese women, for example, populations in Central Europe and Eastern Europe and other regions.[104,105]

Outdoor Air Pollution

There is abundant evidence that lung cancer rates are higher in cities than in rural settings.[106] However, this pattern, may result from confounding by other factors, notably tobacco smoking and occupational exposures, rather than from air pollution. Cohort and case–control studies are limited by difficulties in assessing past exposure to the relevant air pollutants. The exposure to air pollution has been assessed either on the basis of proxy indicators—for example, the number of inhabitants in the community of residence, residence near a major pollution source—or on the basis of actual data on pollutant levels. These data refer to total suspended particulates, sulfur oxides, and nitrogen oxides, which are not likely to be the agents responsible for the carcinogenic effect, if any, of air pollution.[107] Furthermore, the sources of data may cover quite a wide area, masking small-scale differences in exposure levels.

The combined evidence suggests that urban air pollution may confer a small excess risk of lung cancer on the order of 50%, but residual confounding cannot be excluded. In four cohort studies, assessment of exposure to fine particles was based on environmental measurements (Table 1.4). The results of these studies suggest a small increase in risk among people classified as most highly exposed to air pollution. In 2013, the International Agency for Research on Cancer classified outdoor air pollution as an established cause of lung cancer in humans.[108]

Drinking Water Contamination

An increased risk of lung cancer has been consistently reported among people exposed to arsenic in drinking water. Investigations include ecologic studies from Argentina, Chile, and Taiwan and case–control and cohort studies from Taiwan—in particular, in areas endemic for blackfoot disease, caused by chronic arsenic poisoning—Japan, the United States, and Chile.[109] An exposure–response relationship was observed in most of these studies. In particular, in a cohort study from a contaminated area in Taiwan, the relative risk of lung cancer according to cumulative estimated

exposure to arsenic from drinking water was 4.0 for 20 or more milligrams per liter of drinking water contamination compared with uncontaminated water.[110]

CONCLUSION

Given the poor prognosis of lung cancer and the lack of effective screening procedures, primary prevention remains the main weapon against this neoplasm and control of tobacco smoking is by far the most important preventive measure. Although the effects of tobacco control on the incidence of the disease can be demonstrated in several populations, much remains to be done, especially among women and in low-income countries. Control of exposure to other lung carcinogens, in both the general and the occupational environment, is another measure that has been taken and, at least in some instances, has had substantial effects. Priorities for the prevention of lung cancer, in addition to tobacco control, include understanding the carcinogenic and preventive effects of dietary and other lifestyle factors, control of occupational exposures, avoidance of high exposure to outdoor and indoor pollution, and elucidation of conditions that entail increased genetic predisposition to lung cancer.

Lung cancer in never-smokers is not a rare disease. Occupational factors, passive smoking, and indoor exposure to radon explain a portion of these cases, and nutritional, infectious, and genetic factors are receiving attention as additional risk factors.

Lung cancer was the most important epidemic of the 20th century, and it is likely to remain a major public health problem in the 21st century. It is ironic that this cancer causes more deaths than any other malignancy in the world, even though epidemiologic research has led to the identification of more than 10 causes of the disease, including the quantitatively dominant cause, tobacco smoking. Lung cancer is also a paradigm of the superiority of prevention over treatment and a reminder that scientific knowledge is not sufficient per se to ensure human health.

2 Tobacco Control and Primary Prevention

Matthew A. Steliga and Carolyn M. Dresler

SUMMARY OF KEY POINTS

- Smoking is the predominant risk factor for development of lung cancer. As tobacco is introduced to societies, common patterns emerge. Typically, it is first used in men, then later in women. A 20- to 25-year lag between smoking rates and lung cancer rates reflects this.
- The World Health Organization (WHO) Framework Convention on Tobacco Control (FCTC) provides a comprehensive global tobacco-control strategy. Six key concepts are described with the mnemonic "MPOWER."
  - **M**onitor Tobacco Use and Prevention Policies: The WHO has standardized surveys and metrics to make comparisons possible between societies and over time.
  - **P**rotect People from Tobacco Smoke: Secondhand smoke is a risk factor for lung cancer. Implementation of public smoking bans has been linked to decreased disease from tobacco smoke (asthma exacerbations, acute coronary events, etc.).
  - **O**ffer to Help Quit Tobacco Use: Physician advice, pharmacotherapy, and tobacco quitlines improve cessation rates, but are underutilized.
  - **W**arn About the Dangers of Tobacco: Public service messages are effective. Written and graphic warning labels on tobacco packages reach each user and are effective at decreasing use.
  - **E**nforce Bans on Tobacco Advertising, Promotion, and Sponsorships: Often tobacco marketing targets youth and socioeconomically disadvantaged populations. Restricting marketing prevents initiation and decreases use.
  - **R**aise Taxes: Taxation suppresses use while raising money; unfortunately, most tobacco tax funds do not support other tobacco-control measures.

Many lives have been saved by tobacco control over the past 50 years. However, due to ongoing use of tobacco, millions of preventable deaths have occurred. Tobacco use has steadily grown and spread across the globe to such a degree that tobacco-induced death and disability have attained epidemic proportions. Many diseases and conditions attributable to smoking, such as cerebrovascular disease, heart disease, emphysema, and cancer—especially lung cancer—have led to death and disability. This chapter highlights the growth, spread, and current status of the tobacco epidemic worldwide; global efforts to curb the use of tobacco; and the potential impact of control measures on outcomes, specifically lung cancer–related mortality.

As tobacco use is encouraged, promoted, and perpetuated with a variety of mechanisms, there is a need to intervene and provide tobacco prevention and cessation in multiple dimensions. Various tobacco-control strategies have been used in the past, with varying degrees of success across different populations. The WHO FCTC provides a unified multidimensional approach to tobacco control for the 21st century, with a structure to discuss implementation of comprehensive tobacco control. Although

societies around the globe differ widely in terms of language, cultural norms, economic resources, and smoking rates, nearly all societies are afflicted with the tobacco epidemic, and a concerted effort involving the use of evidence-based strategies has the potential to save millions of lives.

HISTORICAL CONTEXT OF THE TOBACCO EPIDEMIC

Tobacco is indigenous to the Americas, and, prior to its European discovery in 1492, tobacco was unknown in the rest of the world. After Europeans were introduced to tobacco—and nicotine addiction—consumption steadily grew in Europe. Despite its popularity, King James I of England issued "A Counterblaste to Tobacco" as one of the first documented efforts of tobacco control. In 1604, he not only stated the harm to the smoker as being "… hatefull to the Nose, harmefull to the braine, dangerous to the Lungs …" but also discussed the implications of second-hand smoke in the context of a woman whose husband smokes and "resolve[s] to live in a perpetuall stinking torment."[1] One of the first documented tobacco-control policies was his accompanying "Commissio pro Tabacco," which levied a tax on tobacco importation.[2] In these early years of the spread of tobacco, much of its use was in the form of chew tobacco, pipe tobacco, cigars, or snuff. Tobacco was even touted as medicinal. Despite the proclamation from King James I, government taxation, and various religious edicts, tobacco use continued to grow throughout Europe.

The Industrial Revolution included the development of cigarette-rolling machines in the late 1800s, which not only spawned mass production and increased the use of tobacco but also shifted the bulk of tobacco use to cigarette smoking. Cigarettes are smoked with deeper inhalation than pipe tobacco or cigars, leading to absorption in the pulmonary parenchyma rather than in buccal and pharyngeal parenchyma. As a result of pulmonary delivery, a much more rapid and intense peak in nicotine levels leads to a greater addiction potential. This more addictive product, combined with industrialization, global transportation, and aggressive marketing to men, women, and children across the globe, led to an explosion in tobacco use and a highly profitable industry.

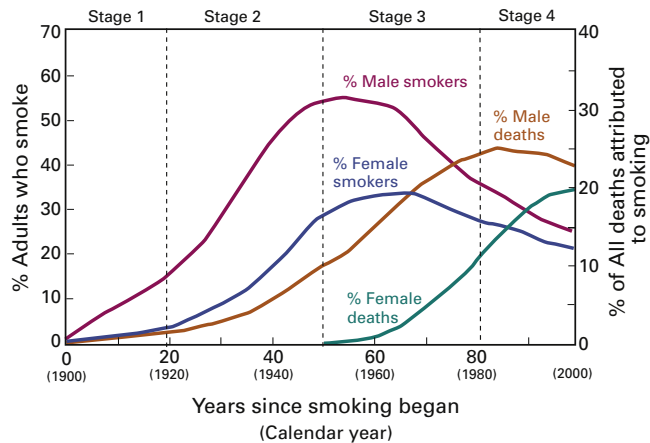
The epidemiologic relationship between smoking rates in a population and death rates attributable to smoking has been extensively analyzed on a global scale, and fascinating patterns tend to recur predictably from one society to another. Lopez et al.[3] noted that the rise in the prevalence of cigarette smoking was reflected in the rise in the death rate caused by smoking-related illnesses, with an approximately 20-year to 25-year lag.[3] Overall, it has been demonstrated that death rates from tobacco-induced disease occur at a rate of roughly half of the smoking rate, given this time lag (e.g., for a population with a 60% smoking rate, 30% of the deaths 20 years later are secondary to smoking). Stage I of a smoking epidemic represents initiation, with low smoking rates and very low death rates due to smoking (Fig. 2.1). Stage II consists of a rapid rise in the smoking prevalence among men to its peak, with the beginning of a rise in deaths. During this time, smoking among women just starts to increase, but there are few deaths. Stage III consists of a decline in smoking among men, with a continued increase in smoking among women. During this time, the death rate among men continues to rise following the 20-year to 25-year lag from the peak in smoking, and the death


Fig. 2.1. Lopez curve from 1994 demonstrating the stages of the tobacco epidemic in countries with developed economies as indicated by the rates of smoking and smoking-attributable deaths (based on lung cancer data) for men and women. *(Reprinted with permission from Thun M, Peto R, Boreham J, Lopez AD. Stages of the cigarette epidemic on entering its second century. Tob Control. 2012;21(2):96–101.)*

TABLE 2.1 Measures to Assist With Implementation of Effective Tobacco Control

Monitor tobacco use and prevention policies
Protect people from tobacco smoke
Offer help to quit tobacco use
Warn about the dangers of tobacco
Enforce bans on tobacco advertising, promotion, and sponsorship
Raise taxes on tobacco

rate among women also begins to increase. Stage IV consists of a decline in smoking rates among men and a plateau or fall in smoking rates among women, with an eventual decline in death rates. The Lopez model has been applied to many societies, and, in general, developing nations tend to be represented by stages I and II, whereas many industrialized nations have experienced their peak in smoking rates and deaths, particularly among men, and are in stages III or IV.

This rise and fall in the number of smoking-related deaths closely parallels the rise and fall in lung cancer incidence and mortality rates in the United States. Smoking was relatively uncommon before 1900, correlating with Lopez stage I. The smoking rate among men in the United States increased from the 1900s and peaked around 1965 (stage II). After the Surgeon General's report of the link between smoking and cancer,[4] smoking rates among men decreased, yet smoking-related deaths among men continued to increase (stage III). This increase in male smoking prevalence eventually led to a peak and decrease in lung cancer–related deaths among men approximately 20 years later. During this time, the smoking rate among women rose and plateaued. In the late 1990s and beyond, the death rate among women was just beginning to decrease (stage IV). According to the Lopez model, the incidence of lung cancer and lung cancer–related mortality should continue to fall for men and women in the United States as smoking rates have declined.

This descriptive model has also been applied to many other societies. Rates of smoking in China and Japan have risen for men, and the rates of smoking-attributable deaths continue to rise in these societies (stage II). However, countries such as Australia, New Zealand, the United Kingdom, and Sweden have progressed through all phases of the Lopez model and are in stage IV, with declining rates of smoking-related deaths among men and women. Despite the decrease in tobacco use in some of the aforementioned countries, tobacco use is growing in other countries, particularly India, Japan, and China, where societal and cultural shifts are leading to growing numbers of people who smoke, particularly women. The growth of the global population, the spread of tobacco use to more countries, and the rising rates of smoking among women are all contributing to a projected rapid global increase in tobacco use and tobacco-induced deaths. The toll of tobacco is considerable, with an estimated 100 million deaths globally in the 20th century; currently, 5 million deaths

are reported annually, with 1 billion deaths projected globally in the 21st century if the trajectory is not changed.[5]

As smoking rates have declined in some countries, they have stabilized or increased in other countries as a result of aggressive marketing by the tobacco industry and lax or nonexistent tobacco-control policies. With the irrefutable evidence that this aggressively marketed, addictive product leads to premature death and disability among people who smoke (with one in two people who continue to smoke dying of tobacco-related disease) and illness in people exposed to secondhand smoke, tobacco control not only can be seen as a public health crisis but also can be viewed from ethical and human rights perspectives.[6,7] By the end of the 20th century, the tobacco epidemic had steadily grown into a massive global crisis in which, currently, 5 million people die annually as a result of its use. Attempts at tobacco control have varied among different countries, and often by state or province within a country. The production, marketing, and distribution of cigarettes are predominantly controlled by a few international corporations: Philip Morris, Altria, British American Tobacco, Japan Tobacco, R. J. Reynolds, and China National Tobacco. The production, marketing, and distribution of cigarettes had become a globally organized network, and although the battle was being fought on many fronts, there was no global consensus on measures of tobacco control, and unified countermeasures to combat this problem were lacking.

21ST CENTURY TOBACCO-CONTROL MEASURES

The need for a comprehensive, unified, and enforceable global strategy to combat this global epidemic was initially conceptualized by Roemer and Taylor in 1993.[8] These authors subsequently presented a strategy for a FCTC to the WHO in 1995. Persistent efforts led to adoption of the WHO FCTC at the World Health Assembly in 2003. The WHO FCTC came into force in 2005 as the first international treaty adopted under the WHO and was ratified by 177 parties in 2013. The United States notably remains a nonparty. This unprecedented agreement between party nations became the first international legal instrument for a unified approach to combat the global tobacco epidemic. The multidimensional treaty delineates universal standards declaring the dangers of tobacco and outlines strategies for limiting its use worldwide through provisions regarding education, production, advertisement, distribution, sale, and taxation.

The details of the entire WHO FCTC are beyond the scope of this chapter, but the WHO produced an internationally applicable summary of the essential elements of a tobacco-control strategy, publicized as the mnemonic "MPOWER," which includes six components (Table 2.1). Examples of successful tobacco-control strategies are discussed here using these categories as a construct.

Monitor Tobacco Use and Prevention Policies

If an epidemic is to be treated, it must first be measured. It is crucial to dramatically improve global surveillance of tobacco use among adults and youths. Until recently, the extent of the epidemic has not been well documented, particularly in developing countries. Differences among nations with regard to the tools

that have been used to measure this epidemic have made comparisons difficult. The WHO Global Tobacco Surveillance System is a uniform comprehensive format for measuring the epidemic and gauging the impact of measures when implemented. The system comprises three school-based components (the Global Youth Tobacco Survey, the Global School Personnel Survey, and the Global Health Professions Student Survey) and one adult component (the Global Adult Tobacco Survey). These surveys contain the same basic data fields in all queries, and individual countries can add other specific points if they wish. Uniformity is necessary to compare one society and/or time point with another. The system involves three sequential phases: a survey workshop, data analysis, and a programmatic workshop that is designed to determine the needs and priorities to suit that area at that time. The surveys are intended to be conducted shortly after the implementation of control measures and then repeated every few years. Monitoring with reliable tools to obtain accurate data is the only way to truly determine where tobacco control is most needed, what type of tobacco control is most appropriate, who the target audience should be, and the outcomes of any implemented policies.

Protect People From Tobacco Smoke

The harm that smoking causes to people who smoke has been a driving force for tobacco control, but the effects of smoking on nonsmokers has led to another arm of tobacco control: protecting all people from tobacco smoke. Secondhand smoke, also known as environmental tobacco smoke or passive smoking, is a risk factor for asthma, bronchitis, and respiratory infections and also has been demonstrated to be a risk for the development of lung cancer and cardiovascular disease. Rates of lung cancer are higher for women who have never smoked but have husbands who smoke, with a relative risk ranging from 1.3 to 3.5.[9] Rates are higher for women with husbands who are "heavy" smokers (>20 cigarettes per day), suggesting a dose–response relationship.[9]

Mackay et al.[10] and Pell et al.[11] reported on the effect of a 2006 policy to prohibit smoking in all enclosed places in Scotland on health conditions related to secondhand smoke. In analyzing hospital data, the authors found that the rate of hospitalizations for childhood asthma was increasing 5.2% per year before the policy and fell by 18.2% per year after the policy took effect; this change was noted for both preschool and school-age children. In addition, after implementation of the policy, the rate of admissions for acute coronary syndrome decreased by 14% among active smokers, by 19% among former smokers, and by 21% among individuals who had never smoked. When the 12-month periods before and after implementation of the policy were compared, the rate of admissions for acute coronary syndrome fell by 17%. In comparison, during that time in England (where there were no smoke-free laws), the rate fell by only 4%, and during the preceding decade in Scotland, the rate decreased by an average of 3% per year. Serum cotinine was measured in patients during this time. The self-reported exposure to secondhand smoke decreased among nonsmokers, and this decrease was validated on the basis of lower cotinine levels in those individuals.[11] Many other examples demonstrate the impact of smoke-free laws on public health, and it is not surprising that improved outcomes are seen among nonsmokers, but it is encouraging that improved outcomes can be found among smokers as well, likely as a result of a reduction in tobacco use despite the fact that they are still smoking.

Offer Help to Quit Tobacco Use

Many people who use tobacco may not actively seek assistance with cessation because of either a lack of interest in quitting, the perceived futility of cessation efforts, the stigma associated with tobacco use, or a lack of willingness to invest the time and financial resources to support their desire to quit. The International Association for the Study of Lung Cancer conducted a survey regarding the smoking-cessation practices among its members (response rate, 40.5%).[12] According to the survey, 90% of respondents believe that current smoking affects clinical outcomes and that cessation should be a standard part of care; 90% ask their patients about smoking at the time of the initial visit; 81% advise their patients to quit (but only 40% discuss pharmacotherapy); and 39% provide cessation assistance. These survey results likely represent a best-case scenario for cancer providers, as the respondents were members of an international multidisciplinary lung cancer organization who were motivated to respond to the survey and because the survey responses were self-reported. By contrast, the rates of primary physician queries about smoking and advice on cessation have been disappointingly low, likely driven by the perceived of lack of efficacy of such efforts among practitioners.

However, although many people who smoke may not quit on the basis of their physician's advice, brief counseling from primary physicians at every visit could have a substantial impact. In one of the first landmark studies on this subject, published in 1979, researchers from London found that physician practices such as asking patients about tobacco use, advising patients to stop smoking, providing informational pamphlets, and telling patients they will be called for follow-up yielded a 5.1% quit rate at 1 year.[13] Although this quit rate was modest, it was significantly higher than the rate for the control group (0.3%; $p < 0.001$). This finding suggests that active cessation interventions by primary care physicians could substantially impact the number of people who would quit. Unfortunately, as yet, primary care providers often do not follow the most basic steps of asking patients about smoking, advising them to stop smoking, and referring them to a cessation service such as a telephone quitline or other resource.

In many countries, quitlines are able to offer assistance with cessation. In the United States, many, but not all, of the quitlines run by individual states provide pharmacotherapy such as nicotine-replacement therapy. However, most countries are not able to afford this type of intervention. For many people who smoke, the cost of the nicotine-replacement therapy can exceed the cost of cigarettes. The convenience of the quitline, the availability of nicotine-replacement therapy, and the free-of-charge service would lead one to think that quitlines are popular, but the penetrance of quitlines is low, even in developed countries. For example, Australia has extremely aggressive and successful tobacco-control programs, with the quitline number displayed in all retail outlets, on every package of cigarettes, and in advertisements as part of a mass media campaign, yet one study demonstrated that only 3.6% of people who smoke used the service in 1 year, suggesting that many people who smoke may not initiate the call for help in quitting and may not be interested in asking for help.[14]

Compared with face-to-face counseling with a physician or other health-care provider, quitlines are more convenient, less costly, and more easily approached by reluctant smokers. A cost analysis of a national quitline in Sweden demonstrated a 31% self-reported 1-year quit rate with an estimated cost of $1052 to $1360 per quitter and of $311 to $401 per life year saved, indicating that the quitline was less costly than other modalities that were analyzed, such as counseling by a general practitioner, a community mass media campaign, and bupropion treatment.[15]

Warn About the Dangers of Tobacco

Education regarding the addictive and harmful nature of smoking can be delivered in multiple ways, including (but not limited to) physician–patient interactions, education in schools, public announcements on television and radio, warning labels on cigarettes, and print and outdoor advertisements related to the effects

of tobacco. One of the simplest and least expensive ways to distribute education about tobacco is through mandatory warning labels on tobacco packaging. A 2006 study conducted in four countries (the United States, the United Kingdom, Australia, and Canada) demonstrated that larger warnings and graphic warnings were more effective for communicating the risks of smoking compared with the very inconspicuous United States warnings.[16] Another report on warnings in these same countries was published in 2009, after the use of graphic warnings had been implemented in Australia. The impact of health warnings was evaluated by comparing graphic warnings from Australia and Canada with text-only warnings from the United Kingdom and the United States.[17] The new graphic warnings in Australia increased smokers' salience (reading and noticing), cognitive reactions (thinking about harm and quitting), and behavioral responses (forgoing cigarettes and avoiding the warnings).

Clearly, graphic warning labels are important means of communication in areas with lower literacy rates, but, even for populations with higher literacy rates, the graphic labels have greater impact and are associated with lower smoking rates. While public media campaigns and advertisements that warn about the dangers of tobacco have been shown to be effective, they do require financial resources for the creation and distribution of the messages and ongoing funding for maintenance. The implementation of policies regarding enlarging warning labels and including graphic warnings does not require ongoing cost to the government and literally puts an effective warning message in the hands of every tobacco user.

Enforce Bans on Tobacco Advertising, Promotion, and Sponsorship

The tobacco industry spends tens of billions of dollars annually to promote its product, which in turn kills up to half of its users. The industry depends on promotion to maintain its current customer base and to recruit "replacement smokers," that is, to replace the minority of smokers who successfully quit and the masses who die of tobacco-related diseases. An Article of the WHO FCTC states that all parties must implement comprehensive restrictions on tobacco advertising, promotion, and sponsorship within 5 years.[13] In many countries, particularly those with developing economies, tobacco use among women traditionally has not been high and women are viewed as a growth market by industry because of growing financial and social independence. It is unsurprising that women and minors have been the targets of many tobacco advertising, promotion, and sponsorship activities, with the rate of smoking among women expected to double between 2005 and 2025.[18] Because of this selective targeting, tobacco control also needs to be gender and age based in its approach. Exposure to tobacco advertising, promotion, and sponsorship is associated with a higher prevalence of smoking, and a comprehensive ban on such activities leads to lower exposure to these messages, a finding that has held true across different socioeconomic groups.[19] Bans on tobacco advertising, promotion, and sponsorship have been shown to decrease smoking rates in both developed and developing countries.[20,21]

Raise Taxes on Tobacco

"Of all the concerns, there is one—taxation—that alarms us the most. While marketing restrictions and [restrictions on] public and passive smoking do depress volume, in our experience taxation depresses it much more severely."[22]

These words from the tobacco industry, written more than 25 years ago, still hold true today. A 10% rise in retail price will result in a 4% decrease in cigarette sales through both increased cessation and reduced consumption by active smokers in developed nations and in an estimated 8% decrease in middle- to lower-income countries.[23] The fact that tobacco disproportionately affects lower socioeconomic groups that are linked with a greater elasticity (i.e., reduced sales with increased price) makes increasing the cost a logical tobacco-control strategy, particularly with respect to these lower socioeconomic groups. While some tobacco-control policies (e.g., media campaigns and cessation-support services) require ongoing financial resources and others (e.g., clean indoor air policies and policies banning advertisement) are fairly inexpensive to implement, taxation has the unique ability to effectively suppress tobacco use and generate revenue. Unfortunately, of the $133 billion globally generated by tobacco taxation, less than 1% of revenues collected in tobacco taxes are reinvested in prevention or cessation efforts.[24] A progressive approach to tobacco taxation was implemented in Costa Rica in 2012, with a rise in tobacco taxes of approximately $0.80 per pack. This change increased total taxes from approximately 56% to 71% of the cost of a pack of cigarettes, and all of the new tax revenue was earmarked for cancer treatment, tobacco-prevention and cessation services and research, support of the nation's Health Promotion Act, and other health-related measures. Although not all of these measures are directly related to tobacco control, some of the increased funds will directly benefit prevention, cessation, treatment, and patient-support efforts. A provision of this act is that taxes will automatically increase annually to keep pace with inflation.[25] Taxes passed as a flat tax amount per quantity of tobacco will be eroded by inflation over time unless levied as a percentage of the price or adjusted for inflation.

Combinations of Measures

Typically, successful tobacco control is implemented not as a single measure but rather as part of a more comprehensive multifaceted approach involving several of the aforementioned concepts; therefore it may be difficult to distill the impact of one measure on smoking rates when several are implemented in combination. For example, in California, clean indoor air legislation was accompanied by increased tax and antitobacco advertising. This combination resulted not only in a lower smoking prevalence but also lower per capita cigarette consumption. Reducing smoking is the aim of these programs, but the deeper overall goal is to improve public health, and therefore outcomes such as the lower mortality from heart disease and the decreased rates of bladder cancer and lung cancer that were found following the implementation of the California comprehensive tobacco program[26,27] further strengthen the need for multidimensional tobacco-control programs.

Some of the strongest tobacco-control measures that have an impact on several of the aforementioned categories have been developed in Australia. For example, the implementation of plain packaging regulations in Australia acts in several dimensions by providing health warnings and the quitline number while also eliminating brand image and advertising and promotion on the packaging itself. This approach not only has resulted in the distribution of warnings and the promotion of quitlines but has also been shown to decrease the appeal of smoking and to increase thoughts about quitting.[28]

Impact of Tobacco Control on Lung Cancer Mortality

As described in the previous section, effective tobacco-control efforts have been well defined and have a strong evidence base. The MPOWER strategy was developed by the WHO to assist countries in implementing the FCTC. The impact of tobacco-control efforts on the incidence of and mortality resulting

from lung cancer is demonstrated by the Lopez curves describing the stages of the smoking epidemic and the consequent epidemic of lung cancer (Fig. 2.1).[29] Unfortunately, only a few of the more economically developed countries heeded the epidemiologic news from the 1950s that smoking causes lung cancer.[30,31]

Doll et al.[32] demonstrated significantly improved survival for British male physicians who were nonsmokers (Fig. 2.2) and also significant benefits for physicians who had smoked but quit. Predominantly because of this cessation, Britain was also the first country to have a drop in lung cancer rates among men (Fig. 2.3).[29] Australia and the United States were close behind, but, interestingly, the decline was slower. Unfortunately, the lung

cancer rates among women do not replicate the rates among men in different countries because of the variety of cultural influences on smoking prevalence. These changes in the United States and the United Kingdom were primarily driven by smoking cessation as a result of epidemiologic evidence linking disease to smoking. In the United States, the peak prevalence of male smokers started to decline after the 1930 birth cohort as a result of smoking cessation (Fig. 2.4).[33] In the United Kingdom, the rates of smoking among both male and female individuals and the annual rates of lung cancer–related death (Fig. 2.5) declined.[34] These changes indicate that smoking cessation occurs as a result of public education about the risks of smoking in the years following these early epidemiologic studies on lung cancer.

In both the United Kingdom and the United States, large-cohort epidemiologic studies were established to quantify the risk of lung cancer with continued smoking and the markedly decreased risk with cessation. Data from the United Kingdom demonstrate that the decrease in lung cancer mortality depends on the age at the time of tobacco cessation (Fig. 2.6).[34] These data indicate that even middle-aged individuals who stop smoking before they have incurable lung cancer or another fatal disease avoid most of their risk of being killed by tobacco. Smoking cessation before middle age reduces the risk further.[33]

As already noted, education can lead to cessation, which results in fewer people smoking and a decrease in the incidence of lung cancer. Sharing of educational information with the public was the first demonstration of how tobacco-control efforts could affect the incidence of tobacco-related disease, such as lung cancer. Subsequently, other countries implemented policies that have an impact on the incidence of lung cancer.

Another mechanism to reduce smoking levels was introduced in Sweden, where the GOTHIATEK standard for the manufacturing of a smokeless tobacco product (Swedish snus) was instituted in the 1980s and 1990s.[35] The transition to the GOTHIATEK standard was an incremental process and was influenced by regulatory oversight by the Swedish Food

Fig. 2.2. Survival after 35 years of age for continuing smokers and non-smokers among male physicians in the United Kingdom (born between 1900 and 1930). Authority in the 1970s. Smokeless tobacco products were initially manufactured by the government-controlled Swedish tobacco industry, but, since the 1990s, the manufacturing was privatized into the company Swedish Match North Europe AB. As a result of marketing efforts, lower price, social pressure, or,

most likely, some combination of these influences, men in Sweden began to use more Swedish snus than combusted tobacco (as in cigarettes).

Snus is a smokeless product that has been manufactured in Sweden since the 1800s and has since spread to other, mostly Scandinavian, countries. Snus also has migrated to the United States and is now manufactured by several different tobacco companies, although Swedish Match notes that these products are not analogous to Swedish snus because they are not made with adherence to the GOTHIATEK standard. The GOTHIATEK standard was developed to be consistent with Swedish food standards and, through the adherence to several manufacturing standards, provides for low levels of microbiologic growth, heavy metals, and nitrosamines. As a result of Swedish men switching to snus in the 1970s, the rate of smoking among Swedish men decreased (Fig. 2.7).[35] Between 1980 and 2010, smoking rates in Sweden dropped from 36% to 12% among men and from 29% to 13% among women.[36,37] During those same years, the prevalence of snus use increased from 16% to 20% among men and from 1% to 4% among women,[36,37] which subsequently had an effect on the incidence of lung cancer and the trend in lung cancer–related mortality (Figs. 2.8 and 2.9).[38,39] Switching to a tobacco product that causes fewer deaths among men, particularly deaths from lung cancer, is a type of smoking cessation, but this change resulted from both educational awareness of tobacco-induced mortality and the marketing of a smokeless tobacco product manufactured according to GOTHIATEK standards, which allowed for a substantial change of the addictive habit

from a combusted to a noncombusted nicotine-delivery product. Women in Sweden have been slower than men to switch to snus or to stop smoking.

The next movement in tobacco control was the push for smoke-free environments. The rationale for smoke-free environments was based on data demonstrating that exposure to secondhand smoke is also detrimental to health, with increased asthma attacks and more deaths from conditions related to

Fig. 2.6. Cumulative risk of smoking cessation at different ages in the United Kingdom. *(Reprinted with permission from Peto R, Darby S, Deo H, Silcocks P, Whitley E, Doll R. secondhand combusted tobacco or from lung cancer–related deaths among individuals exposed to secondhand smoke than individuals not exposed. The intention of these laws was built on the evidence that eliminating exposure to secondhand smoke would benefit the health of those who had been previously exposed. Although many localities established second-hand smoke laws, Ireland was the first country to implement a comprehensive ban on smoking in the workplace. Other regions restrict where smoking is allowed, specifying that smoking is not allowed in such locations as the workplace, public spaces, or outdoor venues (e.g., stadiums, parks, or beaches). These restrictions have had an impact on how much individuals smoke; as a result of smoke-free workplace policies, cigarette consumption has decreased in the United States, Germany, and Japan.[40–42] It is important to note, however, that the risk of lung cancer is more strongly related to the duration of smoking than to the number of cigarettes smoked per day.[43,44] Other tobacco-control policies as delineated by MPOWER also will decrease the number of people who smoke or use other tobacco products. Price controls (usually through increased taxes), restrictions prohibiting advertising and marketing, and measures designed to help people to quit are a few of the major policies that have been recommended. Different countries are in various stages of implementing these policies, and the strength and breadth of their implementation and enforcement will have an impact on the rates of smoking and, as a direct consequence, the rates of lung cancer.

Various grading systems have been developed to illustrate the relationship between the degree of tobacco-control implementation and lung cancer. A tobacco-control scorecard was proposed by Levy et al.[45] in 2004 to assess the success of implemented policies. Joossens and Raw,[46] in a report prepared for the Association of European Cancer Leagues, described the use of The Tobacco Control Scale to examine policies across countries in the European Union. Interestingly, the United Kingdom and Ireland were considered to have the best tobacco-control policies among the participating countries in the European Union, whereas Sweden was ranked ninth, despite having the lowest rates of male individuals who smoke and the lowest rates of lung cancer for men among developed countries. Thus the correlation between tobacco-control policies and smoking prevalence is not yet tight.

Concern about passive smoking and tobacco control policies in European countries: an ecological study.* BMC Public Health. *2012;12:876.)*

More recently, denormalization of tobacco use has been considered as a potential powerful driver for decreasing tobacco use (smoking or using smokeless tobacco) and increasing support for tobacco-control policies. Willemsen and Kiselinova[47] compared the European Union Tobacco Control Scale with each country's smoking rates, and the only significant finding was the correlation between concern for the health effects of secondhand smoke and stronger tobacco-control policies (Fig. 2.10). In turn, there was an association between strong tobacco-control policies and lower smoking rates, although the association was not significant. The achievement of significance was based entirely on the data from the United Kingdom and Ireland. Both of those countries have strong tobacco-control polices and lower smoking rates. As noted earlier, the decline in smoking in the United Kingdom, particularly among male individuals, started as a result of the epidemiologic studies from the 1950s, and Ireland was the first country to institute a strong secondhand smoking law (in 2004) that had strong societal support. Willemsen and Kiselinova[47] suggested that denormalization of tobacco use in a society is a result of education and internalization of the harms of secondhand smoke and leads to stronger tobacco-control policies and, probably, to lower smoking rates.

To address the question of whether tobacco-control policies, which do decrease tobacco use, also will decrease the incidence of lung cancer, Thun and Jemal[48] estimated that decreases in smoking rates in the United States resulted in 146,000 fewer lung cancer–related deaths among men between 1991 and 2003. Building on that study, six universities developed models to address the impact of tobacco-control policies on smoking rates and lung cancer mortality.[49] In the development of these models, the authors considered what would have happened if there had been no tobacco-control efforts and the smoking rates of the 1950s had persisted. Next, they considered the impact of the changes resulting from tobacco-control efforts and the actual decreases in smoking rates in the United States. Lastly, they considered what the lung cancer mortality rates would have been if there had been so-called complete tobacco control; that is, all smoking stopped abruptly as of the 1965 Surgeon General Report. The findings are striking (Fig. 2.11). The results of this modeling suggested that 795,851 deaths were prevented between 1975 and 2000 (552,574 in men and 243,277 in women) as a result of actual tobacco-control efforts. Although the number of deaths prevented alone is remarkable, the total number of preventable deaths with optimal tobacco control is threefold greater. If complete tobacco control had been achieved, 2,504,402 deaths from lung cancer could have been prevented between 1975 and 2000.

CONCLUSION

Various tobacco-control strategies have been used with various degrees of success across populations. The WHO FCTC outlines an international collaborative front to this globally spreading epidemic. Although societies around the globe differ widely in language, cultural norms, economic resources, and smoking rates, nearly all societies are afflicted with the tobacco epidemic, and a concerted effort using evidence-based strategies can alter the future course of this epidemic, with the potential to save millions of lives. One cannot truly consider the magnitude of the effect of good tobacco control (or even complete tobacco control) and its impact on global morbidity and mortality from lung cancer without questioning why we are not doing much, much more than we already are.

3 Assessing and Treating Tobacco Use in Lung Cancer Care

Jamie S. Ostroff and Elyse R. Park

SUMMARY OF KEY POINTS

- Addressing tobacco dependence in patients with cancer increases the quality of care by reducing their risk for treatment complications, improving their prognosis, and reducing the risk of disease recurrence and second primary cancers.
- Smoking cessation after a diagnosis of lung cancer has been shown to have a beneficial effect on performance status.
- Many patients with cancer who smoke want to quit but unfortunately do not receive support and evidence-based tobacco treatment.
- Further provider training and research are needed to determine strategies to implement best practices for treating tobacco dependence among patients with cancer.
- In the absence of tobacco cessation interventions, lung cancer specialists are encouraged to follow general clinical practice guidelines for treating tobacco use and dependence.
- Lung cancer screening provides an invaluable opportunity to promote tobacco cessation.
- There is much debate and little data as to whether e-cigarettes or other electronic nicotine delivery devices will facilitate or impede smoking cessation.

In 1964, the landmark US Surgeon General's report, Smoking and Health, first linked smoking to lung cancer. This irrefutable knowledge about the harms of tobacco spawned five decades of tobacco prevention and control research and policy, resulting in a rich compendium of comprehensive national and international evidence-based, population-based, and clinical practice guidelines aimed at reducing tobacco-related morbidity and mortality.[1–3] Smoking not only has a causal link with disease and death but also has adverse effects on outcomes for patients with a wide range of chronic diseases, including cancer.[4] Now more than ever, tobacco cessation is firmly within the purview of modern oncology. By highlighting the specific adverse effects of persistent tobacco use on cancer outcomes, this chapter provides justification for why lung cancer specialists should assess and treat tobacco use and direction for how lung cancer specialists can help their patients stop smoking.

WHY LUNG CANCER SPECIALISTS SHOULD HELP THEIR PATIENTS STOP TOBACCO USE

Cigarette smoking is the primary risk factor responsible for 87% and 70% of lung cancer deaths in men and women, respectively,[5] making tobacco prevention and cessation essential goals for lung cancer prevention and control. Despite five decades of national and international public health accomplishments in reducing the morbidity, mortality, and economic costs of tobacco-induced diseases, there are currently an estimated 42.1 million current smokers (18.1% of all adults) in the United States alone and at least one billion smokers worldwide.[6,7] Tobacco kills nearly six million people each year; more than five million of those deaths are the result of direct tobacco use, and more than 600,000 are the result of nonsmokers being exposed to secondhand smoke. Unless urgent action is taken, the annual death toll could rise to more than eight million by 2030.[8]

Risks of Persistent Smoking and Benefits of Cessation on Lung Cancer Outcomes

Health-care providers who treat patients with cancer may assume that it is too late after diagnosis to intervene about smoking. However, an emerging body of evidence demonstrates that smoking is associated with several adverse outcomes for patients with cancer, such as increased complications from surgery, increased treatment-related toxicity, decreased treatment effectiveness, poorer quality of life, increased risk of recurrence, increased risk of second primary tumors, increased noncancer-related comorbidity and mortality, and decreased survival.[9–11] Although the number of clinical studies on the effects of smoking cessation in patients with cancer is limited, the existing data suggest that many of the adverse effects of smoking can be reduced with cessation.[12]

Although these adverse outcomes are applicable to patients diagnosed with a wide range of cancers, much of this research has focused on identifying the adverse effects of smoking for patients diagnosed with lung cancer.[12,13] Continued smoking after the diagnosis of lung cancer has been associated with treatment delays and increased complications from surgery, radiotherapy, and chemotherapy.[14] Adverse effects from continued smoking at the time of surgery include complications from general anesthesia, increased risk of severe pulmonary complications, and detrimental effects on wound healing. Complications from smoking while receiving radiotherapy include reduced treatment efficacy and increased toxicity and side effects. Smoking while receiving chemotherapy alters the metabolism of many chemotherapy drugs, decreases the effectiveness of treatment, and increases drug toxicity.[15–20] Smoking cessation before lung cancer treatment reduces the risk of recurrence and the development of additional smoking-related cancers.[21,22] Although further research is needed to examine the beneficial effects of smoking cessation in patients with cancer, smoking cessation after a diagnosis of lung cancer has been shown to have a beneficial effect on quality of life and performance status.[23,24]

Prevalence of Persistent Smoking Among Patients With Lung Cancer

Despite these risks, at least 15.1% of all adult cancer survivors report current cigarette smoking.[25] Patients with lung cancer tend to be motivated to quit smoking at higher rates than patients diagnosed with other cancers.[26,27] Focusing exclusively on the prevalence of smoking in lung cancer, 90.2% of patients with lung cancer report ever-smoking. At the time of diagnosis, 38.7%

of patients with lung cancer report current smoking, whereas 5 months after diagnosis, at least 14.2% of patients with lung cancer report current smoking.[28] Despite heavy encouragement to quit smoking and strong intentions to quit, continued tobacco use after diagnosis and resumption of smoking after initial quit attempt remains a problem in this patient population, with an estimated 10% to 20% of all patients with lung cancer smoking at some point after diagnosis.[28–32]

FACTORS ASSOCIATED WITH PERSISTENT SMOKING AMONG PATIENTS WITH LUNG CANCER

Physicians who treat patients with cancer, especially lung cancer specialists, may not understand why some patients continue to smoke. A few studies have examined factors associated with persistent smoking and smoking relapse after quit attempts.[33–35] For patients with lung or head and neck cancer who were smoking within the week before surgery, smoking relapse in the following year was predicted by lower baseline quitting self-efficacy, higher tendency for depression, and greater fears about cancer recurrence; whereas among patients who had stopped smoking before surgery, higher perceived difficulty quitting and lower cancer-related risk perceptions predicted smoking relapse.[33] In another longitudinal study of patients with early-stage lung cancer, low household income, exposure to environmental tobacco smoke at home, and evidence of depression were positively associated with return to smoking.[34] In a particularly noteworthy study, Park et al.[28] also examined factors associated with continued smoking among patients with lung cancer enrolled in the national, population-based Cancer Care Outcomes Research and Surveillance (CanCORS) cohort; at 4 months after diagnosis, younger age, more advanced disease, history of cardiovascular disease, lower social support, poorer perceived health, higher fatalism, greater pain, and depression were all identified as significant factors associated with continued smoking ($p < 0.05$).

ASSESSING TOBACCO USE AND INTEGRATING EVIDENCE-BASED TOBACCO TREATMENT IS AN INDICATOR OF HIGH-QUALITY ONCOLOGY CARE

Addressing tobacco dependence in patients with cancer increases the quality of care by reducing their risk for treatment complications, improving their prognosis, and reducing the risk of disease recurrence and second primary cancers. Clinicians have a responsibility to their patients to provide them with the best quality of care possible, and this care should include cessation treatment for those patients who smoke.[36,37] Growing awareness of the cancer-specific health risks, the emerging lines of evidence that quitting smoking may improve the prognosis for patients with cancer, and the prevalence of persistent smoking provide a strong argument for providing evidence-based treatment of tobacco dependence as a standard of quality care in cancer settings.[35,38,39] In fact, there is a growing consensus among oncology leadership organizations that assessment of tobacco use and treatment should be a metric for quality of care.[40–43] As such, oncologists are encouraged to assess smoking status and advise cessation for patients who smoke.[10,44,45] In keeping with this quality-of-care perspective, the American Society of Clinical Oncology's Quality Oncology Practice Initiative (ASCO QOPI) includes documentation of current smoking status and counseling for all smokers, by the second office visit, as a core quality indicator.[42,46,47] In recognition of the few number of clinical trials that assess tobacco use, a National Cancer Institute-American Association for Cancer Research (NCI-AACR) Task Force on Tobacco Use and Assessment has recommended assessment of tobacco use in cancer clinical trials.[48]

DELIVERY OF EVIDENCE-BASED TOBACCO DEPENDENCE TREATMENT IN CANCER SETTINGS IS CURRENTLY SUBOPTIMAL

Many patients with cancer who smoke want to quit but do not receive support and evidence-based tobacco treatment. During cancer treatment, many smokers are not even advised to quit, and after cancer treatment is completed, tobacco use is often not addressed.[49,50] In a recent survey of ASCO members, the ASCO Tobacco Subcommittee found that oncologists provide quitting advice to 25% of their patients.[51] In addition, most cancer care settings have not yet established tobacco cessation treatment as standard care; a 2012 survey found that 97% of NCI-designated comprehensive cancer centers in the United States said that having a tobacco treatment program was "very important," but only half had any type of tobacco treatment program.[52]

Most germane to determining the current status of assessing and treating tobacco dependence among patients with lung cancer are the findings of an online survey of International Association for the Study of Lung Cancer (IASLC) members, which addressed the practices, perceptions, and barriers to tobacco assessment and cessation in patients with thoracic cancer.[53] More than 90% of the 1507 physician respondents (representing 40.5% of all IASLC members) said that current smoking affects outcome and that cessation should be a standard part of clinical care. At the initial patient visit, 90% said they ask patients about tobacco use, 79% said they ask patients whether they will quit, and 81% said they advise patients to stop tobacco use, but only 40% said they discuss medication options, and 39% said they actively provide cessation assistance; fewer respondents said they address tobacco use at follow-up. Respondents identified pessimism regarding their ability to help patients stop using tobacco (58%) and concerns about patient resistance to treatment (67%) as the leading barriers. Only 33% said they felt adequately trained to provide cessation interventions.

These survey findings highlight the need to examine barriers to tobacco treatment delivery in cancer care. Barriers to addressing tobacco use include patient-related factors (shame, helplessness, addiction), physician-related barriers (lack of training and referral options, beliefs about patients' lack of interest or ability to quit), and system-level factors (inadequate identification of smokers, costs) that impede the delivery of effective tobacco programs.[54] In recognition of this problem, the NCI convened a conference to review the state of tobacco treatment at NCI-designated comprehensive cancer centers and formulate recommendations for improvement.[55] The survey findings underscore the considerable need for further provider training and research aimed at determining strategies to implement best practices for treating tobacco dependence among patients with cancer.

TREATMENT OF TOBACCO DEPENDENCE IN LUNG CANCER CARE

As summarized in a recent review, randomized controlled trials of pharmacologic and counseling interventions for cessation conducted with tobacco-dependent patients with cancer have generally not shown significant treatment effects, with 6-month point abstinence rates ranging from 14% to 30% among patients assigned to the intervention conditions.[56] Few randomized controlled trials have been conducted to test the effectiveness of cessation pharmacotherapy for patients with cancer who smoke. Schnoll et al.[57] conducted a placebo-controlled trial to evaluate the efficacy of bupropion and found benefit (reduced withdrawal symptoms and increased abstinence rates) only for the subset of patients with cancer who had symptoms of depression. In a pilot study, Park et al.[58] found significantly higher quit rates among patients with thoracic cancer who received varenicline and intensive counseling than among patients who received usual

(unspecified) care (smoking abstinence at 3 months: 34.4% vs. 14.3%; *p* = 0.18). Ostroff et al.[27] examined the utility of adding a presurgical tapering regimen to nicotine-replacement therapy and cessation counseling by telephone and found a 32% rate of smoking abstinence at 6-month follow-up for both interventions. In terms of optimal timing for the delivery of tobacco treatment, it appears that the closer to the time of diagnosis that smoking cessation treatment is delivered, the higher the likelihood for continued smoking abstinence.[59,60] These findings illustrate the need for continued development and evaluation of novel smoking cessation interventions that are acceptable and efficacious for patients with cancer and are feasible to deliver across a wide range of cancer care settings. In the absence of tobacco cessation interventions tailored and targeted to patients with cancer, lung cancer specialists are encouraged to follow general clinical practice guidelines for treating tobacco use and dependence.[61]

Guidelines for Treating Tobacco Use

Most recently updated in 2008, the US Public Health Service Treating Tobacco Use and Dependence Clinical Practice Guideline (PHS guideline) recommends that evidence-based tobacco treatment be delivered to all smokers in health-care settings.[3] Specifically, these guidelines recommend that a combination of medication and counseling be used, that counseling involve multiple sessions, and that clinicians use the five As: ask, assess, advise, assist, and arrange. Clinicians, especially thoracic cancer specialists, are encouraged to ask all their patients about their smoking status at every encounter. Once current smokers are identified, clinicians should assess their readiness to quit in order to determine what forms of assistance are needed. Smokers' quitting readiness is commonly classified as either precontemplation (no immediate plans to quit), contemplation (plan to quit within 6 months), preparation (planning to quit within a month), action (quitting for less than 6 months), or maintenance (staying quit for at least 6 months). Clinicians should strongly advise their patients against smoking, providing a personalized risk of persistent smoking and benefits of cessation in relation to the patient's disease and treatment. The next A, assist, speaks to the active role the clinician should play in his or her patients' cessation efforts by providing education, addressing barriers to quitting (such as concerns about coping), suggesting behavioral strategies that may help them overcome these barriers, developing a quit plan, and prescribing pharmacotherapy, as needed. For patients who are reluctant to quit, clinicians need to provide motivational counseling in an effort to encourage them to at least reduce their daily cigarette consumption. Considering the high rate of smoking relapse, patients who have recently quit (maintenance phase) should be reassessed for smoking lapses and given prolonged support and encouragement to remain abstinent from smoking. Lastly, clinicians are encouraged to arrange follow-up support, such as reevaluation of the smoking status during subsequent visits or referrals to other resources, such as quit-lines or onsite tobacco treatment specialists.

Pharmacotherapy

The PHS guideline strongly recommends that pharmacotherapy be used along with counseling in order to optimize cessation outcomes. Several medications are safe and effective for smoking cessation: nicotine-replacement therapies (in the form of a patch, gum, lozenge, nasal spray, or inhaler), bupropion, and varenicline (Table 3.1).

Because they are well-tolerated and acceptable to most patients, nicotine-replacement therapies should be recommended to all smokers except for patients in whom these treatments are contraindicated. Bupropion is an antidepressant that reduces withdrawal symptoms and, although it is not limited to patients

with cancer, it may be especially useful in such patients who have depression. Varenicline is a partial nicotinic agonist that reduces the urge to smoke by binding to the nicotine receptors in the brain. Neuropsychiatric adverse events (e.g., depression, agitation, suicidal ideation) are rare, but patients should be monitored closely for this and other adverse effects.

It has been shown that combination pharmacotherapy may be more effective than single-agent treatment for tobacco dependence. Nicotine-replacement therapies may be combined, with a long-acting treatment such as the patch, used to maintain a steady level of nicotine and thus decrease cravings and withdrawal symptoms throughout the day, and a short-acting treatment, such as a lozenge, gum, or inhaler, used as needed. In comparison to monotherapy, the use of combination nicotine-replacement therapies increases the likelihood of achieving long-term smoking abstinence.[3] Nicotine-replacement therapies may also be used in conjunction with sustained-release bupropion.

After completion of cancer treatment, resumption of smoking is common and therefore it is essential for clinicians to reassess smoking status during follow-up visits and provide motivational counseling to help patients remain abstinent. For patients who decline pharmacotherapy support or in whom cessation drugs are contraindicated, counseling should still be included as part of treatment.

SPECIAL CONSIDERATIONS IN TREATING TOBACCO DEPENDENCE IN PATIENTS WITH CANCER

Considering the negative effects of smoking for patients with cancer,[62] oncologists should include cessation as part of treatment planning and address barriers to quitting. Because most patients will have made prior quit attempts, clinicians must provide empathy and support for their patients' quitting efforts. Some unique barriers that may exist for patients are ambivalent motivation, self-blame and internalized stigma, nihilism ("why bother?"), psychologic distress, and living with other smokers. Encouraging patients to seek psychosocial support services acknowledges the need for assistance in developing alternative strategies for coping with the stress of cancer and its treatment. Little progress has been made to integrate these guidelines into cancer care settings and there is a paucity of data on how best to promote cessation among patients with cancer.

FUTURE DIRECTIONS

Two emerging hot topics relevant to tobacco treatment and lung cancer warrant further attention from lung cancer specialists: lung cancer screening and e-cigarettes.

Lung cancer screening provides an invaluable opportunity to promote tobacco cessation. The findings from the National Lung Cancer Screening Trial and the release of the US Preventive Services Task Force recommendations for annual low-dose computed tomography screening for lung cancer for adults aged 55 to 80 years old who are at high risk for lung cancer because of their age and smoking history provide a compelling opportunity for the delivery of smoking cessation treatment.[63,64] Because lung cancer screening programs are being developed for people with a longstanding history of heavy tobacco use, these programs provide an exciting vehicle for integrating smoking cessation efforts into lung cancer screening protocols. Several studies have reported cessation rates ranging from 6.6% to 42% following enrollment in lung cancer screening programs.[65–73] The authors of a 2012 review describe these studies as collectively providing much promise for lung cancer screening as a so-called teachable moment for reaching smokers and promoting cessation through the delivery of evidence-based tobacco cessation treatment.[74] Although smokers seeking lung cancer screening appear motivated to quit,[71] the use of evidence-based smoking cessation

TABLE 3.1 Pharmacotherapy for Smoking Cessation

Pharmacotherapy	Dosage	Duration (wks.)	Availability	Precautions/ Contraindications	Adverse Effects	Patient Education
Nicotine patch	If smoking ≥11 cigarettes/d: 21 mg/24 h 14 mg/24 h 7 mg/24 h If smoking ≤10 cigarettes/d: 14 mg/24 h 7 mg/24 h	6 2 2 6 2	Over the counter	Uncontrolled hypertension	Skin irritation (redness, swelling, itchiness) Sleep disruptions (nightmares, vivid dreams)	Rotate patch site daily Remove patch before bedtime if sleep is disrupted and bothersome
Nicotine polacrilex gum	If smoking ≤24 cigarettes/d: 2 mg If smoking ≥25 cigarettes/d: 4 mg	Up to 12	Over the counter	Poor dentition Xerostomia	Hiccups Upset stomach Jaw ache	Chew gum on a fixed schedule Chew each piece of gum and then place between the gums and cheek for 30 min (so-called chew and park) Avoid eating or drinking anything except water 15 min before chewing and during chewing Do not exceed 24 pieces of gum in 24 hours
Nicotine lozenge	If smoking first cigarette more than 30 min after waking up: 2 mg If smoking first cigarette within 30 min after waking up: 4 mg	Up to 12	Over the counter	Xerostomia	Local irritation to mouth and throat Upset stomach	Avoid eating or drinking anything except water 15 min before and during use of a lozenge The lozenge will take 20–30 min to dissolve Do not use more than 20 lozenges in 24 h
Nicotine inhalation system	6–16 cartridges/d	Up to 26	Prescription		Local irritation to mouth and throat Upset stomach	Each cartridge will take 80–100 inhalations over 20 min Puff on inhaler like a cigar
Nicotine nasal spray	0.5 mg/inhalation/ nostril 1–2 times/h (or as needed)	Up to 12	Prescription	Sinus infections	Irritation to nose, eye, or upper respiratory system	Nasal irritation may become less bothersome with continued use
Bupropion	Days 1–3: 150 mg daily Thereafter: 150 mg twice daily	12	Prescription	History of seizures History of eating disorders (bulimia, anorexia)	Insomnia Xerostomia Restlessness Dizziness	Overlap with smoking for 1–2 weeks Do not need to be tapered off drug
Varenicline	Days 1–3: 0.5 mg daily Days 4–7: 0.5 mg twice daily Day 8–end of treatment: 1 mg twice daily	12[a]	Prescription	Kidney problems or treatment with dialysis Pregnancy or plan to become pregnant Breastfeeding	Mild nausea Sleep problems Headaches	Take medication with a full glass of water after eating a meal Allow 8 h between each dose Take medication a few hours before bedtime to avoid restlessness

[a]If the patient has quit smoking, treatment for another 12 weeks may be given to prevent smoking relapse.

treatments among screening enrollees is low, and the rate of persistent smoking is high 1 year after enrollment. All smokers seeking lung cancer screening should be advised to quit and provided with access to evidence-based cessation treatments.[75] Further research examining the development and evaluation of tobacco treatment interventions for smokers seeking lung cancer screening is needed.

Identified as a so-called disruptive technology in the field of tobacco control,[76] e-cigarettes are battery-powered devices that mimic the hand-to-mouth sensory experience of smoking and typically deliver nicotine to the user. Cigarette smokers report using e-cigarettes to manage nicotine cravings and withdrawal symptoms, to reduce daily smoking consumption, and to quit smoking or avoid smoking relapse.[77] Given the increasing popularity and availability of e-cigarettes in the general population and the strong advice to quit smoking traditional cigarettes at the time of diagnosis, patients with cancer are likely to consider use of e-cigarettes.

There is much debate and little data as to whether e-cigarettes will facilitate or impede smoking cessation and reduction of known hazards of traditional cigarettes and other combustible tobacco products.[66] One recent observational study found no evidence that the use of e-cigarettes promoted smoking cessation among patients with cancer who were referred to a hospital-based smoking cessation program.[78] On the other hand, promising results were reported in two clinical trials conducted among smokers from the general population. Cessation outcomes were comparable with those observed in trials of nicotine replacement therapies.[79,80] Until more is known about the risks and benefits of e-cigarettes for patients with cancer, oncologists are likely to struggle with these complexities and face challenges in how to respond to patient inquiries. In 2014, the IASLC Tobacco Control and Smoking Cessation Committee published a commentary providing guidance to oncologists about what to recommend to their patients who may be struggling to stop smoking or wondering about e-cigarettes.[81] According to this guidance, oncologists should advise smokers to

quit smoking traditional cigarettes, encourage the use of FDA-approved cessation medications, refer patients for tobacco-cessation counseling, and provide education about the potential risks and lack of known benefits of e-cigarette use with regard to long-term cessation. These recommendations are quite similar to those made by an AACR-ASCO Task Force on electronic cigarettes and other electronic nicotine delivery systems.[82]

CONCLUSION

There is a strong rationale for assessing tobacco use and promoting smoking cessation among patients with cancer. The risks of persistent smoking for patients diagnosed with lung cancer are well established and include adverse outcomes such as treatment toxicities, cancer recurrence, second primary malignant tumors, decreased survival, and poorer quality of life. Given the cancer-specific health risks and the availability of clinical practice guidelines for treating tobacco dependence, oncologists are encouraged to assess smoking status and advise cessation for patients who smoke. Further research examining patient-, provider-, and system-related strategies for engagement and retention of smokers into evidence-based tobacco treatment is needed.

4 Lung Cancer in Never-Smokers: A Different Disease

Adi F. Gazdar and Caicun Zhou

SUMMARY OF KEY POINTS

- The known or suspected etiologic factors for lung cancer arising in never-smokers are weak carcinogens or rare factors, which cannot explain the relatively high frequency of cancer in never-smokers. This also applies to environmental tobacco smoke.
- Genetic factors play an increasing role in the etiology of lung cancer in never-smokers. These include rare high penetrance mutations in crucial genes such as the T790M mutation in the *EGFR* gene. However, high-frequency, low-penetrance variations in susceptibility genes are playing an increasingly prominent role. These include loci that predispose to smoking as well as those that may contribute directly to cancers arising in smokers and never-smokers.
- The molecular alterations in lung cancers arising in smokers and never-smokers are very different. Smoke related tumors are associated with high numbers of mutations, especially C:G>A:T transversions, while never-smoker tumors are associated with low numbers of mutations targeting C:G>T:A transitions.
- The specific mutational targets are also different in smoker and never-smoker tumors. Thus *KRAS* mutations are more frequent in ever-smoker tumors, while *EGFR* mutations and *ALK* translocations are more frequent in never-smokers. Paradoxically, the number of therapeutic actionable mutations is more frequent in never-smoker tumors.
- Lung cancers arising in never-smokers show major differences based on ethnicity, gender, and histology. The ethnic differences point out the importance of genetic susceptibility loci in the development of lung cancers.
- The major clinical, ethnic, gender, and histology differences between lung cancers arising from smokers and never-smokers, coupled with their different etiologic factors and major molecular differences, indicate that they represent very different tumor types, confirming that lung cancers in never-smokers represent a different form of cancer.

Lung cancer is the leading cause of cancer-related mortality worldwide, with about 1.4 million deaths each year.[1] In 2008, lung cancer was the most commonly diagnosed cancer globally, the leading cause of cancer-related death in men, and the fourth most commonly diagnosed cancer and second leading cause of cancer-related death in women.[1] The lung cancer incidence rate for men in East Asia ranks as the fifth highest in the world, after Eastern and Southern Europe, North America, Micronesia, and Polynesia, with an age-standardized incidence rate by gender and area of the world of 45.0 per 100,000 cases.[1] For women, the third highest lung cancer incidence rate is found in East Asia, Australia, and New Zealand, with 19.9 per 100,000 cases.[1] Interestingly, the lung cancer incidence rate for women is higher in China (21.3 cases per 100,000 women) than in Germany (16.4) and Italy (11.4), although adult smoking prevalence is substantially lower in China (4% vs. 20%).[2]

The World Health Organization estimates that lung cancer is the cause of 1.37 million deaths globally per year, or 18% of all cancer deaths.[1] An estimated 71% of lung cancers are caused by smoking, indicating that about 400,000 deaths each year are caused by lung cancer in lifetime never-smokers.[1] It has been estimated that 15% of men and 53% of women with lung cancer worldwide are never-smokers.[3] Thus, lung cancer in never-smokers is among the seven or eight most common causes of cancer death. However, lung cancer in never-smokers is often grouped together with lung cancer in ever-smokers. In this chapter, we describe the clinical-pathologic and molecular differences between these two types of lung cancer. Although several review articles have addressed this topic,[4–6] this chapter focuses on lung cancer in never-smokers in East Asian countries, where the incidence rate is higher than in other geographic regions. In addition, we discuss molecular differences between lung cancer in never-smokers and ever-smokers. For these purposes, we use standard definitions as follows:

KEY TERMS

Ever-smoker. An individual who has smoked 100 or more cigarettes during his or her lifetime.

Never-smoker. An individual who has smoked fewer than 100 cigarettes during his or her lifetime.

Current smoker. An individual who is currently smoking or who has quit smoking during the past 12 months.

Former smoker. An ever-smoker who quit more than 12 months earlier.

EPIDEMIOLOGY OF NONSMOKING-RELATED LUNG CANCER

Although numerous articles on lung cancer in never-smokers in Asia have been published, some data are inconsistent and other data are suspect, as the definitions of never-smokers are not uniform, and the quality of some of the data is questionable. Also, smoking incidence rates differ among women even within a single country. For example, the smoking incidence rates among women in northeastern China are considerably higher than the rates among women in southern China.[7] For these reasons, we extensively cite reviews or meta-analyses that combine data from multiple published reports and from cancer registries. By doing so, we can avoid some of the biases from small, individual studies, and we can place ethnic, gender, and geographic differences in their proper context. Findings from a case–control study on epidemiologic risk factors for lung cancer in never-smokers are described in a 2010 article by Brenner et al.[8]

A review of published studies on the epidemiology of lung cancer (18 studies, comprising 82,037 people) showed a marked gender bias that lung cancer among never-smokers appears to affect women more frequently than men, irrespective of geography (*p* < 0.0001).[5] The proportion of women with lung cancer who reported never having smoked regularly is particularly high in East Asia (61%)[9–14] and South Asia (83%),[15,16] whereas only

15% of women with lung cancer in the United States are never-smokers.[17–21] In contrast, only 11% of men with lung cancer in East Asia are never-smokers.[5]

Thun et al.[7] published an analysis of 13 cohorts and 22 cancer registry studies with data from nearly 2.5 million never-smokers and from cancer registries in 10 countries covering several decades. Some of the key findings from this comprehensive analysis regarding lung cancer in never-smokers include the following:

- death rates from lung cancer were higher among men than women across all age and racial groups
- incidence rates among men and women were similar, with some variation by age
- death rates were higher among East Asian individuals (but not among those living in the United States) and black Americans than among white Americans
- no temporal trends were seen for American women
- lung cancer incidence rates were higher and more variable among East Asian women.

KNOWN OR SUSPECTED ETIOLOGIC FACTORS FOR LUNG CANCER IN NEVER-SMOKERS

Because tobacco use is a powerful carcinogen and the major cause of lung cancer, most attention has focused on environmental tobacco exposure as the major cause of lung cancer in lifetime never-smokers. Although environmental tobacco exposure has been identified as a contributing factor for lung cancer in never-smokers since 1986, the Surgeon General of the United States 2006 report confirmed that environmental tobacco exposure modestly increased the risk of lung cancer.[22] However, the odds ratios for the development of lung cancer in the United States indicated that such exposure is a very weak carcinogen compared with active smoking, as cited in the Surgeon General's report.[22,23] According to that report, the odds ratio is 1.0 for never-smokers who do not have environmental tobacco exposure and 1.2 for never-smokers who do have such exposure; in contrast, the odds ratio is 40.4 for ever-smokers.[23] Thus, if environmental tobacco exposure is a weak carcinogen and cannot be the major cause of lung cancer in never-smokers, other known or suspected factors should be considered, such as indoor air pollution, environmental and occupational toxins (e.g., arsenic, radon, asbestos), and human papillomavirus (HPV) infection (and possibly other infections). Genetic factors should also be considered, and these are discussed later.

Indoor Air Pollution

The relatively high burden of lung cancer among women in China who have no history of regular smoking is attributed to indoor air pollution from coal smoke generated by unventilated coal-fueled stoves, volatilization of oils from cooking at high temperatures in open woks, and secondhand smoke.[7,24–29] A meta-analysis of seven studies from China and Taiwan of never-smokers found that cooking oil vapors are the risk factor associated with lung cancer for women, and indoor coal and wood burning is a risk factor for both women and men.[30] Indeed, a retrospective study on the association of household stove improvement and risk of lung cancer in rural China indicated that changing from unvented fire pits to stoves with chimneys was associated with a subsequent reduction in the lung cancer incidence rate.[31] Other factors thought to contribute to higher lung cancer incidence among rural Chinese women who are never-smokers include a higher prevalence of nonsmoking women in Asian countries and viral factors of HPV infection.[32]

Environmental and Occupational Toxins

Exposure to some environmental and occupational toxins has been shown to increase the risk of lung cancer for smokers and, to a lesser extent, for never-smokers.[11,29,33] These toxins include arsenic, radon, asbestos, chromium, organic dust, and others.[34–36]

As summarized in a meta-analysis,[34] several studies indicate that high levels of arsenic in the major source of drinking water of highly defined geographic regions (southwestern Taiwan, the Niigata Prefecture, Japan, and northern Chile) were associated with increased incidence of lung cancer, both for smokers and never-smokers. The authors of the meta-analysis concluded: "Despite methodologic limitations, the consistent observation of strong, statistically significant associations from different study designs carried out in different regions provide[s] support for a causal association between ingesting drinking water with high concentrations of arsenic and lung cancer."[34]

Present in soil and groundwater, radon is a gaseous decay product of uranium-238 and radium-226, which is capable of damaging respiratory epithelium by emitting alpha particles.[40,41] The increased risk of lung cancer among uranium miners has been more clearly established and is thought to be caused by radiation from radon,[42] although most miners are ever-smokers.[40] The role of radon in the home is more difficult to assess.

An analysis of occupational asbestos exposure in the Netherlands found a relative risk of lung cancer of 3.5 after controlling for age, smoking, and other factors.[37] In a French study of 1493 cases, some occupational exposure was identified in 9.4% and 48.6% of female and male never-smokers, respectively, in whom lung cancer developed.[38] In a Canadian case–control study, the odds ratio for lung cancer risk from occupational exposures in never-smokers was 2.1 (95% confidence interval [CI], 1.3–3.3) but was higher for exposure to solvents, paints, or thinners (odds ratio, 2.8; 95% CI, 1.6–5.0).[8] A meta-analysis that focused on lung cancer risk for painters demonstrated a relative risk of lung cancer for all painters of 1.35 (95% CI, 1.29–1.41), but 2.0 (95% CI, 10.9–3.67) among never-smokers.[39]

Human Papillomavirus

Several studies have found that HPV infection is associated with lung cancer, particularly in China and Taiwan. Cheng et al.[44] reported a high incidence of HPV infection among never-smoking women in Taiwan. Results of a case–control study (141 cases and 60 controls) in Taiwan showed that the prevalence of HPV16 and HPV18 infection was significantly higher among never-smoking women with lung cancer who were older than 60 years; HPV 16 and HPV 18 infection was thought to be associated with the high lung cancer incidence and death rates among never-smoking women in Taiwan.[44] Results of a similar study in Wuhan, China, indicated that no association with clinical-pathologic features was noted.[45] However, the role of HPV infection in lung cancer pathogenesis in never-smokers might be restricted to certain geographic areas because the incidence rate of lung cancer associated with HPV infection varies widely based on geographic location and is reported to be low in Australia, Europe, and North America.[46–48]

CLINICAL-PATHOLOGIC FEATURES OF LUNG CANCER IN NEVER-SMOKERS

Adenocarcinoma is the most common form of nonsmall cell lung cancer (NSCLC) in most parts of the world and the predominant form of lung cancer in never-smokers worldwide,[5] followed by large cell carcinoma, which may represent an undifferentiated form of adenocarcinoma. Squamous cell carcinoma is rare among never-smokers with lung cancer, and small cell lung cancer almost never occurs. However, another neuroendocrine tumor, the bronchial carcinoid, may be slightly more common among never-smokers, although no relationship to smoking status has been shown.[49]

The age at which lung cancer is diagnosed varies according to geographic location and smoking status. Studies from East Asian countries, such as Singapore and Japan, as well as Hong Kong, demonstrate an earlier age at the time of diagnosis among never-smokers compared with smokers,[9,12,33] whereas the same or older age at the time of diagnosis among never-smokers has been found in studies from the United States and Europe.[1,18,21,50–52] The possible reasons for this geographic variation include the greater contribution of risk factors other than active smoking in East Asian countries, much later age of initiation of smoking among East Asians with a smoking history compared with individuals from Western countries, and different degrees of detection bias between countries.[53]

A retrospective study in Singapore comparing differences in the epidemiologic characteristics and survival outcomes between never-smokers and former and current smokers showed that never-smoker status was associated with a significantly better performance status, younger age at the time of diagnosis (10 years and 5 years earlier, respectively), higher proportion of women (68.5% vs.12% to 13%), and more advanced stage at the time of diagnosis.[9] The variation in disease stage at the time of diagnosis might be explained by late presentation of symptoms and delayed diagnosis by physicians. The survival outcome for never-smokers was significantly better than that for smokers, with a 5-year overall survival rate of 10.8% and 7.7%, respectively ($p = 0.0003$).[9] Differences in treatment response and survival outcome between never-smokers and smokers with lung cancer may be attributed to differences in pathogenesis and tumor biology.

THE GENETICS OF LUNG CANCER

Inherited cancer syndromes are associated with rare and highly penetrant single-gene mutations, but genetic factors also play a role in sporadic cancers, as reported in numerous family-based studies. About 100 genes with mendelian inheritance cause an even smaller number of cancer syndromes, but these syndromes provide an explanation for only a minor part of the familial clustering of common cancers.[54] Linkage analyses of high-risk families may identify other rare high-penetrance genes, and such studies have identified a lung cancer susceptibility locus on chromosome 6q.[55] Smoking appeared to increase the susceptibility. Further studies indicated that the regulator of G-protein signaling 17 (*RGS17*) gene at this location was a major candidate for lung cancer susceptibility.[56]

The major mechanism of acquired resistance to tyrosine kinase inhibitors in lung cancers with epidermal growth factor receptor (*EGFR*) gene mutations is the appearance of a second activating mutation, T790M (substitution of threonine 790 with methionine).[57] However, T790M may be inherited as a rare familial mutation.[58] Our recently published study of a large family with an inherited T790M mutation and lung cancer, combined with analysis of published cases, indicates that inherited T790M predisposed lifetime never-smokers (and women) to lung cancer.[59] These findings have, in part, been independently confirmed.[60] Of interest, although *EGFR* mutations occur more frequently among East Asians, no case of an inherited T790M mutation has been described among East Asians. However, V843I, an even rarer inherited *EGFR* gene mutation that predisposes to lung cancer, has been reported in both Asian and non-Asian families.[61,62] Another recent report described a Japanese family with an autosomal inherited germline mutation in human epidermal growth factor receptor 2 (*HER2*) associated with lung cancer risk, which may also target women and light or never-smokers.[63]

It is now believed that alleles with high frequency (typically greater than 10%) and low penetrance (typically less than a twofold increased lifetime risk) contribute substantially to susceptibility to many diseases, including lung cancer. Genome-wide association studies (GWAS) using population-based designs have identified many genetic loci associated with risk of a range of complex diseases, including lung cancer;[54] however, each locus exerts a very small effect, and combinations of genes are required to exert a significant effect on risk. GWAS are often based on large microchip analyses of single nucleotide polymorphisms (SNPs), and more than one million SNPs can be analyzed on a single microchip. These studies of weak associations often consist of many thousands of cases and controls, and meta-analyses may be required for confirmation. In lung cancer, more than 150 GWAS have been published. Although some findings are widely accepted, others are controversial or require confirmation. In 2008, three studies identified three potential susceptibility loci for lung cancer.[64,65] Two of these loci, on chromosomes 15q25 and 5p15.33—the site of the telomerase reverse transcriptase (*TERT*) gene, essential for telomerase activation—have been confirmed, but the cancer-associated role of the locus on 6p21-6p22 remained more controversial; however, it may be histology related.[64] Additional studies, including a meta-analysis, confirmed that the major susceptibility locus was on 15q25, encoding several genes, including the nicotinic acetylcholine receptor (nAChR) genes: cholinergic receptor, nicotinic, beta 4 (neuronal) (*CHRNB4*), alpha 5 (neuronal) (*CHRNA5*), and alpha 3 (neuronal) (*CHRNA3*).[66] Because the variants at 15q25 are also associated with nicotine dependence, they may influence lung cancer risk at least in part through an effect on smoking behavior rather than a direct effect on lung carcinogenesis. A large meta-analysis of lung cancer in female never-smokers in six Asian countries showed no evidence of association for lung cancer at 15q25 in that population, which the authors said provided "strong evidence that this locus is not associated with lung cancer independent of smoking."[67] Other studies, including meta-analyses, have identified additional variants associated with increased risk, such as smoking, ethnicity, gender, and histology.[64,66–71] Thus, although genetic variation of the *TERT* locus appears to be involved in susceptibility to all lung cancers, the 15q25 locus predisposes to smoking, the cyclin-dependent kinase inhibitor 2A (*CDKN2*) locus at 9p21 may influence susceptibility to squamous cell carcinomas, and the tumor protein p63 (TP63) locus may influence susceptibility to lung adenocarcinoma in East Asian populations.

As confirmed by the GWAS cited previously, nicotine and its derivatives, by binding to nAChR on bronchial epithelial cells, can regulate cellular proliferation and apoptosis by activating the protein kinase B (PKB/Akt) pathway. Lam et al.[72] found different nAChR subunit gene expression patterns between NSCLCs from smokers and nonsmokers, and a 65-gene expression signature was associated with nonsmoking nAChR alpha-6 beta-3 expression.

MOLECULAR CHARACTERISTICS OF NONSMOKING EAST ASIAN INDIVIDUALS WITH LUNG CANCER

With the development of molecular genetic therapies for lung cancer, the molecular profile of East Asian individuals with lung cancer was found to differ from that of white individuals with lung cancer. Mutations in Kirsten rat sarcoma viral oncogene homolog (*KRAS*) and *EGFR* genes are mutually exclusive and demonstrate striking frequency differences related to ethnicity. *EGFR* mutation is the first specific molecular alteration associated with lung cancers arising among never-smokers. A relatively high incidence of somatic mutations in *EGFR* has been found in a specific subpopulation: women, never-smokers, patients with adenocarcinoma, and Asians. In the First Line Iressa versus Carboplatin/Paclitaxel in Asia (Iressa Pan-Asia Study [IPASS]) study, with 1214 (99.8%) of 1217 patients of East Asian origin and 1140 (93.7%) of 1217 never-smokers, the incidence rate of *EGFR* mutation was 59.7% in the 437 patients evaluable for *EGFR* mutation.[73] A recent multinational study demonstrated variations in the *EGFR* gene mutation rates in Asian countries, with the lowest frequencies from India.[74,75]

Nevertheless, a review of nine published studies showed that the frequency of *EGFR* mutation among US never-smokers with NSCLC was substantially lower (20%).[76] In addition, even in an unselected population, the frequency of *EGFR* mutation among East Asian individuals with NSCLC was also considerably higher than that for white individuals. In the review, which included an analysis of data on 2347 patients for whom ethnicity was noted, the frequency of *EGFR* mutations among East Asian patients was significantly higher compared with non-Asian patients (33% vs. 6%; *p* < 0.001).[77] Unlike *EGFR* mutations, *KRAS* mutations occur less commonly in lung cancers among individuals from East Asia and more frequently in lung cancers among smokers.[76]

In pooled data summarizing three published studies comprising 1536 patients with NSCLC, *EGFR* and *KRAS* were shown to be mutually exclusive in the same tumors.[76,78,79] *KRAS* mutations were detected in 20% of patients with NSCLC, particularly patients who smoked or who had adenocarcinoma.[77] A study investigating the *EGFR* and *KRAS* status of 519 unselected patients with NSCLC showed that *KRAS* mutations were present more frequently in smokers than never-smokers (10% vs. 4%; *p* = 0.01), among non–East Asians than East Asians (12% vs. 5%; *p* = 0.001), and among patients with adenocarcinoma than patients with nonadenocarcinoma histologies (12% vs. 2%; *p* < 0.001).[76] Several studies found that *KRAS* mutations were present in 20% to 30% of white patients with lung adenocarcinoma but only 5% of patients with lung adenocarcinoma from East Asia.[80–82] In addition, in previous studies from Hong Kong and Taiwan, *KRAS* mutations were found in 13% to 19% of men with adenocarcinoma but in none of the women studied.[83,84] A potential explanation for the distinction between genders may be that the vast majority of Chinese female patients were never-smokers.

A Japanese case–control study assessing the impact of smoking and gender on the risk of NSCLC with or without *EGFR* mutation demonstrated that ever-smoking was a substantial risk factor for NSCLC without *EGFR* mutation but not for NSCLC with *EGFR* mutation.[85] Cumulative exposure to smoking was associated with a linear increased risk of NSCLC without *EGFR* mutation only. This finding was consistent for both men and women. Age at the start of smoking among ever-smokers and years since quitting smoking among former smokers also showed a strong correlation between NSCLC without *EGFR* mutation and smoking. *EGFR* mutation was present more frequently among patients who smoked no more than 20 pack-years. Similarly, in another Japanese study, *EGFR* mutation was found more frequently among patients who quit smoking at least 20 years before the date of lung cancer diagnosis.[86] These findings suggest an inverse correlation between *EGFR* mutation and exposure dose of cigarette smoking.

Smoking status is a risk factor affecting not only *EGFR* mutations but other somatic mutations as well. The authors of a Korean study screened genetic tests for *EGFR* mutations, *KRAS* mutations, and enchinoderm-microtubule-associated protein-like 4-anaplastic lymphoma kinase (*EML4-ALK*) fusions in 200 fresh surgical specimens of primary lung adenocarcinoma by polymerase chain reaction (PCR), Sanger sequencing, and fluorescence in situ hybridization. They then performed high-throughput RNA sequencing in 87 lung adenocarcinoma specimens that were negative for the three known driver mutations (three samples with insufficient RNA quality were excluded). The results showed that people who had a smoking history of at least 40 pack-years harbored significantly more somatic point mutations than did people who had a smoking history of fewer than 40 pack-years or of never-smoking. In addition, important differences in mutation patterns exist between lung cancer in never-smokers and ever-smokers.[87]

Given the difference in the incidence rate of *EGFR* mutations between East Asian and white populations, several studies have investigated ethnic differences in *ALK*, c-ros oncogene 1 receptor

tyrosine kinase (*ROS1*), and ret proto-oncogene (*RET*) fusions after these three novel driver fusions were identified in NSCLC. Most studies showed that *ALK* fusions occurred in 2.4% to 5.6% of NSCLC cases,[88–91] and no differences in incidence rate between Asian and non-Asian populations have been identified to date. However, a Chinese study screening *ALK* fusions by rapid amplification of complementary DNA ends (RACE)-coupled PCR sequencing found that *ALK* fusions existed in 12 (11.6%) of 103 individuals with NSCLC, 10 (16.13%) of 62 individuals with adenocarcinomas, and 10 (19.23%) of 52 never-smokers.[92] This high incidence of *ALK* fusions in a selected East Asian population may be explained by the relatively small sample size and use of a different screening method. Unlike ethnicity, smoking status is regarded as an important factor affecting the incidence rate of fusion genes. Similar to *ALK* fusions, *ROS1* and *RET* fusions appear to occur more frequently among never-smokers.[93,94] Given a very low frequency of *ROS1* as well as *RET* fusions identified in NSCLC, a large sample study is warranted to prove the role of smoking status in the occurrence of fusion genes.

Several Chinese studies have demonstrated the previously described differences in the molecular profile of lung cancer between never-smokers and smokers. An et al.[95] screened for candidate driver genes in 524 Chinese patients with NSCLC with the use of several methods, including sequencing, high-resolution melt analysis, quantitative PCR, or multiplex PCR and RACE, and analyzed the differences in driver gene alterations among a subgroup based on histology and smoking status (Table 4.1).[95] The findings demonstrated that the driver gene alterations in nonsmokers differ completely from driver gene alterations in smokers, irrespective of histologic type. In adenocarcinoma, *EGFR*, phosphatase and tensin homolog (*PTEN*), and phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (*PIK3CA*) mutations and *ALK* fusions were present more frequently among never-smokers, whereas *KRAS* and serine/threonine kinase 11 (*STK11*) mutations were present more frequently among smokers. The met proto-oncogene methylated CpG (mCpG) sequences (*MET*) and v-raf murine sarcoma viral oncogene homolog B (*BRAF*) mutations did not differ substantially by smoking status. As expected, fewer squamous cell carcinomas were present, and discoidin domain receptor tyrosine

TABLE 4.1 Driver Mutations in Lung Cancers Among Chinese Never-Smokers and Ever-Smokers Adjusted for Histologic Type and Smoking Status[95]

ADENOCARCINOMA (*n* = 347)		
Gene	**Never-Smokers (66%)**	**Ever-Smokers (34%)**
EGFR	49.8	22.0
PTEN	9.9	2.6
ALK	9.3	4.5
PIK3CA	5.2	2.1
STK11	2.7	11
KRAS	4.5	12
C-MET	4.8	4
BRAF	1.9	3.1
SQUAMOUS CELL CARCINOMA (*n* = 144)		
Gene	**Never-Smokers (35%)**	**Ever-Smokers (65%)**
DDR2	0	4.4
FGFR2	0	2.2

ALK, anaplastic lymphoma receptor tyrosine kinase; *BRAF*, v-raf murine sarcoma viral oncogene homolog B; *C-MET*, growth factor receptor c-Met; *DDR2*, discoidin domain receptor tyrosine kinase 2; *EGFR*, epidermal growth factor receptor; *FGFR2*, fibroblast growth factor receptor 2; *KRAS*, Kirsten rat sarcoma viral oncogene homolog; *PIK3CA*, phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha; *PTEN*, phosphatase and tensin homolog; *STK11*, serine/threonine kinase 11.

kinase 2 (*DDR2*) and fibroblast growth factor receptor 2 (*FGFR2*) mutations, although infrequent, were present only in tumors from smokers.

In another Chinese study limited to lung cancers from never-smokers, Li et al.[96] identified driver mutations in 89% of the tumors (Table 4.2). Of interest, these mutations were mutually exclusive, consistent with their driver status. Although the mutation figures may be lower among lung cancers in never-smokers in Western countries, most of these tumors contain potentially actionable driver mutations. In conclusion, driver gene alterations in NSCLC are shown to be associated with smoking status rather than gender.

GENOME-WIDE MOLECULAR CHANGES

Although we have discussed specific genes mutated in lung cancer in never-smokers or ever-smokers, some genome-wide changes also are characteristic of both forms of lung cancer. Point mutations may represent changes involving purine to pyrimidine or pyrimidine to purine (transversions) or purine to purine or pyrimidine to pyrimidine (transitions). At the turn of the 21st century, it was noted that the point mutations in the tumor protein p53 (*TP53*) gene present in lung cancer were of a different pattern than the point mutations seen in most other types of solid tumor. The most frequent mutation change in the *TP53* gene in lung and other tobacco-associated cancers (head and neck or bladder) represented a G to T transversion.[97–99] These mutations frequently occur at mCpG hotspots. 5-Methylcytosine in DNA is genetically unstable, and mCpG sequences frequently undergo mutation resulting in a general depletion of this dinucleotide sequence in mammalian genomes. In human genetic disease-relevant and cancer-relevant genes, mCpG sequences are mutational hotspots.[99] Although initial attention focused on the *TP53* gene, whole genome sequencing studies have confirmed that G to T transversions are the most frequent type of point mutation in tobacco-associated cancers, and G to A transitions are the most common type of point mutation in lung cancers among never-smokers.[87,100]

Seo et al.[87] extensively analyzed the transcriptomes of 87 lung adenocarcinoma specimens from Korean patients. The authors found that the expression signature, as well as the mutation pattern, was highly related to active smoking. In another study of nontumorous lung tissues, Bosse et al.[101] compared gene expression levels between never-smokers and current smokers, as well as time-dependent changes in gene expression in former smokers. A large number of genes (3223 transcripts) were differentially expressed between the groups. Moreover, some genes showed very slow or no reversibility in expression, including serpin peptidase inhibitor, clade D (heparin cofactor), member 1 (*SERPIND1*), which was found to be the gene that was most

consistently permanently altered by smoking. Thus, their findings indicate that smoking deregulates many genes, many of which reverse to normal after smoking cessation. However, a subset of genes remains altered even decades after smoking cessation and may account, at least in part, for the residual risk of lung cancer among former smokers. In another study, Lam et al.[102] evaluated the expression patterns of a small number of cell lines established from smokers and never-smokers in Hong Kong. These authors identified 71 genes that were differentially expressed or showed class predictive significance.

Whole genome sequencing has shown that the number of synonymous and nonsynonymous mutations in lung cancer in ever-smokers is remarkably high and that this lung cancer is among the cancers with the highest number of such mutations.[103]

However, major differences exist between lung cancer in never-smokers and ever-smokers with respect to the number of mutations and complexity of molecular changes, with this number being 10-fold or less in never-smokers.[87,100] These findings indicate that exposure to tobacco carcinogens induces DNA instability, resulting in the formation of numerous driver and passenger mutations. By contrast, although the number of driver mutations may be similar, the etiologic agents associated with lung cancer in never-smokers induce a more modest total number of changes.

PRENEOPLASTIC CHANGES

For more than a decade, we have known that the development of invasive lung carcinoma is preceded by numerous and widespread molecular alterations in the respiratory tree that commence in histologically normal epithelium.[104,105] However, similar studies on the development of *EGFR* mutant lung cancers indicate a far more modest field effect, largely limited to the field immediately surrounding the invasive carcinoma.[106] Although these observations may be partly due to differences in the field effects of centrally arising squamous cell carcinomas compared with peripherally arising adenocarcinomas, they also suggest that smoking induces much or all of the respiratory epithelium to undergo molecular changes very early in lung cancer pathogenesis, whereas lung cancers arising in never-smokers have much more restricted field effects.

DNA METHYLATION

Although most molecular studies have focused on genetic changes, epigenetic differences in lung cancer between ever-smokers and never-smokers demonstrate multiple differences in the overall methylation pattern and in methylation (and occasionally downregulation) of several genes. However, some studies describe contradictory findings and others are unconfirmed. One study of 59 matched lung adenocarcinoma/nontumor lung pairs, with genome-scale verification on an independent set of tissues, used the older Infinium HumanMethylation27 platform (Illumina, San Diego, CA, USA).[107] Although more than 700 genes were found to be differentially methylated between tumor and nonmalignant lung tissue, comparison of DNA methylation profiles between lung adenocarcinomas of current smokers and never-smokers showed modest differences, identifying only the lectin, galactoside-galactoside binding, soluble, 4 (*LGALS4*) gene as significantly hypermethylated and downregulated in smokers. *LGALS4*, encoding a galactoside-binding protein involved in cell-cell and cell-matrix interactions, is a known tumor suppressor. Other studies have examined individual or small numbers of genes, which have included Ras association (RalGDS/AF-6) domain family member 1 (*RASSF1A*), cyclin-dependent kinase inhibitor 2A (*CDKN2A*), and others (Table 4.3).[108–115] The association between *CDKN2A* methylation and active smoking was confirmed by meta-analysis.[116] The association between inactivation of *CDKN2A* and inactivation by any mechanism and its

TABLE 4.3 Summary of Major Differences Between Lung Cancers Arising in Ever-Smokers and Never-Smokers

FACTOR	LC IN EVER-SMOKERS	LC IN NEVER-SMOKERS
Clinical and Pathologic Factors		
Major etiologic factor	Cigarette smoking	Unknown or diverse
Major histologic types	NSCLC and SCLC	Largely adenocarcinoma
Field effects	Widespread	More limited
Stage at time of diagnosis	More advanced in never-smokers	
Response to therapy and overall survival	Improved in never-smokers	
Age at time of diagnosis	Younger for never-smokers (especially in East Asia)	
Gender	Higher ratio of women among never-smokers (worldwide)	
Genetics		
RGS17 locus (chromosome 6q)	Lung cancer susceptibility locus for ever-smokers	
Polymorphisms	Patterns differ according to smoking status and ethnicity. *CHRNA5* predisposes to smoking	
Molecular Changes		
Total number of mutations	Much higher in ever-smokers	
Most frequent mutation	G to A transitions	G to T tranversions
Specific mutations	*KRAS, STK11, SMARCA4*	*EGFR, ALK, PTEN, PIK3CA*
Percentage of cancers with potential targets for treatment	Approximately 60% (East Asia)	More than 90% (East Asia)
Gene expression signatures	More deregulation of gene expression in lung tumors and adjacent tissue in ever-smokers	
DNA methylation	Multiple genes show differential methylation, predominantly affecting cancers in never-smokers	
Methylated genes (some are unconfirmed)	*RASSF1A, CDKN2A, MTHFR, HtrA3, LGALS4*	*NFKBIA, TNFRSF10C, BHLHB5, BOLL*

ALK, anaplastic lymphoma receptor tyrosine kinase; *BHLHB5*, basic helix-loop-helix domain containing, class B5; *BOLL*, boule-like RNA-binding protein; *CDKN2A*, cyclin dependent kinase inhibitor 2A; *CHRNA5*, cholinergic receptor, nicotinic, alpha 5 (neuronal); *EGFR*, epidermal growth factor receptor; *HtrA3*, HtrA serine peptidase 3; *KRAS*, Kirsten rat sarcoma viral oncogene homolog; *LC*, lung cancer; *LGALS4*, lectin, galactoside-binding, soluble, 4; *MTHFR*, methylenetetrahydrofolate reductase (NAD(P)H); *NFKBIA*, nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha; *NSCLC*, nonsmall cell lung cancer; *PIK3CA*, phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha; *PTEN*, phosphatase and tensin homolog; *RASSF1A*, Ras association (RalGDS/AF-6) domain family member 1; *RGS17*, regulator of G-protein signaling 17; *SCLC*, small cell lung cancer; *SMARCA4*, SWI/SNF (switching/sucrose nonfermenting) related, matrix associated, actin dependent regulator of chromatin, subfamily a, member 4; *STK11*, serine/threonine kinase 11; *TNFRSF10C*, tumor necrosis factor receptor superfamily, member 10c, decoy without an intracellular domain.

relationship to smoking has been demonstrated, with one interesting study examining gene promoter methylation assayed in exhaled breath and finding differences between smokers and individuals with lung cancer.[117]

CONCLUSION

We focused on lung cancer in never-smokers in East Asia because this type of lung cancer occurs most frequently in this geographic region. However, East Asia is a vast region, containing 10 countries and the Asian Pacific islands. It encompasses more than one-fifth of the world's population. Thus, lung cancer differences among heterogeneous East Asian subpopulations may also occur. We believe that the observations and findings summarized in this chapter demonstrate conclusively that lung cancers arise as a result of complex interactions among several factors, including exposure to tobacco through either active smoking or secondhand smoke, gender, ethnicity, and genetic predisposition. For lung cancer in never-smokers, other largely unknown environmental carcinogens or lifestyle factors may be contributors; however, no single factor or combination of factors identified to date can be responsible for the majority of cancers.

As a result, major clinical, pathologic, demographic, gender, ethnic, molecular, and genetic predisposition factors differ between lung cancers in smokers and never-smokers. We summarize many of the important differences between these two groups of lung cancers (Table 4.3). Studies have conclusively demonstrated that lung cancers arising in ever-smokers and never-smokers are very different and should be regarded as separate tumors with different pathogeneses and their own clinical, genotypic, and phenotypic features.

However, many questions remain, in particular regarding the major etiologic cause or causes of lung cancer in never-smokers. There may be no simple or universal answers, with this type of cancer remaining a heterogeneous cancer with a pathogenesis influenced by genetics, ethnicity, environmental tobacco exposure, other environmental or occupational carcinogens, and geography.

5   Gender-Related Differences in Lung Cancer

Silvia Novello, Laura P. Stabile, and Jill M. Siegfried

SUMMARY OF KEY POINTS

- Epidemiology of lung cancer is still changing: in the last 10 years lung cancer became the first cause of cancer-related deaths in both men and women in many countries, while having previously been a rare disease in females.
- Smoking is the first cause of lung cancer also among women: no conclusive data are present in the literature about female smokers and their susceptibility to develop lung cancer, compared with their male counterparts.
- The risk of lung cancer is 2.5 times more common in female lifetime nonsmokers compared with male non-smokers with different geographic distribution: in Asia the proportion of female lung cancer patients who are never-smokers ranges from 61% to 83%.
- Several publications describe a more favorable prognosis of lung cancer in women than in men, and this is regardless of a longer life expectancy or the influence of other factors.
- Population studies and preclinical studies suggest that steroid hormone pathways, as well as progesterone receptors, are involved in the biology of lung cancer: these pathways are consequently promising targets for lung cancer therapy.
- From a molecular biology point of view, lung cancer in women should be considered a specific entity, and this fact must be taken into account in diagnosis and therapeutic approaches.

For several decades, lung cancer has been considered a neoplastic disease affecting mainly men; however, during the past 40 years, the incidence of the disease has increased exponentially among women. From 1990 through 1995, in many Western countries, the incidence of lung cancer among men has gradually declined as a result of antitobacco campaigns, which, in turn, led to a progressive reduction in incidence rates for men and women, with a projection of equal incidences by 2020.[1]

The mortality rate for lung cancer among women shows a clear inverse trend compared with most other cancers. Whereas deaths from gastric and uterine cancer have plummeted in the past four decades and deaths from breast cancer have steadily declined since a peak in 1990, deaths from lung cancer have continued an upward trajectory, reflecting the consequences of tobacco smoking among women. Overall, lung cancer causes death for more women than the combination of the three most common cancers among women (breast, colorectal, and ovarian cancer).[2]

Whether women are more or less susceptible than men to the carcinogenic effects of cigarette smoking is controversial. Compared with men, women are less likely to have a smoking history and are more likely to be younger at the time of diagnosis and to have a better survival at any stage (Fig. 5.1).[3] Adenocarcinoma of the lung is the most common histologic subtype among women.

EPIDEMIOLOGY

Worldwide, lung cancer accounts for the most cancer diagnoses (1,600,000 new cases; 12.4% of total new cancer cases) and is the leading cause of cancer-related deaths in both men and women (1,378,000 deaths; 17.6% of total cancer deaths).[2] The estimated number of lung cancer cases worldwide has increased by 51% since 1985 (a 44% increase in men and a 76% increase in women).[4]

The World Health Organization (WHO) estimates that worldwide lung cancer deaths will continue to increase, largely as a consequence of an increase in global tobacco use, primarily in Asia. Despite efforts to curb tobacco smoking, there are approximately 1.1 billion smokers around the world, and if the current trends continue, that number will increase to 1.9 billion by 2025.[5,6]

United States

In the United States, it is estimated that 118,080 men and 110,110 women were diagnosed with lung cancer in 2013, and 87,260 men and 72,220 women died of the disease. The age-adjusted death rate for the period from 2006 to 2010 was 63.5/100,000 and 39.2/100,000 for men and women per year, respectively.[3]

The most common cancers expected to occur in men in 2013 included prostate, lung and bronchus, and colorectal, which account for about 50% of all newly diagnosed cancers (prostate cancer alone accounted for 28%, or 238,590 of all new cases).[2] In women, the three most commonly diagnosed types of cancer in 2013 were breast, lung and bronchus, and colorectal, accounting for 52% of estimated cancer cases (breast cancer alone accounted for 29%, or 232,340 of all new cases). These cancers continue to be the most common causes of cancer death (Fig. 5.2).[2] In 2013, lung cancer was expected to account for 26% of all cancer-related deaths among women and 28% of all cancer-related deaths among men.[2] Of the 2,437,163 deaths recorded in the United States in 2009, 567,628 were caused by cancer. Lung cancer is the leading cause of death among men aged 40 years and older and is the leading cause of cancer-related deaths among women aged 60 years and older.[2]

The Hispanic/Latino population is the largest and fastest growing major demographic group in the United States, accounting for 16.3% (50.5 million/310 million) of the US population in 2010. In 2012, an estimated 112,800 new cases of cancer were diagnosed and 33,200 cancer-related deaths occurred among Hispanic individuals.[7] The incidence and mortality rates for all cancers combined and for the four most common cancers (breast, prostate, lung and bronchus, and colorectal) are lower for the Hispanic population than for the non-Hispanic white population, but the incidence and mortality rates are higher for cancers of the stomach, liver, uterine cervix, and gallbladder. These differences in rates reflect greater exposure to cancer-related infectious agents, lower rates of screening for cervical cancer, differences in lifestyle and dietary patterns, and possibly genetic factors.[7]

The considerable efforts in implementing tobacco-control strategies in the United States since the 1950s and the subsequent favorable changes in smoking behaviors in 1975 to 2000 have averted more than 240,000 lung cancer-related deaths in women.[8] However, it is estimated that 20.6% of all American
Fig. 5.1. Five-year relative survival of people with lung cancer according to the age at the time of diagnosis. Based on data from 2001 to 2008 in 17 areas covered by the US Surveillance, Epidemiology and End Results (SEER) database.[1]

Estimated New Cases*

Men   **Women**

	Men			Women	
Prostate	238,590	28%	Breast	232,340	29%

Fig. 5.2. Estimated number of new cases and deaths for the 10 leading types of cancer in men and women in the United States for 2013. (*Estimates are rounded to the nearest 10 and exclude basal cell and squamous cell skin cancers and in situ carcinoma, except urinary bladder.) *(Modified with permission from Siegel R, Naishadham D, Jemal A. Cancer statistics, 2013. CA: Cancer J Clin. 2013;63:11–30.)*

adults 18 years and older continue to smoke, a percentage that has changed slightly since approximately 1997.[9] Smoking prevalence in the United States has decreased from a high of 53% for men and 32% for women in 1964 to rates of 21.6% for men and 16.5% for women in 2011.[10]

Large geographic differences in public policies against tobacco use and socioeconomic factors affect the distribution of lung cancer mortality rates across states. California has been a leader in introducing public policies designed to reduce cigarette smoking. It was the first state to establish a comprehensive state-wide tobacco-control program in 1988 through increased excise taxes on cigarettes, and as early as the mid-1970s it had local government ordinances for smoke-free work places. As a result, progress in reducing smoking prevalence and mortality associated with smoking-related diseases, including lung cancer, has been much greater in California than in the rest of the United States. Jemal et al.[1] evaluated state-specific lung cancer mortality rates among white women to assess regional differences in lung cancer trends. The decrease in age-specific lung cancer mortality rates among white women continued in younger age groups and birth cohorts in California, but the decline was slower or even reversed among women younger than 50 years of age and for women born after the 1950s in the remaining 22 states analyzed, especially in the South and Midwest.[11]

Europe

Worldwide, the estimated incidence of lung cancer among women is 516,000, of which 100,000 are diagnosed in the United States and 70,000 in Europe.[2,12] There are still differences when incidence rates from European cancer registries are compared with rates in the United States, suggesting that the lung cancer epidemic among women in Europe may not yet have reached the US rate from the 1990s (>25 lung cancers/100,000 women). Nevertheless, in the European Union (EU), the lung cancer mortality rate for women increased by 50% between the mid-1960s and the early 2000s and steady upward trends have been seen even in the youngest age groups in some southern European countries such as France and Spain up to the early 2000s.[13]

In the EU, lung cancer mortality rates for women increased during the past decade, from 11.3/100,000 to 12.7/100,000 (2.3% per year) for all ages (a further increase is predicted to reach 14/100,000 women in 2015) and from 18.6/100,000 to 21.5/100,000 (3.0% per year) for middle-age women (Fig. 5.3).[14]

Despite the reduction in breast cancer mortality, this disease is still the leading cause of cancer-related deaths among women across the EU, as well as specifically in France, Germany, Italy, and Spain. Lung cancer is the leading cause of cancer-related deaths in several countries in Northern and Eastern Europe, including Denmark, Hungary, the Netherlands, Poland, Sweden, and the United Kingdom.[14–17] The projected cancer mortality rate has increased among women in several European countries. In Serbia, colorectal cancer in men and lung cancer in women are estimated to have the most significant increase over time (2010 to 2014): 0.42/100,000 (*p* = 0.036) and 0.626/100,000 (*p* < 0.001) per year, respectively.[18] From 1996 to 2001, the National Health Service Breast Screening Programme in the United Kingdom recruited 1.3 million women into the Million Women Study.[16]

Fig. 5.3. Age-standardized (world population) death rates for lung cancer in women from major European countries and the European Union as a whole from 1970 and 2009, and predicted rates for 2015. *(Modified with permission from Bosetti C, Malvezzi M, Rosso T, et al. Lung cancer mortality in European women: trends and predictions.* Lung Cancer. *2012;78:171–178.)*

The women signed consent forms and completed a questionnaire about lifestyle, medical history, and sociodemographic factors and were resurveyed by mail about 3 years and 8 years later. Twenty-three of the 30 most common causes of death occurred more frequently in smokers; the rate ratio for lung cancer was 21.4 (19.7–23.2). The increased mortality among smokers compared with never-smokers was mainly from diseases such as lung cancer that can be attributed to tobacco smoking. Among former smokers who stopped smoking permanently between the ages of 25 years and 34 years or between the ages of 35 years and 44 years, the respective relative risks were 1.05 (95% CI, 1.00–1.11) and 1.20 (95% CI, 1.14–1.26) for all-cause mortality and 1.84 (95% CI, 1.45–2.34) and 3.34 (95% CI, 2.76–4.03) for lung cancer–specific mortality.[19]

In the EU in 2012, nearly 88,000 women died from breast cancer, corresponding to almost 16% of all cancer deaths among women. The projected lung cancer-related deaths for 2015 are 187,000 for men and 85,204 for women.[14–20] In a pooled analysis of 13,169 lung cancer cases and 16,010 controls from Europe and Canada, the most common histologic subtype was squamous cell carcinoma among men (4747 of 8891; 53.4%) and adenocarcinoma among women (1013 of 2017; 50.2%). No clear-cut evidence for gender preference was found among the major subtypes of small cell lung cancer (SCLC): 19.8% in men and 21.9% in women. Never-smoking status was reported for 220 (2.1%) men and 609 (24.2%) women; the most common subtype was adenocarcinoma (57.6% in men and 70.1% in women).[21]

Similar to US data, an epidemiologic study conducted in Poland showed that a higher proportion of women (23%) were diagnosed with lung cancer at a younger age (less than 50 years) compared with men (12%).[22]

Asia

In Asia, the lung cancer mortality rates for women are lower than in the United States and Europe. However, these rates are increasing across several Asian countries, including China, South Korea, and Japan.[23–25] Adenocarcinoma tends to be the most common histologic type in women in Asia, and this proportion continues to increase over time.[26–31] Although tobacco smoke is the most common cause of lung cancer in women throughout the rest of the world, the cause of lung cancer in Asian woman is considered more complex (Fig. 5.4). The proportion of women

Fig. 5.4. Data from a review of published studies over the past 25 years showing geographic and gender variations in lung cancers in never-smokers. *(Modified with permission from Sun S, Schiller JH, Gazdar AF. Lung cancer in never smokers—a different disease. Nat Rev Cancer. 2007;7(10):778–790.)*

with lung cancer who are never-smokers ranges from 61% to 83%.[32,33] In fact, the smoking rate is higher than 10% only for Filipino and Japanese women.[34] Environmental tobacco smoke and indoor pollutants, including cooking oil fumes and burning coal, have been implicated in increasing the risk of lung cancer among nonsmoking Asian women.[35–46]

In China, cancer incidence and mortality data for 2009, including demographic information from 104 population-based cancer registries, were reported to the National Central Cancer Registry, a government organization for cancer surveillance.[46] After an evaluation procedure, data from 72 registries were deemed satisfactory and were then compiled for analysis. According to these data, lung cancer was the most common cancer in China overall and in its urban areas and the second most common cancer in its rural areas. There were 197,833 new cancer cases and 122,136 deaths. The crude cancer mortality was 184.67/100,000 overall, 228.14/100,000 for men and 140.48/100,000 for women. These findings indicate that lung cancer was the most common cancer for men in all areas, particularly urban areas, and second to breast cancer in women, especially in urban areas. Lung cancer was the leading cause of cancer-related deaths in all groups stratified by gender and area. Ages over 50 years were the high-risk age groups because of the increase in incidence and mortality rates that accompany increasing age.[46]

In India, over a 2-year period, 130 trained physicians independently assigned causes to 122,429 deaths in 6671 randomly selected small areas from the 1991 census and monitored all births and deaths in 1.1 million homes representative of all of India.[47] Among people 30 years to 69 years old, the three most common fatal cancers among men were oral (including lip and pharynx, 45,800 [22.9%]), gastric (25,200 [12.6%]), and lung (including trachea and larynx, 22,900 [11.4%]); among women, the three most common fatal cancers were cervical (33,400 [17.1%]), gastric (27,500 [14.1%]), and breast (19,900) [10.2%]). Tobacco-related cancers represented 42.0% (84,000) and 18.3% (35,700) of cancer-related deaths among men and women, respectively, and there were twice as many deaths caused by oral cancers compared with lung cancers.[47]

Data from the Korean National Cancer Incidence Database on 599,288 adult patients diagnosed with solid cancers between 2005 and 2009 were analyzed to identify possible gender differences.[45] For all solid cancer sites combined, the risk of death for women was 11% lower than that for men (relative excess risk 0.89; 95% CI, 0.88–0.90) after adjusting for year of follow-up, age, stage, and case mix. The relative excess risks for cancer of the lung, head/neck, esophagus, small intestine, liver, nasal cavities, bone/cartilage, soft tissue, brain and central nervous system, and thyroid and melanoma were significantly lower for women.[48]

SUSCEPTIBILITY

Never-Smokers

Never-smokers with lung cancer represent a unique subset of all people with lung cancer. Globally, an estimated 15% of lung cancer cases in men and 53% of cases in women are not attributable to tobacco smoking.[4] The risk of lung cancer is 2.5 times more common among female lifetime nonsmokers than among male lifetime nonsmokers.[4] One of the most relevant risk factors for nonsmoking women is environmental tobacco smoke exposure. A meta-analysis of 55 studies of spousal smoking on the risk of lung cancer for a nonsmoking spouse showed a pooled relative risk of 1.27 (95% CI, 1.17–1.37), with risk increasing monotonically with increasing exposure. This association has been replicated in different populations across Asia, Europe, and North America.[49]

Nevertheless, there remains a large fraction of lung cancers among never-smokers that cannot be definitively associated with established environmental risk factors, and limited data
are available on the epidemiologic risk factors for lung cancer in never-smokers according to gender.[50] Although smoking prevalence has decreased, the incidence of lung cancer has increased steadily in Taiwan over the past several decades; only 9% to 10% of women with lung cancer and 79% to 86% of men with lung cancer are tobacco smokers. In a matched case–control study conducted between 2002 and 2009, several epidemiologic factors of lung cancer in never-smokers differed between men and women.[51] The risk for lung cancer was higher for people exposed to environmental tobacco smoke (odds ratio, 1.39; 95% CI, 1.17–1.67) with a history of pulmonary tuberculosis and with a family history of lung cancer in first-degree relatives (odds ratio, 2.44); people with a history of hormone-replacement therapy and who used fume extractors when cooking were protected. For men, only a family history of lung cancer in first-degree relatives was significantly associated with risk of lung cancer (odds ratio, 2.77).[51]

A case–control study in China included 399 lung cancer cases and 466 controls, of which 164 cases and 218 controls were female nonsmokers.[50] Among nonsmoking women, lung cancer was strongly associated with multiple sources of indoor air pollution, including heavy exposure to environmental tobacco smoke at work (adjusted odds ratio, 3.65), high frequency of cooking (adjusted odds ratio, 3.30), and use of solid fuel for cooking (adjusted odds ratio, 4.08) and heating (adjusted odds ratio for coal stove, 2.00). In addition, housing characteristics related to poor ventilation, including single story homes, less window area, absence of a separate kitchen, lack of a ventilator, and limited time with windows open, were associated with lung cancer.[52]

Smokers

A prospective evaluation of 50-year trends in smoking-related mortality in the United States demonstrated that the relative and absolute risks of death from smoking continue to increase among female smokers.[53] The relative risks of death from lung cancer, chronic obstructive pulmonary disease (COPD), ischemic heart disease, any type of stroke, and all causes are now nearly identical for female and male smokers. The risk of death from lung cancer among male smokers appears to have stabilized since the 1980s, whereas it continues to increase among female smokers. For women aged 60 years to 74 years old, the all-cause mortality rate is now at least three times as high among current smokers as among never-smokers.[53]

Currently, no conclusive data are available on the susceptibility of lung cancer among female smokers. Some studies have shown a greater risk of lung cancer for female smokers than for male smokers. Data generated by the American Health Foundation database indicate that the odds ratio for the major lung cancer types is consistently higher for women than for men at every level of exposure to cigarette smoke.[54] The dose–response odds ratios for lung cancer among women are 1.2-fold to 1.7-fold higher than among men. A Canadian case–control study of gender differences in lung cancer from 1981 to 1985 showed that with a 40-pack-year smoking history (compared with lifelong nonsmokers), the odds ratio for the development of lung cancer was 27.9 for women and 9.6 for men.[55] In both of these studies, the increase in lung cancer risk held for all major histologic types. In a pooled analysis that included 13,169 cases and 16,010 controls from Europe and Canada, the odds ratio for different histologies of lung cancer was assessed. For male current smokers (average of 30 cigarettes per day), the odds ratios were 103.5 (95% CI, 74.8–143.2) for squamous carcinoma, 111.3 (95% CI, 69.8–177.5) for SCLC, and 21.9 (95% CI, 16.6–29.0) for adenocarcinoma. For female current smokers, the corresponding odds ratios were 62.7 (95% CI, 31.5–124.6), 108.6 (95% CI, 50.7–232.8), and 16.8 (95% CI, 9.2–30.6).[21]

Other studies have shown comparable risks for men and women when controlling for smoking exposure.[56–60] A gender-smoking interaction in association with lung cancer risk within a population-based case–control study (Lombardy, Italy, 2002–2005) was evaluated in 2100 cases with incident lung cancer and 2120 controls.[61] Lung cancer odds ratios for pack-years (categorical) were higher for men than women, with a negative gender-smoking interaction for women ($p = 0.0009$). For medium (20–29 pack-years) and high (40 pack-years or more) categories, the risk of lung cancer was similar for men and women.[61]

GENETIC FACTORS

Polymorphisms of genes that encode for enzymes involved in the breakdown of tobacco-derived carcinogens may potentially play a role in the development of lung cancer in female smokers and never-smokers. Arylamine N-acetyltransferase (NAT2) is an enzyme involved in biotransformation of xenobiotics, mainly aromatic and heterocyclic amines and hydrazines. NAT2 activity can influence the risk of lung cancer as well as cytochrome P (CYP)450 CYP1A2 activity (see Chapter 6). In nonsmoking Chinese women, low NAT2 activity and fast CYP1A2 activity were associated with a higher risk for the development of lung cancer, with an adjusted odds ratio of 6.9 compared with high NAT2 activity and slow CYP1A2 activity.

CYP1A1 is associated with an increased risk of lung cancer in female nonsmokers (odds ratio, 3.97; 95% CI, 1.85–7.28). CYP1A1 plays a role in converting tobacco carcinogens into DNA-binding metabolites that are important in DNA adduct formation. Glutathione S-transferase (GSTM1) and GSTT1 are relevant for the detoxification of carcinogens. GSTM1 null genotype has been associated with an increased risk of lung cancer in some studies but not in others.[62–65] One study conducted among Japanese women demonstrated an association between GSTM1 null genotype and an increased risk of lung cancer, particularly among female never-smokers with the null genotype.[65] Additionally, an association was found between the GSTM1 null genotype and an increased risk of lung cancer in female never-smokers with the null genotype who had a substantial exposure to environmental tobacco smoke (odds ratio, 2.27; 95% CI, 1.13–2.7) compared with female never-smokers without the null genotype who did not have substantial exposure.[66] Similar to GSTM1, the null genotype of GSTT1 increases the risk for the development of lung cancer in never-smokers.[67]

To gain insights into the etiology of lung cancer in never-smoking women, the Female Lung Cancer Consortium in Asia (FLCCA), which includes mainland China, South Korea, Japan, Singapore, Taiwan, and Hong Kong, was founded. The FLCCA identified a distinct pattern of environmental risk factors causally linked to lung cancer in never-smoking Asian women, as well as a distinct molecular phenotype of lung cancer in never-smokers by the identification of three new susceptibility loci at 10q25.2, 6q22.2, and 6p21.32 (Fig. 5.5).[68]

In six Korean female never-smokers, novel genetic aberrations, which included 47 somatic mutations and 19 fusion transcripts, were identified. Most of the altered genes were responsible for disturbances in G2/M transition and mitotic progression, causally linked to tumorigenesis in these patients (Fig. 5.6).[69]

In a study of the genotype of 3026 lung adenocarcinomas, correlation of the major epidermal growth factor receptor (EGFR) mutations (exon 19 deletions and L858R) and V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS) mutations (G12, G13) with demographic, clinical, and smoking history data indicated a higher frequency of KRAS G12C mutations in women, who were also younger at the time of diagnosis than men with the same mutation (median age, 65 years vs. 69 years; $p = 0.0008$) and less exposed to active smoking. These findings support an increased susceptibility to tobacco carcinogens.[70] Distinct
Fig. 5.5. Manhattan plot based on *p* values derived from 1-degree-of-freedom tests of genotype trend effect in unconditional logistic regression analysis adjusted for study, age, and three eigenvectors in a genome-wide association study of lung cancer in never-smoking Asian women (5510 with lung cancer and 4544 controls). The x-axis represents chromosome location, and the y-axis shows *p* values on a negative logarithmic scale. The red horizontal line represents the genome-wide significance threshold of $p = 5 \times 10^{-8}$. Labeled are two previously associated loci (TERT at 5p15.33 and TP63 at 3q28) together with three newly identified loci (VTI1A on chromosome 10 and ROS1-DCBLD1 and the HLA class II region on chromosome 6). *(Reprinted with permission from Lan Q, Hsiung CA, Matsuo K, et al. Genome-wide association analysis identifies new lung cancer susceptibility loci in never-smoking women in Asia.* Nat Genetics. *2012;44:1330–1335.)*

differences in gender, age, and stage distribution were found for the two most common types of EGFR mutations.

FAMILY HISTORY

Nitadori et al.[71] evaluated the association between the incidence of lung cancer and family history in Japan. The authors concluded that, for women, the risk of lung cancer was higher if a first-degree relative was diagnosed with lung cancer (hazard ratio, 2.65, compared with 1.69 for men). However, this has not been a consistent finding. In a Taiwanese study, a family history of lung cancer in first-degree relatives was associated with a significantly increased risk of lung cancer for both men and women.[51] In another study, there was a 1.51-fold increase (95% CI, 1.39–1.63) in lung cancer risk for individuals who had a first-degree relative with lung cancer compared with individuals who had no family history of the disease, after adjustment for proband age, proband gender, ethnicity, education, smoking status of the proband, pack-years of smoking, and study number.[72] For ever-smoking individuals with a family history of lung cancer in a first-degree relative, the risk of lung cancer was increased 3.19-fold compared with never-smokers without a history of lung cancer in a first-degree relative. When stratified by relative type, the association was strongest for individuals who had a sibling with lung cancer (odds ratio, 1.82; 95% CI, 1.62–2.05), compared with a father (odds ratio, 1.25; 95% CI, 1.13–1.39) or mother (odds ratio, 1.37; 95% CI, 1.17–1.61). This pattern was similar in male and female probands (and for every histologic type examined), and the association was stronger among Asian individuals and those who were younger at the time of diagnosis (odds ratio, 1.83 and 1.45, respectively).[72]

VIRAL FACTORS

Human papillomavirus (HPV) may play a role in the development of lung cancer, especially in Asia. Some studies have shown that the prevalence of HPV-16 and HPV-18 infection is higher among never-smoking women older than 60 years of age with lung cancer compared with control patients (without cancer).[73,74] However, other studies have yielded different results.[75] In a retrospective evaluation of 223 lung cancer cases, HPV infection had no role in the pathogenesis of primary lung cancer, whereas HPV positivity was indicative of pulmonary metastasis from a primary HPV-associated cancer elsewhere in the body.[76] HPV has been associated with lung cancer in Asian populations, especially patients with EGFR activating mutations, who are often women. The prevalence of HPV infection among patients with lung cancer was 32% in a study from Taiwan; HPV infection and EGFR mutation were both found to be independently predictive of better survival.[77]

ENVIRONMENTAL EXPOSURES, DIET, AND PREEXISTING LUNG DISEASE

Environmental Exposures

The relationship between gender and the risk of lung cancer due to environmental exposures (asbestos, radiation, other chemicals, radon) and diet has not been extensively investigated. The risk for lung cancer has been higher among never-smoking women exposed to asbestos (odds ratio, 3.5; 95% CI, 1.2–10) and pesticides (odds ratio, 2.4; 95% CI, 1.1–5.6).[78] In a recent review, the burden of lung cancer in never-smokers attributable to previously identified risk factors was evaluated in different geographic regions. The population-attributable fractions of lung cancer related to the selected risk factors varied by geographic region. These risk factors appeared to be responsible for a substantial proportion of lung cancer in China, but accounted for a smaller proportion of cases in Europe and North America. In China, known risk factors accounted for a larger proportion of lung cancer cases in women than in men. For instance, increased levels of several carcinogens were found in the urine of nonsmoking Chinese women who reported frequent wok-style cooking.[50] Radiotherapy for breast cancer has been reported to increase the risk of lung cancer particularly in smokers. Among women who received adjuvant radiotherapy after mastectomy the risk of lung cancer was increased for women who smoked (odds ratio, 18.9; 95% CI, 7.9–45.4), but not for never-smokers.[79] According to data on 558,871 women with breast cancer in the Surveillance, Epidemiology and End Results (SEER) database who were followed for more than 20 years, the mortality rate was increased for women who had radiation therapy during 1973 to 1982 and 1983 to 1992, but not for women who had radiation therapy after 1993.[80]

Exposure to high levels of radon is also associated with an increased risk for the development of lung cancer, particularly in smokers or people exposed to secondhand smoke.[81] Bonner et al.[82] reported data on 66 women that were pooled from several case–control studies in which exposure to secondhand smoke and radon was assessed. Among women exposed to residential radon, the risk of lung cancer was threefold higher for women who had the *GSTM1* null genotype than for *GSTM1* carriers (odds ratio, 3.41; 95% CI, 1.10–10.61), even after adjusting for age, smoking status, and secondhand smoke exposure.[82]

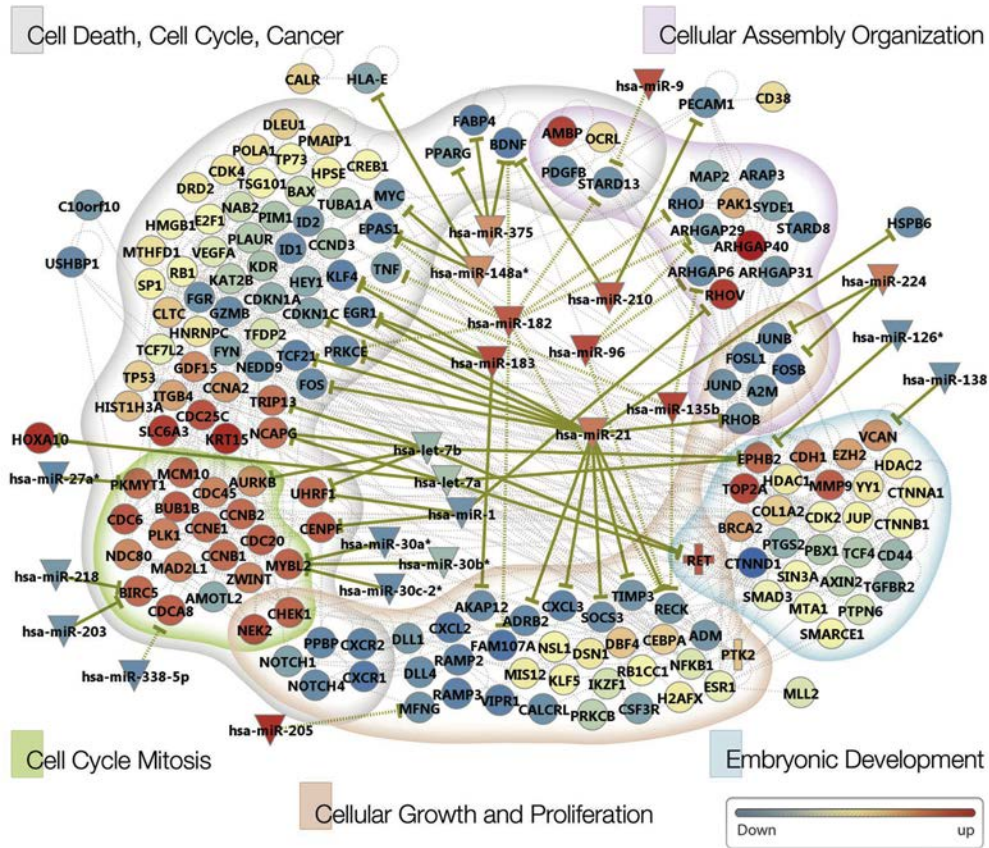
In a Spanish study, the exposure to residential radon was evaluated in 69 never-smokers or light-smokers with lung cancer.[83] The median concentration of radon in men's homes was 199 Bq/m^3, compared with 238 Bq/m^3 in women's homes; the median concentration was 237 Bq/m^3, a level higher than the reference level of 100 Bq/m^3 recently recommended by WHO.[84] Higher radon concentrations were mainly associated with large cell and small cell histology. However, the study has some limitations, including the small cohort and the fact that residential radon concentrations among the participants were almost three times higher than that found in almost 2500 homes in the region studied.[83]


Fig. 5.6. Nonsmall cell lung cancer pathway modeling for female never-smokers. The pathway information was obtained from an ingenuity pathway analysis (IPA) using the 66 network module genes as an input list. The resulting genes were grouped into five functional categories as suggested by IPA. Validated and predicted microRNA-target relations are shown in solid and dotted lines, respectively. Changes in expression levels are indicated by node color (red for upregulation and blue for downregulation). For c-RET and PTK2, the "+" symbol is used to indicate that they are involved in a gene fusion event. *(Reprinted with permission from Kim SC, Jung Y, Park J, et al. A high-dimensional, deep-sequencing study of lung adenocarcinoma in female never-smokers.* PLoS One. *2013;8(2):e55596.)*

Diet

In case–control and cohort studies, high dietary intake of fruits and vegetables has reduced the risk of lung cancer.[85] Tomatoes and cruciferous consumption have also been associated with a decreased risk for lung cancer.[86–88] More than 71,000 Chinese women with no history of smoking or cancer at baseline were prospectively evaluated for their dietary intake with a follow-up time exceeding 11 years.[89] The main food contributors to riboflavin intake were rice, fresh milk, eggs, and bok choy; dietary riboflavin intake was inversely associated with lung cancer risk (hazard ratio, 0.62; 95% CI, 0.43–0.89; $p = 0.03$ for the highest quartile compared with the lowest).[89] In the same cohort, the intake of soy food before the diagnosis of lung cancer was associated with better overall survival.[90]

Preexisting Lung Disease

Preexisting lung diseases such as asthma and COPD can represent other potential risk factors for lung cancer. Several case–control studies have demonstrated an increased risk for the development of lung cancer in both men and women diagnosed with these nonneoplastic lung diseases.[91] Even after controlling for active and passive tobacco exposure, some studies have shown an increased risk for lung cancer.[92] Wu et al.[93] found that the risk for lung cancer was increased for nonsmoking women with

previous lung disease (adjusted odds ratio, 1.56; 95% CI, 1.2–2.0) and this finding was mainly driven by the prevalence of tuberculosis in this population.

STEROID HORMONES IN LUNG CANCER

Classical steroid hormone pathways have been successfully targeted in the treatment of breast and prostate cancer, where hormone-dependent growth has been well established. Steroid hormone receptors are known to be expressed in tissues outside the reproductive tract and to have biologic effects in tumors in nonreproductive sites. Some effects mediated by steroid receptors appear to be independent of steroid ligands and result from activation of steroid receptors by phosphorylation pathways. Steroid hormone receptors could thus have biologic activity via steroid-induced signaling or steroid-independent signaling. The findings of population studies and preclinical research suggest that steroid hormone pathways are involved in the biology of lung cancer, and the estrogen signaling pathway is a promising target for lung cancer therapy. The progesterone receptor (PR) may play a role in lung cancer biology as well.

Estrogen Receptors

The results of studies of gender differences in lung cancer risk and disease presentation suggest that estrogen may be involved
Fig. 5.7. Classic nuclear estrogenic effects in the lung. Nuclear estrogen receptors (ERs) can be activated in a ligand-dependent manner by 17-β-estradiol binding to nuclear ERs at either estrogen responsive elements (EREs) or activator protein 1 (AP1) sites utilizing the fos (F) and jun (J) transcription factors in the promoters of estrogen-regulated genes. Alternatively, nuclear ERs can be activated in a ligand-independent manner, such as through epidermal growth factor (EGF)-mediated ER receptor phosphorylation. EGF receptor (EGFR) activation is an example of such a pathway. *CBP*, calcium binding protein; *ERK*, extracellular regulated MAP kinase; *Grb2/SOS*, growth factor receptor bound protein 2/son of sevenless; *GRIP-1*, glutamate receptor interacting protein 1; *JNK*, c-jun *N*-terminal kinase; *MEK*, MAP kinase-ERK kinase; *P-ER*, phosphorylated estrogen receptor; *PO₄*, phosphate; *Raf*, cellular homolog of viral raf gene (v-raf); *Ras*, rat sarcoma; *Src*, Rous sarcoma oncogene. *(Reprinted with permission from Novello S, Brahmer JR, Stabile L, Siegfried JM. Gender-related differences in lung cancer. In: Pass HI, Carbone DP, Johnson DH, et al. (eds).* Principles & Practice of Lung Cancer. in the etiology of this disease.[94] For example, women are more likely than men to have adenocarcinoma of the lung and to be never-smokers.[54] Also, the rate of diagnosis of lung cancer among never-smoking women is higher than among never-smoking men.[95] Estrogen receptors (ERs), members of the nuclear steroid receptor superfamily, mediate cellular response to estrogen. These proteins either function as ligand-activated transcription factors or can be activated by phosphorylation independent of ligand (Fig. 5.7).[96] Two forms of the ER have been identified, ERα and ERβ, which are encoded by separate genes and display different tissue distributions. In addition, multiple isoforms of ERα and ERβ exist, including at least five ERβ isoforms.[97–99]

The reports on the presence of ERs in lung tumors have been inconsistent. These differences could be due to interpretation of staining, antibodies and dilutions used, variability in the scoring assessment, or differences in patient cohort characteristics. With the identification of antibodies that distinguish between ERα and ERβ and more standard immunohistochemical procedures, it is now clear that ERβ is expressed and functional in most human nonsmall cell lung cancer (NSCLC) cell lines and is present in primary specimens of human NSCLCs from both men and women.[100–105] However, the frequency and function of the different ERβ isoforms in lung cancer are still not completely understood. There is less agreement about the expression of ERα in the lung. ERα was mainly found in the cytoplasm and membrane in immunohistochemical studies and was found to be composed of mostly alternatively spliced variants on immunoblot and RNA analysis.[100] This nonnuclear ERα pool may consist of a variant isoform that lacks the amino-terminal because it is differentially detected by antibodies that recognize the ERα amino- and carboxy-terminal.[100] ERβ, in contrast, is found in both the nucleus

and the cytoplasm and is composed of mainly full-length protein in addition to some variants.[100] ER-mediated RNA transcription and proliferation in lung tumor cell lines support the hypothesis that at least some forms of ER are functional.[100–106]

Several reports relating ER status to survival in NSCLC have shown nuclear localization of ERβ in 45.8% to 69% of lung cancer cases,[101–105] which was found to be a favorable prognostic indicator in some studies. In some reports, the prognostic significance was found only in men or was limited to a subset of patients with a particular mutation. However, most of these studies used antibodies to total ERβ that did not distinguish between the different ERβ isoforms. Recently, cytoplasmic ERβ-1 was identified as an independent negative prognostic factor for lung cancer.[105] This isoform specificity was confirmed in an additional study that showed that ERβ-1, but not ERβ-2, was linked to a worse prognosis in women with stage I lung cancer.[107] Nuclear ERβ-1 correlated with poor survival for patients with metastatic lung cancer but not in a cohort of patients with early-stage lung cancer.[108] Both ERβ-2 and ERβ-5 have been linked to better survival in lung cancer.[109]

Nuclear ERα expression is never or rarely detected in NSCLC tumors.[102–105] Prognostic significance of ERα was shown to have either no effect on survival or to correlate with poor prognosis.[101,102,105] Kawai et al.[101] reported that the presence of cytoplasmic ERα is associated with a worse prognosis among patients with NSCLC. Clearly, both nuclear and cytoplasmic ERs are important, and each component should be assessed separately and together when examining tissue specimens for clinical evaluation. In addition, further analysis on the various ERβ isoforms will be necessary to completely understand the role of ERβ in lung cancer. Standardized approaches should be developed and

validated for screening of lung tumor ERs to validate the prognostic significance of these hormone markers. These markers may also be useful to identify patients who may have a response to hormone therapy for lung cancer.

Several studies have shown that women with advanced NSCLC live longer than men with advanced NSCLC.[110,111] A population study examining lung cancer presentation and survival in premenopausal and postmenopausal women demonstrated that more premenopausal women had advanced disease at the time of diagnosis, including poorly differentiated tumors with less favorable histologies.[112] However, in that study, survival for the two groups did not differ significantly. In a more recent study, women older than 60 years of age had a significant survival advantage over both men and younger women; the difference compared with younger women is potentially due to higher levels of circulating estrogen in the younger population.[113] Survival did not differ by age among men.

Exposure to exogenous estrogens through hormone replacement therapy (HRT) has a negative effect on lung cancer survival. Ganti et al.[114] evaluated nearly 500 women with lung cancer and found a significant association between both a lower median age at the time of lung cancer diagnosis and a shorter median survival time for women who used HRT around the time of diagnosis compared with women who did not. This effect was more pronounced in women who smoked than in women who did not, suggesting an interaction between estrogens and tobacco carcinogens. The Women's Health Initiative also reported a strong adverse effect on survival after a lung cancer diagnosis in women who received HRT.[115] In that randomized, placebo-controlled trial, more than 16,000 postmenopausal women received placebo or daily HRT for 5 years. The likelihood of dying from lung cancer was significantly greater in the HRT group, with a trend toward more lung cancer diagnoses compared with the placebo group. This increase in lung cancer incidence by HRT was also demonstrated in the Vitamins and Lifestyle Study, and the effect of HRT on lung cancer risk was duration dependent.[116] However, the findings of other studies have suggested that HRT use could actually protect women from the development of lung cancer, especially if they smoked.[117] An inverse relationship was also found between HRT use and NSCLC risk in postmenopausal women with ER-positive but not ER-negative lung tumors.[118] This finding may suggest different effects on the balance between induction of cell differentiation and cell proliferation by estrogen in normal lung epithelium compared with malignant epithelium. Because lung tumors are also known to produce aromatase (discussed later), it is possible that use of exogenous hormones reduced local estrogen production by inhibiting aromatase expression. Exact HRT used, duration of use, and timing of use is crucial information needed to elucidate the exact role of HRT on lung cancer risk and survival of women with lung cancer in future studies.

Retrospective population studies have recently demonstrated that antiestrogen use can influence survival in lung cancer. An observational study that included more than 6500 women with breast cancer showed significantly lower lung cancer mortality for women who received antiestrogen treatment.[119] Similarly, in the Manitoba Cancer Registry, in which 2320 women with or without exposure to antiestrogens were evaluated,[120] antiestrogen use both before and after lung cancer diagnosis was significantly associated with decreased mortality. Together, these studies on HRT and antiestrogen use support the idea of estrogen acting as a promoter of lung cancer aggressiveness and formation and perhaps having a key role not only in the biology but also the outcome of lung cancer.

Preclinical evidence also demonstrates that estrogen is a major driver of lung cancer. Estrogen acts to induce cell proliferation of NSCLC cells in vitro and in vivo and can modulate expression of genes in NSCLC cell lines that are important for inducing cell proliferation.[100,106] Genomic estrogen signaling has been demonstrated to occur mainly through ERβ in NSCLC

cells.[121,122] Furthermore, fulvestrant, an ER antagonist with no agonist effects, inhibits cell proliferation in vitro and lung tumor xenograft growth in severe combined immunodeficient mice by approximately 40%.[100] Thus, preclinical evidence strongly suggests that targeting the estrogen signaling pathway may have therapeutic value in the treatment or prevention of lung cancer.

Three strategies are currently available to target the estrogen signaling pathway in cancer cells: (1) antagonists of ER function through drugs such as tamoxifen and raloxifene; (2) downregulation of ER function through agents such as fulvestrant; and (3) reduction of estrogen levels through aromatase inhibitors, such as the reversible nonsteroidal agents letrozole and anastrozole and the irreversible steroidal inactivator exemestane.[123,124] Tamoxifen and raloxifene have partial agonist effects in certain tissues, such as endometrium. Tamoxifen has been shown to increase lung tumor xenograft growth and is not an appropriate choice of therapy for NSCLC.[121] Additionally, the National Surgical Adjuvant Breast and Bowel Project Breast Cancer Prevention Trial did not show any decreased risk of lung cancer.[125] Seventeen tumors of the lung, trachea, and bronchus were reported among the placebo group, and 20 were reported among the women in the tamoxifen group. Although not significant, these results suggest that tamoxifen could have some agonistic effects in the lung.

Aromatase

Lung cancer cells can also produce their own estrogen.[126] The aromatase enzyme, a member of the CYP450 family, catalyzes the conversion of the androgens androstenedione and testosterone to estrone and estradiol, respectively, and is expressed in the lung.[127,128] Preclinical work suggests that aromatase inhibitors are also potential inhibitors for lung cancer therapy. Aromatase protein was expressed in lung tumor cell lines and tumor tissue and was demonstrated to be functional.[126] Additionally, the growth of lung tumor xenografts decreased substantially when treated with anastrozole. Anastrozole was recently shown to prevent tobacco-induced lung carcinogenesis in female mice, and this effect was further enhanced when anastrozole was combined with fulvestrant.[129] Interestingly, in this animal model of lung cancer prevention, aromatase expression was confined almost exclusively to inflammatory cells that had infiltrated preneoplastic areas of the lungs, whereas the abnormal epithelial cells were mostly negative.[129] Thus, an important source of estrogen synthesis may be inflammatory cells that infiltrate the lungs in response to carcinogens, beginning early in carcinogenesis. This local production of estrogen may be part of the chronic inflammatory reaction occurring in lung tumors. Aromatase inhibitor therapy in lung cancer is further supported by Coombes et al.,[130] who reported a decreased incidence of primary lung cancer in women with breast cancer who were treated with exemestane after 2 years to 3 years of tamoxifen therapy (4 women) compared with continued tamoxifen treatment (12 women).

Mah et al.[131] identified aromatase as an early-stage predictive biomarker of lung cancer survival. Among women older than 65 years of age, lower levels of aromatase in tumor tissue predicted a greater chance of survival compared with women who had tumors with higher levels of aromatase expression. Furthermore, the prognostic value of aromatase expression was greatest for patients with stage I or II lung cancer. In this population of patients with low levels of circulating estrogen levels (because of decreased production by the ovaries), tumor cells could compensate for the loss by producing estrogen through aromatase. However, no general association between aromatase and lung cancer survival was found in a separate cohort unless aromatase expression was combined with that of other markers, such as ERβ, EGFR, and PR.[129] These results strongly suggest that aromatase inhibitors, which are already approved to treat breast cancer, may be of use to treat lung cancer in women with lung cancers that have high levels

of aromatase. Aromatase expression may also be a new tool to predict survival at an early stage of disease, when more treatment options are available. A phase I clinical trial (NCT01664754) is currently underway to evaluate the side effects and best dose of the aromatase inhibitor exemestane in combination with pemetrexed and carboplatin to treat late-stage lung cancer. Other enzymes involved in intratumoral production and metabolism of estrogens are currently under investigation as potential targets for lung cancer therapy.[132]

Nongenomic Estrogen Signaling and Interactions With Growth Factor Receptor Signaling Pathways

In addition to the nuclear mechanisms of ER action, such as increased cell proliferation and gene transcription, estrogen can also rapidly activate signaling in seconds to minutes. These rapid signaling effects are referred to as nongenomic effects and occur via nonnuclear ERs located in the membrane or in the cytoplasm (Fig. 5.8). In human breast cancer cells, a membrane ER was identified as a G protein–coupled receptor called GPR30.[133,134] Expression of GPR30 has recently been demonstrated in lung cancer cells, but the function and regulation of GPR30 in the lung is still unknown.[135] In NSCLC cells, other extranuclear ERs have been identified in plasma membrane fractions and cytoplasmic fractions and have been shown to promote rapid stimulation of signaling pathways.[122,136] These effects can be inhibited by the addition of fulvestrant.

Fig. 5.8. Nonnuclear mechanism of estrogen action in the lung through rapid activation of growth factor receptors such as epidermal growth factor receptor (EGFR) and insulin growth factor receptor (IGFR1) in the cell membrane. Estrogen can bind to the estrogen receptor (ER) and activate G-proteins, which can activate Rous sarcoma oncogene (Src) and cause matrix metalloproteinases (MMPs) to cleave growth factor receptor ligands, such as amphiregulin, heparin-binding–epidermal growth factor (HB-EGF), tumor growth factor-α (TGF-α), and insulin-like growth factor-1 (IGF-1), to allow them to bind to EGFR. The ERK downstream signaling pathway is then activated, which ultimately leads to cell proliferation and survival. *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *MAPK/ERK1/2*, mitogen-activated kinase-like protein/elk-related tyrosine kinase; *MEK*, MAP kinase-ERK kinase; *PO₄*, phosphate; *Ras*, rat sarcoma; *Raf*, cellular homolog of viral raf gene (v-raf). *(Reprinted with permission from Novello S, Brahmer JR, Stabile L, Siegfried JM. Nongenomic ER signaling acts in concert with growth factor signaling pathways, such as EGFR/HER-1 and the insulin-like growth factor 1 receptor (IGF-1R). EGFR is a member of the tyrosine kinase receptor family that also includes HER2, HER3, and HER4.[137] These receptors have been implicated in proliferation, cell motility, angiogenesis, cell survival, and differentiation.[138] Clinically, overexpression of EGFR correlates with poor prognosis in people with NSCLC.[101,139] Furthermore, combined overexpression of EGFR and ERα was demonstrated to be an independent indicator of poorer prognosis in lung cancer, consistent with cross-talk between these two pathways.[101] An interaction between ER and EGFR has been demonstrated in lung cancer cells.[121,140] In this regard, estrogen can rapidly activate EGFR in lung cancer cell lines (ligand-dependent signaling) and the combination of fulvestrant and gefitinib, an EGFR tyrosine kinase inhibitor (TKI), in NSCLC can maximally inhibit cell proliferation, induce apoptosis, and affect downstream signaling pathways both in vitro and in vivo.[121,141] The more clinically relevant EGFR TKI, erlotinib, also showed superior antitumor activity in NSCLC tumor xenograft experiments when used in combination with fulvestrant compared with single agent therapy as well as a multitargeted TKI, vandetanib.[141,142] A synergistic effect of gefitinib and the aromatase inhibitor anastrozole was found in lung cancer cell lines, further supporting a functional interaction between these pathways.[143] In addition, membrane ERs were found to be colocalized with EGFR in lung tumors.[136] Ligand-independent nongenomic signaling can also occur. EGF can directly phosphorylate ER at specific serine residues.[144] These residues were found to be phosphorylated in 87.5% of ER-positive lung tumors examined.[140]

A reciprocal control mechanism was also observed between ER and EGFR in lung cancer cells. EGFR protein expression was downregulated in response to estrogen and upregulated in response to fulvestrant in vitro, suggesting that the EGFR pathway is activated when estrogen is depleted.[121] Conversely, ERβ protein expression was downregulated in response to EGF and upregulated in response to gefitinib, providing a rationale to target these two pathways simultaneously.[121] Similar cross-talk has also recently been reported between the estrogen signaling pathway and the IGF-1R pathway in lung cancer. The IGF-1R signaling pathway has been implicated in lung cancer development. Estrogen has been shown to upregulate IGF-1R expression specifically through ERβ in lung cancer cells and tissues.[145] Furthermore, both aromatase and ERβ expression were positively correlated with IGF1 and IGF-1R expression. These pathways have also been demonstrated to act synergistically to promote the development of lung adenocarcinomas in mice.[146] Additionally, combined treatment with fulvestrant and an IGF-1R inhibitor showed maximum antitumor effects compared with single agent treatment in a carcinogen-induced lung cancer murine model.[146] Targeting EGFR through small molecule TKIs is of limited use in the absence of an EGFR mutation, which occurs in a minority of patients. Interestingly, the patients who have a response to EGFR TKIs are mainly women and never-smokers, which may relate to the bidirectional signaling between EGFR and ER in lung cancer.[147] Additionally, some studies have demonstrated a correlation between EGFR mutation and ER expression.[148,149] These observations have been translated to a phase I clinical trial using drugs that target these two signaling pathways to assess the toxicity of combined treatment with gefitinib and fulvestrant in 22 postmenopausal women.[150] Targeting both pathways was found to be safe and have antitumor activity in women with stage IIIB/IV NSCLC. Additionally, nuclear ERβ was correlated with improved patient survival. A phase II trial comparing the combination of erlotinib and fulvestrant with erlotinib alone showed that the combination treatment was well tolerated and progression-free survival was similar for the two treatments.[151] In patients with EGFR wild-type tumors, the clinical benefit rate was significantly higher among patients treated with the combination

(3 people who had a partial response) compared with erlotinib alone, with a trend toward improved survival. The findings of these clinical trials suggest that targeting the ER signaling pathway via both nuclear and extranuclear receptors in conjunction with the EGFR signaling pathway has increased beneficial antitumor effects in NSCLC, as has been observed in breast cancer cells,[152] particularly in patients whose tumors do not contain an EGFR mutation. The combination of antiestrogen therapy with an IGF-1R inhibitor also warrants clinical investigation.

Progesterone Receptors

Progesterone effects are mediated through the PR. There are two main isoforms of PR, PR-A and PR-B, which play different roles in modulating cellular responses to progesterone. In general, the presence of PR in breast cancer indicates a more differentiated tumor that is responsive to antiestrogen therapy, and PR is a known estrogen-responsive gene. The ratio of PR-A:PR-B is thought to affect the clinical outcome in breast cancer. Several studies have demonstrated the expression of total PR by primary NSCLC, although the reported frequency of expression has varied greatly.[104,105,153–158] Several studies found little or no PR in NSCLC,[104,155,158] whereas PR expression was lower in lung tumors than in matched normal lung tissue.[105] Two studies showed that PR is a strong protective factor for lung cancer.[105,156] The antibodies used in these lung cancer survival studies do not distinguish between the PR-A and PR-B isoforms, which could exert different functions. Enzymes capable of synthesizing progesterone were also detected in many NSCLCs, and a positive correlation was found between intratumoral levels of progesterone and the presence of three enzymes that participate in progesterone synthesis.[156] Progesterone treatment led to growth inhibition of tumor xenografts and concomitant induction of apoptosis, in agreement with clinical data suggesting that the presence of PR was correlated with longer overall survival in NSCLC.[156] In addition, progesterone has been shown to inhibit the migration and invasion of lung cancer cell lines.[159] In breast cancer, PR is known to signal through ligand-independent mechanisms due to phosphorylation by kinases.[160] One mechanism for low tumor PR expression in breast tumors is through increased growth factor signaling, which leads to a more aggressive tumor biology with faster progression.[161] Whether this same mechanism occurs in lung tumors is unknown and is currently being investigated.

Progesterone derivatives have been useful in the treatment of both endometrial cancer and breast cancer.[162,163] Agents such as medroxyprogesterone acetate, which can be given orally, have potential for treatment of lung cancer, perhaps in combination with agents that suppress either the ER pathway or act on growth factor pathways such as EGFR or c-Met, or other TKIs. Long-term progesterone treatment may even be feasible for chemoprevention of lung cancer.

Implications for Lung Cancer Therapy

Research on estrogen in lung cancer is likely to benefit both men and women. Because lung tumors from both men and women express ER and aromatase and cell lines derived from both men and women respond to estrogens, antiestrogens, and aromatase inhibitors, these types of treatments may be beneficial for both populations, not solely women. Preclinical evidence suggests that these hormone therapies are effective in male mice (Stabile and Siegfried, unpublished data). Further understanding of the role of estrogen, estrogen synthesis, and ERs in lung cancer will provide a rationale for future targeting of this pathway for therapy earlier in the course of disease and possibly for lung cancer prevention. Additional understanding of the role of nonnuclear versus nuclear ERs as well as PRs in lung cancer and which drugs affect which receptors will be important for designing new effective treatments and clinically exploitable strategies. As hormone therapies are currently being evaluated in the clinic for lung cancer, identification of patients most likely to benefit is warranted to guide the design of future clinical trials targeting this pathway. Biomarker identification will be key to selecting the best candidates for hormone therapy in lung cancer. Because antiestrogens are safe and can be given for long periods of time, there is tremendous potential to bring them to clinical use for lung cancer.

GENDER AS A PROGNOSTIC FACTOR IN EARLY-STAGE LUNG CANCER

Although several studies have addressed different aspects of gender and lung cancer, the causes of these differences are still not yet well-defined, and, consequently, gender differences are not currently accounted for in terms of public health or of diagnosis and treatment. Several authors have reported a more favorable prognosis of lung cancer in women than in men, regardless of a longer life expectancy or the influence of other factors (Fig. 5.9). For all cancer sites combined, studies have shown better survival for women than for men. In an observational analysis performed in Tyrol, after adjusting for staging distribution, investigators found that the risk of death was lower among women (compared with men) who had lung, stomach, or head and neck cancer, as well as for all cancer sites combined, after adjusting for case mix.[164] A study of 3742 people with lung cancer (26% women), showed a significant reduction of the relative excess risk (0.82; 95% CI, 0.75–0.90) for women compared with men.[164] In a large population-based analysis conducted in patients with early disease, more women had surgery (64% vs. 56%; $p = 0.001$), and more men received radiation therapy (23% vs. 18%; $p = 0.001$). A similar trend, although to a lesser extent, was also reported for patients with local-regional disease.[22] In a Polish cancer registry, information regarding 20,561 patients diagnosed from 1995 to 1998 was collected, and a univariate analysis demonstrated that the relative risk of death for women was significantly inferior ($p = 0.001$) to that for men.[22]

In a French cohort of 208 patients with lung cancer, after adjustment for stage, women with each stage of disease lived significantly longer.[165] Similarly, in a retrospective review of 7553 patients with NSCLC treated between 1974 and 1998, the overall median survival was 12.4 months for women and 10.3 months for men ($p = 0.001$), and again, the survival advantage was uniformly detected across all stages ($p = 0.001$).[166] In these studies, the lack of information about smoking status and cause-specific mortality does not allow any definitive conclusion about the prognostic influence of gender.

In a prospective cohort of 4618 patients diagnosed with NSCLC, gender was identified as an independent prognostic factor after adjusting for age at diagnosis, tumor histology and grade, stage, smoking history (in pack-years), and treatment (resection, radiation therapy, or chemotherapy).[167] Stage of disease at diagnosis and treatment did not differ between men and women. The estimated 1-year and 5-year survival rates were 51% (95% CI, 49%, 53%) and 15% (95% CI, 12%, 17%), respectively, for men, compared with 60% (95% CI, 58%, 62%) and 19% (95% CI, 16%, 22%) for women. Men were at a significantly increased risk for death compared with women (adjusted relative risk, 1.20; 95% CI, 1.11–1.30), especially for men with stage III/IV disease or adenocarcinoma.

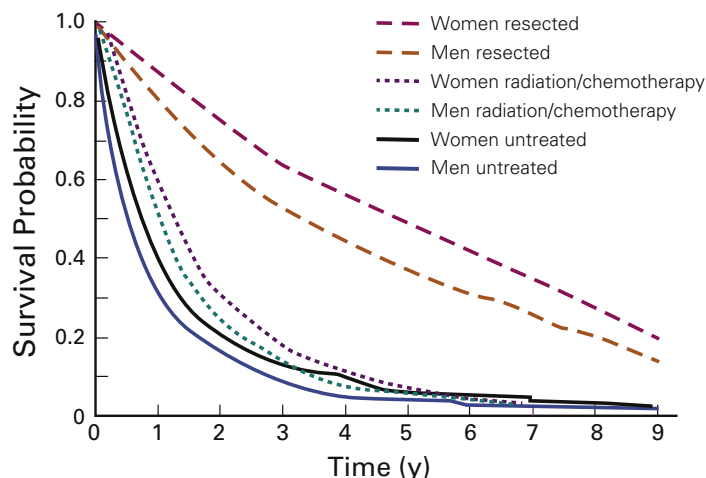
Data on a cohort of 10,908 patients with NSCLC (6665 men and 4243 women) from the Manitoba Cancer Registry showed a significantly better survival rate for women, independent of treatment, age, year of diagnosis, and histology ($p < 0.001$).[168] The adjusted hazard ratio for death for men compared with women was 1.13 (95% CI, 1.04–1.23; $p = 0.004$). Gender modified the effect of surgical treatment (hazard ratio, 1.26; 95% CI, 1.13–1.40; $p < 0.001$) and adenocarcinoma histology (hazard ratio, 1.36; 95% CI, 1.24–1.50; $p < 0.001$) when treatment was taken into account.


Fig. 5.9. Lung cancer–specific survival curves by gender and type of treatment. Women had a significant survival benefit compared with men, regardless of the type of treatment. *(Reprinted with permission from Novello S, Brahmer JR, Stabile L, Siegfried JM. Gender-related differences in lung cancer. In: Pass HI, Carbone DP, Johnson DH, et al. (eds).* Principles & Practice of Lung Cancer. A retrospective analysis of data in a prospectively validated thoracic surgery database demonstrated superior survival for women with all disease stages ($p = 0.0003$).[169] Subset analysis by histologic type demonstrated that, among patients with adenocarcinoma, survival was superior for women ($p < 0.001$); no gender difference was found for squamous cell carcinoma ($p = 0.2$).

One potential explanation for such differences is telomere length in peripheral blood, which would have significant predictive value for risk of recurrence after curative resection in NSCLC. One prospective study including 473 patients with histologically confirmed early stage NSCLC who underwent curative resection between 1995 and 2008 suggests that long relative telomere length is associated with recurrence and that women and patients with adenocarcinoma appear to represent a subgroup in which telomere biology may play an important role.[170]

Researchers analyzing data from the SEER-Medicare database covering the period 2000 to 2005 identified patients who had had lobectomy for stage I NSCLC and evaluated the in-hospital postoperative complications (pulmonary, cardiac, infectious, noncardiopulmonary) that led to a longer hospital stay (>8 days). These complications were significantly associated with male gender, older age at diagnosis (75 years or older), higher comorbidity index, larger tumors, and treatment at nonteaching hospitals ($p < 0.05$).[171]

Some of these findings have been confirmed in prospective studies. Cerfolio et al.[169] analyzed a cohort of 1085 patients and detected an overall age-adjusted and stage-adjusted 5-year survival rate favoring women (60% vs. 50%; $p = 0.001$). Stage-specific 5-year survival rates were also better for women (Table 5.1). Women who received neoadjuvant chemotherapy were more likely than men to have a complete or partial response ($p = 0.025$). These findings were similar to those in a single institution study of patients with completely resected NSCLC, in which pathologic stage, female gender, and squamous cell histology were independent predictors of survival.[173] Women with pathologic stage I disease had a significant survival advantage compared with men ($p = 0.01$), and women with stage II and stage III disease had moderately better survival ($p = 0.3$). This survival benefit was also demonstrated in a small study (Table 5.1).[166] A similar survival trend according to stage, with a more pronounced survival difference for stage I and II, was also confirmed in two other studies, and the impact of gender on survival independent from smoking status was also reported in a large Japanese cohort of 12,703 patients with resected NSCLC.[174–176]

TABLE 5.1 Comparison of Five-Year Survival for Men and Women According to Stage of Lung Cancer in Three Studies

	5-Year Survival (%)	
	Women	**Men**
CERFOLIO ET AL.[172] (414 WOMEN, 671 MEN)		
Stage I	69	64
Stage II	60	50
Stage III	46	37
ALEXIOU ET AL.[173] (252 WOMEN, 581 MEN)		
Stage I	56	42
Stage II	41	32
Stage III	21	16
OUELLETTE ET AL.[165] (104 WOMEN, 104 MEN)		
Stage I	47.2	32.7
Stage II	63.1	51.5
Stage III	14.5	6.1

The survival advantage for women is also maintained among older patient populations. A population-based analysis of data from the SEER database focused on the cases of 18,967 patients aged 65 years or older with stage I or II NSCLC diagnosed between 1991 and 1999.[177] Patients were grouped into three categories according to treatment: surgery, radiation therapy or chemotherapy, or no treatment. Survival data were controlled for competing risks, including lung cancer–specific survival, overall survival adjusting for comorbidities, and relative survival. In all treatment groups, the lung cancer–specific, overall, and relative survival were better for women than for men ($p = 0.0001$), and this benefit was retained in multivariate analysis. Sensitivity analyses demonstrated that these survival differences were not related to different smoking behaviors. Gender differences were also found among untreated patients, and this may suggest that lung cancer has a different natural history in women.[177]

Findings from population-based studies have indicated that more women have earlier stage disease at the time of diagnosis. A higher rate of health-care access among women in ongoing early detection studies raises the issue of whether or not the survival advantage by gender may be attributable to more frequent medical consultation and radiographic assessment rather than to differences in genetic predisposition and natural history of the neoplastic disease.

TABLE 5.2 Survival Data for Men and Women With Advanced Nonsmall Cell Lung Cancer

Author	Treatment	Survival Median (Mos.)		Survival 1 Year (%)	
Albain et al.[111] (1949 men, 582 women)	Platinum and nonplatinum-based (phase II/III)	5.7[a]	4.8	19	14
O'Connell et al.[110] (265 men, 113 women)	Cisplatin and vinca alkaloids	12.4[b]	8.8	NR	NR
Schiller et al.[183] (760 men, 447 women)	Cisplatin and paclitaxel Cisplatin and gemcitabine Cisplatin and docetaxel Carboplatin and paclitaxel	9.2[c]	7.3	38	31

The Early Lung Cancer Action Program screening project gave insights into women and lung cancer.[178] In the International Early Lung Cancer Action Program, baseline computed tomography (CT) screening for lung cancer was done on 14,435 asymptomatic volunteers who were at least 40 years of age, had no history of cancer, were past or current cigarette smokers, and were fit to undergo thoracic surgery.[179] Lung cancer was diagnosed in 111 of 6296 women and 93 of 8139 men. In terms of prevalence, the women-to-men odds ratio was 1.6 ($p \leq 0.001$). Women who were diagnosed with lung cancer were of a comparable age to men (67 years vs. 68 years) but had a significantly reduced tobacco exposure (47 pack-years vs. 64 pack-years). Additionally, women were more frequently diagnosed with clinical stage I disease (89% vs. 80%), but the rate of resection for stage I disease was only slightly higher than that for men (90% vs. 88%). The proportion of adenocarcinoma subtype among women and men was 73% and 59%, respectively.[179]

According to the findings of this study, the hypothesis that women may be more susceptible to tobacco carcinogens appears biologically plausible. If lung cancer risk for women who smoke is indeed higher than the risk for men of the same age who smoke, antismoking efforts directed to girls and women should be even more aggressive than those directed to boys and men. Because early detection programs are conducted among smokers, female gender may call for screening at lower levels of tobacco exposure than the threshold for men.

Consistent findings were reported from NELSON, a European study of CT screening of 15,822 participants.[180] Women diagnosed with lung cancer were significantly younger (58 years vs. 62 years; $p = 0.03$), had a lower smoking load (36 pack-years vs. 43 pack-years; $p = 0.03$), and had a lower body mass index (23.8 vs. 25.9; $p = 0.03$) than men. However, the percentage of current smokers was similar (56.7% vs. 55.9%; $p = 0.93$). Histologic subtypes were evenly distributed between men and women. Significantly more women had an early stage of disease at the time of diagnosis ($p = 0.005$). This finding held true after correcting for gender differences in age, smoking load, and body mass index ($p = 0.028$).[180]

PROGNOSTIC/PREDICTIVE ROLE OF GENDER IN ADVANCED DISEASE

Insights From Therapeutic Trials: NSCLC

Chemotherapy

Gender may be potentially considered either prognostic or predictive of a higher effectiveness of chemotherapy. The findings of a retrospective population-based study of 15,185 Japanese and 13,332 white patients treated between 1991 and 2001 suggested that Japanese ethnicity ($p = 0.003$) and never-smoking status ($p = 0.010$) were independent favorable factors for overall survival in addition to female gender and other variables such as younger age, early stage, and treatment received.[181]

A large retrospective study was conducted to review 13 Southwestern Oncology Group (SWOG) trials in which 2531 women were enrolled in clinical trials between 1974 and 1987.[108] Women had a survival advantage, with a median survival of 5.7 months compared with 4.8 months for men, and 1-year survival rates of 19% and 14% ($p < 0.01$). This benefit, however, was not maintained in multivariate analysis. Similarly, a nonsignificant difference in survival by gender was reported in the setting of multimodality therapy for locally advanced disease (median survival, 21 months for women vs. 12 months for men).[182] Survival advantage according to gender was also demonstrated in a single institution study of 378 patients with advanced stage NSCLC treated with chemotherapy, in which female gender was one of four predictors of improved survival in a multivariate analysis, and in the Eastern Cooperative Oncology Group (ECOG) 1594 study (Table 5.2).[110,183,184]

The prognostic role of gender was extensively assessed in ECOG 1594 because of the lack of survival difference among four treatment arms.[183,184] The median survival for the 1207 enrolled patients was 8 months, and all the other efficacy outcomes were comparable among the four arms. Men were more likely to have weight loss (65% vs. 58%, $p = 0.02$) and to be slightly older (mean age, 61.9 years vs. 60.5 years, $p = 0.02$). Women were more likely to have adenocarcinoma histology (63% vs. 53%, $p = 0.003$). The overall response rate did not differ by gender (19% in both cohorts; $p = 0.15$). The median progression-free survival and median survival time differed by gender; the median progression-free survival was 3.8 months for women compared with 3.5 months for men ($p = 0.022$), and the median survival was 9.2 months for women and 7.3 months for men ($p = 0.004$). Survival was also better at 1, 2, and 3 years: 38%, 14%, and 7% for women, respectively, compared with 31%, 11%, and 5% for men. This survival difference remained significant after adjusting for performance status, weight loss of more than 10%, presence of brain metastases, and stage (IIIB vs. IV). In terms of toxicity, nausea, vomiting, alopecia, neurosensory deficits, and neuropsychiatric deficits tended to be common among women.

The European Lung Cancer Working Party retrospectively analyzed 1052 patients treated between 1980 and 1991 for locally advanced or metastatic NSCLC.[185] The statistical analysis included 23 pretreatment variables, and female gender was one of eight variables significantly associated with improved survival, with a relative risk of death of 0.7 ($p = 0.03$) in a multivariate analysis.

Gender-related differences in survival were not identified in a study by the North Central Cancer Treatment Group.[183] Nine trials (6 phase II and 3 phase III) conducted from 1985 to 2001 were retrospectively considered. The chemotherapy regimen was platinum-based in five of the trials. In the multivariate analysis, gender was not an independent prognostic factor for improved overall survival and time to progression. Similar to the ECOG 1594 study, a difference in toxicity was found: the rates of both grade 3 hematologic and nonhematologic toxicities were higher for women than men, with an odds ratio of 1.60 ($p = 0.0007$) and 1.71 ($p < 0.001$), respectively.[186]

The TAX 326 trial was a multinational, phase III study of docetaxel plus carboplatin or docetaxel plus cisplatin compared with a reference regimen of vinorelbine plus cisplatin.[184] Baseline characteristics were well-balanced across treatment groups. Approximately two-thirds of the patients in each treatment group had stage IV disease. Within each arm of the study, a trend favored a survival advantage for women.[187,188] Again, gender differences in toxicity were noted: women were more likely than men to have grade 3 nausea and vomiting and neurotoxicity across all three treatment arms, whereas the rate of hematologic and other nonhematologic toxicity was similar for both groups.

A large randomized clinical trial compared cisplatin plus gemcitabine to cisplatin plus pemetrexed in 1725 chemotherapy naive patients (515 women) with stage IIIB or IV NSCLC.[189] The study showed the superior activity (better response rate and overall survival) of cisplatin and pemetrexed in "nonsquamous" NSCLC. Factors that had a significant prognostic impact on survival (independent of treatment) included gender, race, performance status, disease stage, and histology.

As a consequence of the prognostic significance of gender, a hypothetical clinical trial of a new therapy that includes patients with lower stages of disease, performance status of 0 or 1, and a high percentage of women will yield favorable results based on these selection factors alone, independent of the efficacy of therapy.

One potential explanation for better survival among women is gender differences in DNA-repair capacities that make tumors in women more responsive to platinum-based chemotherapies. DNA-repair machinery has been shown to be more defective in women, making them more susceptible to respiratory carcinogens but also more sensitive to DNA-interfering agents. Wei et al.[190] showed an association between suboptimal DNA repair and an increased risk of lung cancer. These findings were subsequently confirmed in other studies, which identified pack-years smoked as an independent predictor of lung cancer risk and also found higher DNA repair in patients with a greater smoking history and lower DNA repair in women than in men.[190,191]

NSCLC is considered to be relatively refractory to chemotherapy, which has been associated with elevated nucleotide excision repair in tumor tissue. In a case–control study, 375 patients with newly diagnosed NSCLC were accrued, and nucleotide excision repair activity was estimated by the DNA repair capacity (DRC) measured in the patient's peripheral blood lymphocytes by the host cell reactivation assay.[192] For every unit of increase in DRC, there was a progressive increase in the relative risk of death. Of the 86 patients who received chemotherapy, patients in the top quartile of the DRC distribution were at twice the relative risk of death as patients in the lowest quartile (relative risk, 2.72; 95% CI, 1.24–5.95; $p = 0.01$), whereas effective DRC was not a risk factor for death among patients who did not receive chemotherapy. In univariate analysis of the relationship between DRC and clinical and demographic variables, DRC was significantly higher in men than in women ($8.37\% \pm 2.92\%$ vs. $7.13\% \pm 2.37\%$; $p < 0.001$) but was not related to stage of disease, histology, differentiation of the tumor, or self-reported weight loss.[192]

Targeted Therapies

From a molecular biology perspective, lung cancer in women should be considered a specific entity. For instance, EGFR mutation appears to occur more frequently in women than in men, leading to a better response rate to treatment with an EGFR TKI.[193] When primary lung tumor tissues from surgically treated patients (50 men, 50 women) were analyzed and compared for expression of some hormone receptors and EGFR and KRAS mutations, EGFR mutation was significantly more frequent in women than in men ($p = 0.05$).[194] In addition, a positive link between EGFR expression and both ERα ($p = 0.028$) and ERβ ($p = 0.047$) expression both in men and women was found. The frequency of KRAS mutation was similar for men and women (13%).

In the Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination trial, 255 patients with previously treated NSCLC were randomly assigned to four separate phase II targeted-therapy treatments (erlotinib, erlotinib and bexarotene, vandetanib, and sorafenib), guided by the analysis of 11 prespecified markers assessed in core tumor biopsies.[195] Tumor tissue biomarkers showed distinct differences by gender and age: women were more likely to have an EGFR mutation (9.8% vs. 5.6%, $p = 0.02$) and EGFR gene amplification (9.9% vs. 6.1%, $p = 0.04$), whereas men were more likely to have a BRAF or KRAS mutation. Nelson et al.[196] showed that, among smokers, female gender and the presence of KRAS mutation were significantly associated, and this association persisted after adjustment for carcinogen exposures (odds ratio, 3.3; 95% CI, 1.3–7.9).[196] These findings suggest a possible role of estrogen exposure in either the initiation or the selection of KRAS mutant clones in adenocarcinoma.

Data from several phase II and III clinical trials that evaluated the role of reversible EGFR TKIs, erlotinib and gefitinib, in the setting of second- and third-line treatment of NSCLC indicate a higher responsiveness to these agents among women. In the Iressa Dose Evaluation in Advanced Lung Cancer (IDEAL) 1 and 2 studies, female gender was associated with improved outcomes with gefitinib for treatment of advanced NSCLC that had been previously treated with one or two lines of chemotherapy (Table 5.3).[193,197] In the IDEAL 2 study, 50% of women had improvement in symptoms compared with 31% of men, and 82% of the partial responses occurred in women.[193]

In a randomized double-blind, placebo-controlled phase III trial in second- and third-line treatment of advanced NSCLC, the response rate for patients treated with daily erlotinib was 8.9%, with a median survival of 6.7 months; the median survival was 4.7 months for patients who received placebo, resulting in a 42% improvement in median survival associated with erlotinib.[198] The 1-year survival rate was 31% in the erlotinib arm and 21% in the placebo arm. The response rate was significantly superior in women (Table 5.3), but in the multivariate analysis, gender was not predictive of increased response to erlotinib.

In a large phase II study, 138 patients with a diagnosis of bronchoalveolar carcinoma received gefitinib as first- or second-line treatment. Superior activity was reported for women, and survival was significantly superior for previously untreated women compared with untreated men ($p = 0.04$).[199]

Deng et al.[200] conducted a prospective clinical study that enrolled 40 Chinese women (97.5% never-smokers) with locally advanced or metastatic NSCLC (mostly adenocarcinomas) that had not responded to at least one platinum-based chemotherapy regimen.[200] The women received gefitinib monotherapy (250 mg/day), and the overall response rate was 62.5%. The median overall survival was 20 months (95% CI, 11.9–28), with 70% of women surviving 1 year and 32.5% surviving 2 years. Survival for women who had clinical benefit (complete response, partial response, or stable disease) was significantly longer than that for women who had progressive disease ($p = 0.024$), and survival for

TABLE 5.3 Gender Differences in Patients With Nonsmall Cell Lung Cancer Treated With an Epidermal Growth Factor Receptor (EGFR) Inhibitor

Author	Treatment	Overall Response Rate (Men and Women) (%)	Gender Difference
Fukuoka et al.[197]	Gefitinib 250 mg (78 men, 26 women) Gefitinib 500 mg (70 men, 36 women)	18.4 19.0	Odds ratio, W:M: 2.6 (p = 0.017)
Kris et al.[193]	Gefitinib 250 mg (60 men, 42 women) Gefitinib 500 mg (63 men, 51 women)	12 10	Response rate: 10% (women) vs. 2% (men)
Shepherd et al.[198]	Erlotinib (315 men, 173 women) Placebo (160 men, 83 women)	8.9 <1	Response rate: 14.4% (women) vs. 6.0% (men)

women with stable disease was not inferior to that for women with complete or partial response (p = 0.742). The median progression-free survival was 13 months (95% CI, 8.0–17.9).[200]

To date, none of the randomized trials addressing the role of EGFR TKIs as first-line treatment compared with platinum-based chemotherapy has shown gender differences in terms of efficacy or toxicity profile.

Published data indicate that the majority of lung adenocarcinomas from nonsmoking East Asian women can be molecularly characterized by targetable oncogenic mutant kinases, mainly EGFR mutation and anaplastic lymphoma kinase (ALK) rearrangement. Sun et al.[201] reported that the rate of EGFR mutation was as high as 82.9% in pulmonary adenocarcinoma samples from 41 Chinese women who were nonsmokers.[201] Furthermore, Wu et al.[202] documented a 34% rate of ALK rearrangement among Taiwanese patients with wild-type EGFR.[202] In another study, 104 Chinese never-smoking women with resected lung adenocarcinoma were analyzed for EGFR mutation; ALK rearrangement; and mRNA expression of the ERCC1, RRM1, TS, and BRCA1 genes. EGFR mutation was documented in 70.2% of the women and ALK rearrangement in 9.6%.[203] Specimens that harbored activating EGFR mutation were more likely to express low ERCC1 and TS mRNA levels, whereas specimens with ALK rearrangement were more likely to express low TS mRNA levels. These findings support the hypothesis that EGFR mutation and ALK rearrangement affect the efficacy of chemotherapy through the pathways of DNA repair and synthesis genes (Fig. 5.10).[203]

Vandetanib is an oral TKI with dual activity against both the vascular endothelial growth factor receptor and EGFR pathways that failed to demonstrate a survival improvement in NSCLC. However, across different trials, a trend for greater benefit was found among women who received vandetanib.[204,205]

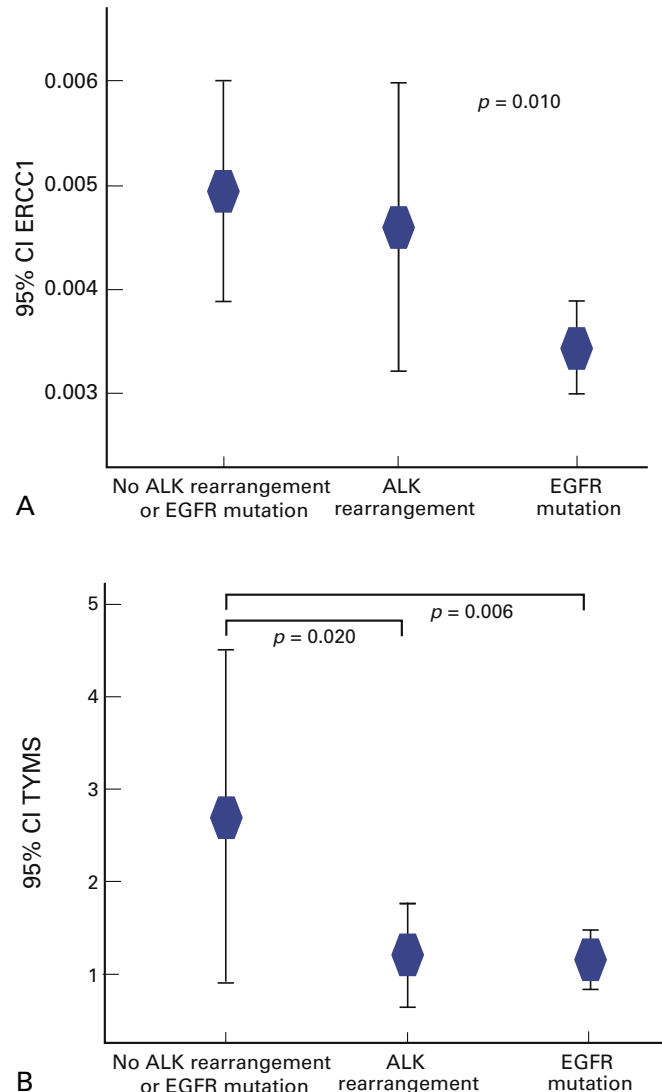
The ECOG 4599 trial compared carboplatin and paclitaxel with or without bevacizumab in patients with advanced-stage NSCLC.[206] Bevacizumab improved all the efficacy outcomes including overall response rate, progression-free survival, and overall survival. However, an unplanned subset analysis did not show a survival benefit for women treated with bevacizumab. Women accounted for 46% (387) of the enrolled patients, with some unbalances in baseline characteristics that were well-balanced in men. Fewer women had liver involvement (11.7% vs. 23.2%, p = 0.003), compared with men in both arms of the study (20.6% and 20.0%, respectively), and this unbalance could be one of the reasons for the different outcomes. A slightly higher proportion of women who received the triplet combination had weight loss of 5% or more before therapy compared with women treated with the doublet


Fig. 5.10. (A) Bar plots illustrating the distribution of excision repair cross-complementing 1 (ERCC1) mRNA expression. (B) Bar plots illustrating the distribution of excision repair cross-complementing thymidylate synthetase (TYMS) mRNA expression. Expression of ERCC1 mRNA and of TYMS mRNA differed significantly among patients who had anaplastic lymphoma kinase (ALK) rearrangement, epidermal growth factor receptor (EGFR) mutation, or neither genetic abnormality. (Three-sided U test p values are given in A and two-sided t test p values are given in B.) *(Modified with permission from Ren S, Chen X, Kuang P, et al. Association of EGFR mutation or ALK rearrangement with expression of DNA repair and synthesis genes in never-smoker women with pulmonary adenocarcinoma. Cancer. 2012;118(22):5588–5594.)*

(32.4% vs. 24.4%, p = 0.09). Although the addition of bevacizumab improved both overall response rate and progression-free survival for men and women, the addition of bevacizumab had a different effect on overall survival. Overall survival was improved in both groups (12.3 months for the triplet vs. 10.3 months for the doublet), but the beneficial effect on survival was limited to men (11.7 vs. 8.7 months; hazard ratio, 0.70; 95% CI, 0.57–0.87; $p \geq 0.001$). The outcomes for women were similar in both groups (13.3 vs. 13.1 months; hazard ratio, 0.98; 95% CI, 0.77–1.25; p = 0.87) (Table 5.4).[203]

In an attempt to explain the lack of survival benefit for women, researchers have already explored some variables, such as the

TABLE 5.4 Efficacy of Bevacizumab in Advanced Nonsmall Cell Lung Cancer, by Gender

	Paclitaxel and Carboplatin		Paclitaxel and Carboplatin and Bevacizumab	
	Women (n = 162)	Men (n = 230)	Women (n = 190)	Men (n = 191)
Response rate (%)	14.2	15.7	41.1	28.8
Progression-free survival (mo)	5.3	4.3	4.3	6.3
Overall survival (mo)	13.1	8.7	13.3	11.7

number of cycles and maintenance with bevacizumab, second-line therapies, and factors that affect clearance of bevacizumab (body mass index, albumin concentration, liver metastases), but whether the survival data are related to statistical chance or represent a true gender-based difference is still unclear. A difference in some toxicities was also noted: grade 5 neutropenia or infections with neutropenia were more common among women than among men who were treated with the triplet regimen. In addition, the rate of constipation was higher (4.7% vs. 1.4%, $p = 0.05$) and the rate of abdominal pain was higher (5.2% vs. 0.9%, $p = 0.01$). However, the potential unbalance in other prognostic factors, such as EGFR mutation, smoking status, or comorbidities, should also be assessed. Further analysis of this patient population showed a differential survival benefit from bevacizumab by age in women, but not men: women aged 60 years or older treated with chemotherapy lived longer than their male counterparts and younger women; in contrast, the survival benefit with bevacizumab was more pronounced in men of any age and in younger women.[113]

Insights From Therapeutic Trials: SCLC

Less information about gender-related differences in survival in SCLC is available. The analysis of four consecutive prospective trials showed a better overall survival favoring women.[207] A total of 2580 patients (from 10 SWOG trials) with limited disease and extensive disease were analyzed for prognostic factors. Female gender was a significant favorable independent predictor of survival only for limited disease ($p \leq 0.0001$).[208]

Individual patient data from six randomized phase II/ III chemotherapy trials investigating chemotherapy regimens in limited stage or extensive stage SCLC, conducted by the Manchester Lung Group and the Medical Research Council from 1993 to 2005, were pooled for analysis: 1707 patients were included, 44% of whom were women.[209] Response rates were similar for women and men (77% vs. 76%, $p = 0.64$), but in univariate and multivariate analyses, female gender predicted longer survival. As in previous studies, grade 3 or grade 4 emesis was more common among women (18% vs. 9%, $p < 0.0001$), as was grade 3 or grade 4 mucositis (13% vs. 8%, $p = 0.005$); no gender differences were found in terms of hematologic toxicities in dose intensity, infections, transfusions, or treatment-related deaths.[209]

CONCLUSION

Although in recent years the mortality rates for lung cancer have reached a plateau, the number of women who will die from lung cancer remains alarmingly high. A better understanding of the genetic, metabolic, and hormonal factors that affect the way women react to carcinogens and lung cancer represents a research priority. This information could affect the way patients who smoke are screened and evaluated, as well as the way smoking cessation and lung cancer prevention programs are directed.

Evidence suggests that the development of lung cancer is different in women than in men. Adenocarcinoma of the lung is more likely to develop in female smokers than in male smokers. Among never-smokers, lung cancer is more likely to develop in women than in men. Women with lung cancer also live longer than men with lung cancer, regardless of therapy and stage, although this is also true of other types of cancer. Differences between men and women with regard to the etiology and clinical presentation of lung cancer are most likely caused by a complex interaction between differences in exposure to lung carcinogenesis as well as hormonal, genetic, and metabolic differences. The variations in response to EGFR inhibitors and antiangiogenesis drugs between men and women are intriguing but insufficient to allow the gender of the patient guide the choice of therapy. All large trials in lung cancer should stratify patients according to gender, and as we enter the era of more personalized medicine, an understanding of how lung cancer in men and women differs will be a crucial factor in therapeutic choice in the future.

6 Genetic Susceptibility to Lung Cancer

Ann G. Schwartz, Joan E. Bailey-Wilson, and Chris I. Amos

SUMMARY OF KEY POINTS

- While 85% to 90% of lung cancer is attributable to cigarette smoking, substantial evidence exists to support genetic susceptibility to this disease.
- A family history of lung cancer is associated with a 1.5 to 4-fold increased risk of lung cancer after adjustment for the clustering of smoking in families.
- A family-based linkage study has identified a region on chromosome 6q that segregates with lung cancer in high-risk lung cancer families. *PARK2* has been identified as one possible lung cancer susceptibility gene in this region.
- Genome-wide association studies have identified several regions associated with lung cancer risk. These include chromosome 15q25, containing *CHRNA3* and *CHRNA5*, chromosome 6p21, containing *BAT3* and *MSH5*, and chromosome 5p15, containing *TERT* and *CLPTM1L*.
- Challenges remain in better defining lung cancer susceptibility genes, with studies underway using whole genome and whole exome sequencing methods and considering other populations including African-Americans and never-smokers.

Lung cancer is the most common cause of cancer death in the United States, with an estimated 158,080 deaths in 2016 (accounting for 27% of all cancer deaths), and the second most frequent cancer diagnosed, behind breast cancer in women and prostate cancer in men, with an estimated 224,390 new diagnoses in 2016.[1] Both lung cancer incidence and mortality rates have decreased with the reduction in tobacco smoking; however, lung cancer continues to be the cause of substantial morbidity and mortality. Survival remains poor, with a 5-year survival rate of about 17%. The 5-year survival rate has changed little over time because lung cancers are still most often diagnosed at advanced stages when treatment is less effective.[2] Only recently has there been evidence that screening for lung cancer using low-dose computed tomography is an effective means of reducing mortality.[3] In 2013, the US Preventive Services Task Force issued a recommendation for lung cancer screening for high-risk individuals.[4] Advances in the treatment of lung cancer have also been slow. Since the early 2000s, treatment targeted to molecular signatures in lung tumors, such as epidermal growth factor receptor (*EGFR*) inhibitors, has resulted in improved survival in particular subgroups of patients.[5,6] Unfortunately, the development of drug-resistant mutations is a problem that affects overall survival for patients with lung cancer, and continued drug development is crucial. To better understand the profile of a high-risk individual and to aid in the development of chemopreventive agents and targeted treatments, it is essential to understand the genetics underlying lung cancer development.

Cancer of the lung has frequently been cited and is a well-established example of a malignancy that is solely determined by the environment,[7] with risks associated with cigarette smoking and certain occupations, such as mining, asbestos exposure, shipbuilding, and petroleum refining.[8–10] About 85% to 90% of lung cancer risk is attributable to cigarette smoking.[11–13] However, lung cancer develops in only 15% of smokers, suggesting a differential susceptibility to the effects of tobacco carcinogens. It is possible that variation in genetic profiles contributes to this differential susceptibility. In addition, 10% to 15% of lung cancers occur in never-smokers. Little is understood about risk in never-smokers, although exposure to secondhand cigarette smoke certainly contributes to the risk of lung cancer. Environmental tobacco smoke exposure has been associated with a 20% to 30% increased risk for the development of lung cancer among never-smokers.[14] In a meta-analysis of 22 studies, the authors reported that exposure to tobacco smoke in the workplace increased the risk of lung cancer by 24% and this increased risk was highly correlated with duration of exposure.[15]

There is overwhelming evidence of the carcinogenic effects of cigarette smoking and other environmental exposures and the occurrence of multiple somatic mutations in lung tumors. Known mutations and loss of heterozygosity in oncogenes and tumor suppressor genes involved in lung carcinogenesis accumulate in individual somatic cells during lung tumor initiation and progression.[16–19] In 2013, the systematic genetic analysis of alterations in lung tumors was described in several published reports. The Cancer Genome Atlas noted that the results of sequencing 178 squamous cell carcinomas demonstrated the complexity of lung tumors, with a mean of 360 exonic mutations, 165 genomic rearrangements, and 323 copy number alterations per tumor.[19] These observations highlight the genetic complexity of lung cancers compared with most other cancers. Recurrent mutations were identified in 11 genes. A total of 64% of cases carried a somatic alteration in a gene for which a targeted treatment could be proposed based on currently existing therapies (although many of these therapies are not currently indicated for lung cancer). Similarly, sequencing of 183 lung adenocarcinoma tumor/normal DNA pairs showed a mean exonic somatic mutation rate of 12 events per megabase.[20] Higher mutation rates were seen among smokers than among never-smokers, and the mutation signature varied with smoking. Several previously identified mutations were reported, including those in tumor protein p53 (*TP53*), Kirsten rat sarcoma (*KRAS*), *EGFR*, serine/threonine kinase 11 (*STK11*), and v-raf murine sarcoma viral oncogene homologB (*BRAF*). In addition, novel candidates were identified. In total, 25 genes were significantly mutated and often associated with smoking history, age, stage, and progression-free survival. Smaller numbers of small cell lung tumors have been sequenced. In another study of 53 tumor samples/normal tissue pairs, investigators identified 22 significantly mutated genes, including members of the sex determining region Y (SRY)-box (*SOX*) family of genes.[21] Susceptibility to selected mutations also varies according to host-specific factors. For example, mutations in *EGFR* are much more common in women, Asians, and never-smokers and individuals presenting with adenocarcinomas,[22] while mutations affecting *KRAS* are more common in men, individuals of European descent, smokers, and those with squamous histology.[23] Susceptibility to somatic mutations may be due to individual differences in risk associated with the inhalation of known carcinogens; i.e., individuals differ in their susceptibility to these environmental insults.[24–26] The potential role that inherited germline genetic variation plays in influencing lung cancer susceptibility is the topic of this chapter.

Evidence indicates that allelic variation at genetic loci affects inherited susceptibility to lung cancer. Epidemiologic evidence demonstrates familial aggregation of lung cancer after adjusting for familial clustering of cigarette smoking and other risk factors, and differential susceptibility to lung cancer is inherited in some families. Studies of inherited susceptibility to lung cancer, including major susceptibility loci and loci with less pronounced effects, are described in this chapter. Also discussed is how these genetic risks relate to well-known environmental factors, particularly cigarette smoking.

BIOLOGIC RISK FACTORS

When determining whether susceptibility to a complex disease or trait such as lung cancer has a genetic component, three questions are typically addressed in family-based studies.

1. Does the lung cancer cluster or aggregate in families? If risk of lung cancer is inherited, one would find more clustering of lung cancer beyond what would be expected by chance.
2. If lung cancer does aggregate in families, can it be explained by shared environmental/cultural risk factors? For lung cancer, one must assess whether familial aggregation of lung cancer is driven solely as a result of clustering of smoking behaviors or other environmental exposures within families.
3. If the excess familial clustering is not explained by measured environmental risk factors, is the pattern of lung cancers in families consistent with mendelian transmission of a major gene; i.e., transmission in some families of a rare, moderately high-penetrance risk allele, and can this gene(s) be localized and identified in the human genome?

In addition, inherited susceptibility may be acquired through a more common, low-penetrance risk allele that may interact with environmental exposures. Evidence in support of this type of inheritance of risk is most likely derived from case-controlled, and not family-based, studies.

EVIDENCE FOR FAMILIAL AGGREGATION OF LUNG CANCER

Twin Studies

For common diseases, investigators often perform twin studies as a first approach to estimating the impact of genetic factors in disease causation. In twin studies, investigators typically report the observed concordance rates for lung cancer among monozygotic (MZ) twins compared with the observed concordance rates for lung cancer among dizygotic (DZ) twins. Identifying enough twins to conduct a meaningful analysis of cancer risk has been challenging; the combination of data from the Swedish, Finnish, and Danish registries with national cancer registries allowed investigators to analyze data on 44,708 pairs.[27] The results of this analysis showed substantial increases in risk for cotwins, with relative risks of 7.7 and 6.7 for male MZ and DZ cotwins, respectively; for female MZ and DZ cotwins, the risks were 25.3 and 1.8, respectively. Furthermore, a biometrical analysis of these data was performed, and investigators estimated that 26% of variance in risk was attributable to heritable factors, 12% to shared environmental factors, and 62% to individual-specific risks. The estimated heritable proportions are comparable to estimates for breast and ovarian cancer but lower than estimates for colorectal or prostate cancers. Strong evidence against the so-called constitutional hypothesis, proposed by Sir Ronald Fisher, was found in studies of MZ twins discordant for smoking, and the same host factors predispose these individuals to both smoking and lung cancer; therefore smoking does not have any direct causal link to lung cancer risk.[28,29] However, a large US study showed a much

lower relative risk when comparing smoking with nonsmoking MZ cotwins (5.5), and higher risk in DZ cotwins (11.0), which suggests a partial role of genetic factors in both smoking and lung cancer.[29]

Case–Control and Case–Family Cohort Studies

In 1963, Tokuhata and Lilienfeld[30,31] showed familial aggregation of lung cancer. After they accounted for personal smoking, the results suggested the possible interaction of genes, shared environment, and common lifestyle factors in the etiology of lung cancer. In their study of 270 people with lung cancer and 270 age-, sex-, race-, and location-matched controls and their relatives, the authors found a 2.0-fold to 2.5-fold increased lung cancer mortality among smoking relatives of people with lung cancer compared with smoking relatives of control participants. Nonsmoking relatives of people with lung cancer were also at higher risk than nonsmoking relatives of control participants. Smoking was a more important risk factor than family history of lung cancer for men, but family history was more important for women. The authors also noted a synergistic interaction between family history of lung cancer and smoking, with a much higher risk of lung cancer among smoking relatives of people with lung cancer than among either nonsmoking relatives of people with lung cancer or smoking relatives of control participants. Additionally, the authors found a substantial increase in mortality related to other respiratory diseases in relatives of people with lung cancer compared with relatives of control participants, suggesting that the relatives of people with lung cancer have a common susceptibility to respiratory diseases. No significant differences were noted between the spouses of people with lung cancer and control participants with respect to lung cancer mortality, mortality from other respiratory diseases, or smoking habits. One strength of this study was that risk factor data, including age and smoking status, were collected for the relatives; however a major weakness of the study was that smoking status alone, and not smoking intensity or duration, was used, so there was potential for residual confounding due to clustering of smoking habits in families.

Since this initial study, authors of several other studies have reported familial aggregation of lung cancer.[32-34] The best designed studies considered the number of relatives in the families and the risk factor profiles of each relative so that the effect of familial clustering of smoking habits could be taken into account, and the discussion focused on these types of studies. In southern Louisiana, authors of case-controlled studies reported an increased familial risk of lung cancer and other smoking-related cancers among relatives of lung cancer probands (the index case leading the family to be studied) after the effects of age, sex, occupation, and smoking history had been accounted for.[33-35] In these studies, investigators performed familial aggregation analyses on 337 lung cancer probands (cases), their spouses (controls), and the parents, siblings, half-siblings, and offspring of both the cases and controls. The probands were white men and women who died of lung cancer between 1976 and 1979 in a 10-parish (county) area of southern Louisiana. A strong excess risk of lung cancer was detected among first-degree relatives of probands compared with relatives of controls after adjustment for age, sex, smoking status, total duration of smoking, number of cigarette pack-years, and a cumulative index of occupational/industrial exposures. The risk of lung cancer for parents of probands was fourfold compared with parents of controls. Women older than age 40 years who were relatives of probands were at a nine times higher risk of lung cancer than similar female relatives of controls, even among nonsmokers without excessive exposure to hazardous occupational materials. Heavy-smoking female relatives of probands had a fourfold to sixfold increased lung cancer risk compared with heavy-smoking female relatives of controls. Overall, the lung cancer risk was greater for male relatives of probands than for

their female counterparts. After controlling for the confounding effects of the measured environmental risk factors, the authors found that relationship to a lung cancer proband (i.e., having a family history of lung cancer) remained a determinant of lung cancer, associated with a 2.4-fold higher lung cancer risk.

This same set of families was evaluated to determine whether cancers other than lung cancer were associated with similar familial aggregation.[35] Proband families were 1.7 times more likely than control families to have one family member other than the proband with cancer, and 2.2 times more likely to have two family members with cancer. Comparing case relatives and control relatives, families that had three cancers or four or more cancers occurred with relative risks of 3.7 and 5.0, respectively. The most striking differences in cancer prevalence between case and control families were noted for cancers of the nasal cavity/sinus, mid-ear, and larynx (odds ratio, 4.6); trachea, bronchus, and lung (odds ratio, 3.0); skin (odds ratio, 2.8); and uterus, placenta, ovary, and other female organs (odds ratio, 2.1). After controlling for age, sex, cigarette smoking, and occupational/industrial exposures, the authors found that the risk of cancers other than lung cancer remained significantly increased for relatives of cases compared with relatives of controls ($p < 0.05$).

Etzel et al.[36] conducted a large case–control study in Texas that adjusted for smoking histories among relatives and discovered similar findings. The authors studied 806 lung cancer cases and 663 matched controls in the Houston area and reported familial aggregation of lung cancer and smoking-related cancers after adjustment for smoking histories of the cases and controls and their relatives. In this study, familial aggregation was not stronger in families of early-onset cases (defined as diagnosed at age 55 years or younger) or in families of never-smokers.

Familial aggregation of lung cancer in families of early-onset lung cancer cases was evaluated by Cote et al.[37] in a large study in metropolitan Detroit that enrolled 692 white and black individuals with early-onset lung cancer (defined as diagnosed before the age of 50 years), along with 773 frequency-matched population-based control participants. Data on risk factors, including smoking pack-years, age, sex, and a history of other lung diseases, were collected for each first-degree relative of the people with early-onset lung cancer and control participants. After adjustment for these risk factors, relatives of people with early-onset lung cancer were twice as likely to have lung cancer compared with relatives of control participants. The lung cancer risk associated with family history of lung cancer was highest in black families. Increased lung cancer risk in relatives of never-smoking individuals with lung cancer was not reported in this study, however the sample size was small. The authors of the study reported a 1.5-fold increased risk of tobacco-related cancers. This risk was even higher when the analysis included only black families.[38]

The largest study of familial aggregation involved the evaluation of people with lung cancer and control participants in Iceland.[39] The authors of the study used a population-based approach and obtained familial risks of 2.69 when parents of people with lung cancer were compared with parents of control participants, and this risk increased to 3.48 when parents of people younger than age 60 years (early-onset lung cancer) were compared with age-matched control participants. The risk to siblings was increased 2.02-fold in general but increased to 3.3-fold for siblings of people with early-onset lung cancer.

Studies of never-smokers with lung cancer are limited.[36,40–43] Schwartz et al.[41] found an increased risk of lung cancer among relatives of younger, population-based nonsmokers with lung cancer compared with relatives of younger control participants after adjustment for smoking, occupation, and medical history of each family member.[41] Mayne et al.[43] studied never-smokers and former smokers (cessation at least 10 years before they were interviewed) and reported that a positive family history of lung cancer was associated with increased lung cancer risk after adjustment for age and smoking status.

In addition to studies that include an analysis of risk factor data among relatives, a meta-analysis of 28 case–control studies and 17 cohort studies demonstrated fairly consistent findings, with an approximately twofold increased risk of lung cancer associated with family history across a range of study designs.[32] Risk was generally higher for relatives of people in whom lung cancer was diagnosed at a young age and when multiple family members were affected. A recent pooled analysis from the International Lung Cancer Consortium included data from approximately 24,000 lung cancer cases and 23,000 controls, making it the largest study to date.[33] The authors reported a 1.5-fold increased risk of lung cancer associated with a family history, after adjustment for smoking and other potential confounders in cases and controls, and a 1.25-fold increased risk for never-smokers. No variation in familial risk by histology was noted. When the analysis was limited to studies that included risk factor data for each family member, relative risks for lung cancer among relatives with a family history of lung cancer were 1.55 overall, 1.53 for white, 2.09 for black, and 1.97 for relatives of people with early-onset lung cancer (diagnosed before 50 years of age). The findings from these studies help to answer the first two questions posed at the beginning of this chapter: there is substantial evidence for familial aggregation of lung cancer and it remains after adjustment for clustering of cigarette smoking within family members.

HIGH-RISK SYNDROMES CONFERRING AN INCREASED RISK OF LUNG CANCER

Further evidence suggesting an inherited component to lung cancer is the occurrence of lung cancer in families with inherited, well-defined cancer syndromes. Leonard et al.[44] reported that survivors of familial retinoblastoma may be at increased risk for small cell lung cancer (SCLC).[44] The standard mortality ratio for SCLC estimates a 15-fold increased risk.[45,46] Kleinerman et al.[46] reported lung cancer developing among individuals with germline retinoblastoma mutations and a history of heavy smoking. Overall, retinoblastoma survivors tend to smoke less than the general population, suggesting that targeting counseling to avoid this risky behavior in this high-risk population may be effective.[47] The retinoblastoma gene is inactivated in 90% of SCLCs, indicating the biologic relevance of this gene in SCLC etiology.[48]

Germline mutations in the *p53* gene cause the inherited Li-Fraumeni syndrome. Individuals with this syndrome are at greater increased risk for many other cancers, including breast and lung cancers, sarcomas, leukemias and lymphomas, and adrenocortical tumors. The standard incidence ratio for lung cancer was estimated at 38 in a prospectively collected cohort of *p53* mutation carriers.[49] Cigarette smoking further increased an individual's risk by threefold.

Mutations in the *EGFR* gene are often found in adenocarcinomas of the lung arising in never-smoking women and in Asian populations.[50] One family with multiple lung adenocarcinomas was found to have segregation of an *EGFR* mutation, indicating that rarely inherited mutations of this locus can increase the risk of lung cancer.[51] However, in another study of 237 familial lung cancer cases from families with three or more affected relatives, including 45 bronchoalveolar cancers, investigators failed to find any germline *EGFR*-T790 mutations, suggesting that inheritable mutations in this gene are uncommon in the general US population.[52]

SEGREGATON ANALYSES OF LUNG AND OTHER TOBACCO-RELATED CANCERS

Given the evidence for familial aggregation of lung and other tobacco-related cancers, after adjustment for familial clustering of smoking habits, determining whether patterns of transmission

within families is consistent with at least one major, high-penetrance genetic locus is the next step in answering the last question posed at the beginning of this chapter. Sellers et al.[53] performed genetic segregation analyses on the lung cancer proband families in the study by Ooi et al.[34] The trait was expressed as a dichotomy, affected or unaffected with lung cancer. These analyses used the general transmission probability model,[54] which allowed for variable age of onset of the lung cancers.[55–57] The likelihood of the models was calculated using a correction factor appropriate for single ascertainment,[58,59] that is, conditioning the likelihood of each pedigree of the probands being affected by their age at examination or death.

Age of onset of lung cancer was assumed to follow a logistic distribution that depended on pack-years of cigarette smoke exposure and its square, an age coefficient, and a baseline parameter. Results indicated compatibility of the data with mendelian codominant inheritance of a rare major autosomal gene that produces cancer at an earlier age of onset. Segregation at this putative locus may account for 69% and 47% of the cumulative incidence of lung cancer in individuals up to ages 50 and 60 years, respectively. The gene was predicted to be involved in 22% of all lung cancer in persons up to age 70 years, a reflection of an increasing proportion of noncarriers becoming affected by long-term exposure to tobacco.[54,60]

Gauderman et al.[61] reanalyzed these same data from Ooi's study using a Gibbs sampler method to examine gene by environment interactions and found evidence of a major dominant susceptibility locus that acts in conjunction with cigarette smoking to increase risk.[61] This analysis was very similar to the previous study results because the codominant mendelian models predicted very small numbers of homozygous susceptibility allele carriers.

Yang et al.[62] performed a complex segregation analysis on the families of never-smoking lung cancer probands in metropolitan Detroit from the study by Schwartz et al.[41] The authors found evidence of mendelian codominant inheritance with modifying effects of smoking and chronic bronchitis in families of never-smoking cases. The estimated risk allele frequency was 0.004. Although homozygous individuals with the risk allele were rare in the study population, penetrance was very high for early-onset lung cancer (85% in men and 74% in women by age 60). The probability of lung cancer developing by 60 years of age in individuals heterozygous for the rare allele was low in the absence of smoking and chronic bronchitis (7% in men and 4% in women), but in the presence of these risk factors it increased to 85% in men and 74% in women, which was the same level predicted for homozygotes. The attributable risk associated with the high-risk allele declined with age, when the role of tobacco smoking and chronic bronchitis become more important. Investigators conducted a small study in Taiwan that analyzed the families of 125 female never-smoking lung cancer probands and found evidence for effects from a dominant genetic locus.[63]

The Taiwan, Detroit, and Louisiana studies share remarkably similar results and provide substantial evidence for at least one major gene that acts in conjunction with smoking and possibly with chronic bronchitis to increase the risk of lung cancer in families. Segregation studies have some limitations. The studies did not include all potential risk factors for lung cancer, such as passive smoking or occupational exposures, in each relative, and only one study included history of other lung diseases in the models. Furthermore, segregation analyses are not sufficient to prove the existence of a major locus because only a subset of all possible models can be tested. Segregation analyses are useful, however, because they provide a model that can be used in family-based linkage studies aimed at the identification of a specific lung cancer gene. These analyses also provide insights into the best study design for identifying genes that confer a high risk of disease.

RARE, HIGH-PENETRANCE GENES: LINKAGE ANALYSIS OF LUNG CANCER

Linkage analysis is a statistical analysis of pedigree data that investigators use to look for evidence of cosegregation of alleles at a genetic "susceptibility" locus and some known genetic "marker" locus (usually a DNA polymorphism) through generations of families. This type of analysis is a powerful method for detecting genetic loci that are highly penetrant (after adjustment for environmental risk factors). Power is greatest to detect susceptibility alleles that are rare and highly penetrant; power decreases as susceptibility alleles become more common and less penetrant. Because cigarette smoking is an extremely strong risk factor for lung cancer, it is important to include this factor in all linkage studies of lung cancer.

Bailey-Wilson et al.[64] published the first evidence of linkage of a lung cancer susceptibility locus to a region on chromosome 6. Data were collected from multiple sites by the Genetic Epidemiology of Lung Cancer Consortium (GELCC). In the initial publication, the authors reported that 13.7% of the 26,108 people with lung cancer screened had at least one first-degree relative with lung cancer. For each family recruited, data regarding cancer status of all family members, birth dates, age at diagnosis, and vital status for affected family members and archival tissue and blood or saliva were collected. Cancers were verified by medical records, pathology reports, cancer registry records, or death certificates for 69% of the individuals affected with either lung or throat cancers and for another 31% through reporting by multiple family members. Initial genotyping of 392 microsatellite (short tandem repeat polymorphisms) marker loci was conducted in 52 families. The data were analyzed using both parametric and nonparametric linkage methods. Marker allele frequencies and linkage analyses were evaluated separately for white and black families, with the results combined in overall tests of linkage.

The primary analytical approach assumed a model with 10% penetrance in carriers and 1% penetrance in noncarriers, with weighting given only to affected individuals. This linkage model was used because of uncertainty about the strength of the relationship between smoking behavior and lung cancer risk in the high-risk families and because software was not available in any multipoint linkage analysis program to model complex gene–environment interactions. In addition, because about 90% of the affected family members smoked, weighting only the affected individuals in a simple dominant, low-penetrance model had the effect of jointly allowing for smoking status. Genetic heterogeneity (different families having different genetic causation) was allowed in the analysis. Secondary analyses used more complex models that included age and pack-years of cigarette smoking to modify the penetrance estimates. A genetic regressive model based on the segregation analysis by Sellers et al.[53] was used. Nonparametric analyses were also performed as secondary analyses with variance component models using Sequential Oligogenic Linkage Analysis Routines (SOLAR) (binary trait option) and mixed effects Cox regression models, in which time to onset of disease was modeled as a quantitative trait.

Multipoint parametric linkage under the simple dominant low-penetrance affected only model yielded a maximum heterogeneity logarithm of the odds (LOD [to the base 10]) (heterogeneity LOD score [HLOD]) score of 2.79 at 155 cM (marker D6S2436) on chromosome 6q23-25 in the 52 families, with 67% of the families estimated to be linked. Multipoint analysis of the subset of 38 families with four affected relatives yielded an HLOD of 3.47 at this same location, with 78% of the families estimated to be linked. For the 23 highest-risk families, i.e., those with five or more affected members in two or more generations, the multipoint HLOD was 4.26, with 94% of the families estimated to be linked to this region.[51] Nonparametric analyses and the two-point parametric analyses that used the model of Sellers et al.[35,53] all provided evidence in support of linkage in this region.

In an update to the GELCC linkage study, additional genotyping was conducted on a total of 93 high-risk lung cancer families.[65] Nearly 400 markers were again genotyped, and the primary analysis used the same model as specified previously. HLODs were calculated from output from SimWalk2 software (a statistical genetics computer application), with initial evidence for linkage estimated from each family separately, and analyses were performed separately within genotyping set and race, with results summed across study and race. Across the 6q linkage region in linked families, the investigators assigned haplotypes using SimWalk2 and visual inspection to assign carrier status. They performed Kaplan-Meier and Cox regression analyses, conditioned on carrier status and smoking behavior, to assess the relationship between smoking and lung cancer risk by carrier status. This extended analysis again identified a region on chromosome 6q, with a maximum HLOD of 4.67 in families with five or more affected individuals in two or more generations. Furthermore, lung cancer risk for putative carriers was higher than for noncarriers, even among never-smokers. Lung cancer risk for smoking noncarriers demonstrated the usual dose–response curves, with increasing risk associated with an increasing amount the individual smoked. Among smoking carriers, although risk was higher than that for noncarriers, the usual dose–response curves were not evident, suggesting that any level of tobacco exposure increased risk among those individuals with inherited lung cancer susceptibility. In this region, a germline mutation in *PARK2* was linked to lung cancer risk in one family with eight affected family members.[66] The authors found additional evidence of linkage for regions on chromosomes 12q, 5q, 14q, 16q, and 20p.[67] This study is ongoing, with additional families being genotyped with more than 6000 genome-wide single nucleotide polymorphism (SNP) markers.

COMMON, LOW-PENETRANCE GENES: GENOME-WIDE ASSOCIATION STUDIES

The GELCC linkage study was designed to identify rare, high-penetrance genes with large effects, but the search for genes contributing to lung cancer susceptibility also includes studies designed to identify more common, low-penetrance genes with more moderate effects. Initially, analyses were done to evaluate specific genetic polymorphisms in biologically plausible pathways, including metabolic genes, growth factors, growth factor receptors, DNA damage and repair genes, oncogenes, and tumor suppressor genes. These studies were typically small, focused on a very limited number of polymorphisms, and the findings have not been replicated. The authors of two reviews provided overviews of these studies.[68,69] With improved technology, the search for more common, low-penetrance genes with modest effects has been conducted in genome-wide association studies (GWAS), in which investigators rely on very large samples and more than 300,000 markers across the genome. The findings from these studies have provided highly significant and reproducible results.

In three articles published at the same time in *Nature* and *Nature Genetics*, researchers identified through GWAS the same region of chromosome 15q25.1 as being significantly associated with lung cancer.[70–72] The region that the authors identified included a neuronal nicotinic acetylcholine receptor gene cluster comprising cholinergic receptor nicotine alpha 3 (*CHRNA3*), *CHRNA5*, and *CHRNA4* subunits. Nicotinic receptors are composed of pentamers that include alpha and beta units and are ubiquitously expressed, but at higher levels in the brain. Thorgeirsson et al.[71] conducted GWAS on 14,000 individuals to identify the 15q region in association with smoking quantity and further explored the effect of the region on smoking dependence and lung cancer risk. The other two studies were lung cancer case–control studies with large sample sizes.[70,72] In all the studies, the authors identified the 15q25 region as being

associated with an approximately 1.29-fold increased risk of lung cancer among individuals carrying a heterozygous mutation (44.2% of controls for marker rs8034191) and about a 1.80-fold increase for individuals homozygous for the mutation (10.7% of controls). Because of the strong linkage disequilibrium among the markers studied and the strong link between smoking and lung cancer risk, the authors reported some disagreement between the studies as to the relevance of the region; i.e., was the region associated with smoking behavior and then indirectly to lung cancer or was the association directly with lung cancer. Thorgeirsson et al.[71] concluded that the region affected smoking behavior. Furthermore, Amos et al.[72] found stronger effects on lung cancer risk that remained highly significant ($p < 1 \times 10^{-17}$) after adjustment for smoking behavior, whereas Hung et al.[70] did not find any association of this region with smoking behavior.[70,72]

Since these initial studies, multiple investigations of the 15q region have been conducted. A meta-analysis in which smokers, people with lung cancer and lung cancer-free controls, and people with chronic obstructive pulmonary disease and controls (no chronic obstructive pulmonary disease) was conducted, and the authors reported that multiple loci within this region were associated with cigarettes smoked per day. One locus was associated with lung cancer independent of the amount the individual smoked.[73]

Findings from GWAS also prompted multiple reports of regions on chromosomes 6p21 and 5p15 being associated with lung cancer risk.[70–72,74,75] Human leukocyte antigen (HLA)-3 associated transcript 3 (*BAT3*) and MutS homolog 5 (*MSH5*) are located in the 6p21 region, but telomerase reverse transcriptase (*TERT*) and cleft lip and palate transmembrane 1-like (*CLPTM1L*) are located in the 5p15 region. Associations with lung cancer risk have been shown to vary by histologic type; however individual GWAS, even with large sample sizes, are limited in the context of lung cancer subtypes. In a large meta-analysis of 14,900 people with lung cancer and 29,485 control participants from 16 GWAS, all of whom were of European ancestry, additional support was provided for loci associated with increased lung cancer risk in the 5p15, 6p21, and 15q25 regions.[76] The 15q25 region associations for the two strongest SNPs were seen in smokers but not in never-smokers. Associations with SNPs in the 5p15 region varied by histologic type. Other than 5p15, 6p21, and 15q25, no SNP-lung cancer association was found to reach genome-wide significance. There were, however, other regions associated with squamous cell carcinomas: 12p13 (*RAD52*), 9p21 (cyclin-dependent kinase inhibitor 1B/antisense noncoding RNA in the INK4 locus [*CDKN1B/ANRIL*]), and 2q32.

Authors of a GWAS conducted in the Han Chinese population also found evidence for lung cancer risk associations in the 5p15 region, along with regions not identified in individuals of European ancestry: the 3q28 (tumor protein 63 [*TP63*]), 13q12 (mitochondrial intermediate peptidase-tumor necrosis factor receptor superfamily, member 19 [*MIPEP-TNFRSF19*]), and 22q12 (myotubularin related protein 3–HORMA domain containing 2-leukemia inhibitory factor [*MTMR3–HORMAD2-LIF*]) regions.[77] With additional samples, Dong et al.[78] were able to identify more regions of interest in the 10p14, 5q32, and 20q13 regions. In the Japanese population, Shiraishi et al.[79] replicated the 5p15 and 3q28 findings reported in the Chinese population and the 6p21 findings in individuals with European ancestry. That study was restricted to adenocarcinomas.

Imputation analysis yielded several new loci influencing lung cancer risk in European descent populations.[80] Notably, an uncommon stop mutation, K3326X, in *BRCA2* occurring in a little less than 1% of Europeans was associated with a twofold overall increased risk for lung cancer and a 2.5-fold increased risk for squamous carcinomas. This increased risk of cancer development has also been noted in other smoking-related

cancers including head and neck and esophageal cancers.[81] The variant was associated with decreased risk of ovarian cancer among *BRCA1* or *BRCA2* mutation carriers and only confers a 1.3-fold increased risk for breast cancer.[82,83] Imputation analysis also identified variants of *TP63* influencing lung cancer risk in European descent individuals and a previously identified rare *CHEK2* variant disruptive of protein dimerization that is associated with decreased lung cancer risk.[84]

Little work has been completed to identify susceptibility genes in European-descent never-smokers using a GWAS approach, in part because these individuals are not as common in the population making it more difficult to identify the numbers of participants needed for GWAS. In never-smoking women in Asia, Lan et al.[85] replicated the 6p21, 5p15, and 3q28 findings discussed previously and also reported regions of interest in 10q25 and 6q22. The authors found no association between lung cancer risk in never-smoking women and SNPs in the 15q25 region. In addition to this study, a large study is underway involving individuals of European ancestry, and results from several smaller studies have been published.[86,87] Even less has been studied in the black population. The associations between lung cancer risk and SNPs in the 15q25, 5p15, and 6p21 regions that have been identified in individuals of European ancestry have been replicated in black individuals.[88,89] A recent GWAS study of African-Americans from multiple US sites did not identify new loci specific to this population but did identify novel African-American specific variants in the *CHRNA5* region.[90]

CONCLUSION

The evidence presented clearly supports the notion of a genetic component to the risk of lung cancer, with multiple genetic loci influencing risk under investigation. The aggregation of lung cancer in families that remains after adjustment for smoking history of each relative suggests that a segment of the population is at risk due to an inherited mutation. The first and only lung cancer linkage study provided evidence of linkage to a region on chromosome 6q. If a susceptibility locus can be identified in this region, it will be of major public health importance because it will allow for the identification of a high-risk group that can be targeted for smoking prevention/cessation and for screening programs. It will also provide new understanding of the mechanism of carcinogenesis and may suggest to clinicians better methods of prevention and targeted treatment. The findings from GWAS of more common and lower penetrance SNPs associated with lung cancer risk will also contribute in the same way; however, the risk for this population may be lower than that found within high-risk families.

Challenges remain in the identification of lung cancer susceptibility genes. Once a region is identified, the actual genetic alteration driving the association has to be determined. Heterogeneity is also a problem that affects multiple points in the discovery process:

(1) at the level of histologic types of lung cancer; (2) at the level of exposure to various environmental risk factors; and (3) at the level of inherited susceptibility; i.e., the locus responsible for lung cancer in one family may not be the same as the locus in another family. The potential for gene–environment interactions and gene–gene interactions must also be considered. Given that lung cancer continues to be the leading cause of cancer death, and with the new potential for effective lung cancer screening, research into the genetic contribution to lung cancer susceptibility remains important.

7   Screening for Lung Cancer

Annette McWilliams, Fraser Brims, Nanda Horeweg, Harry J. de Koning, and James R. Jett

SUMMARY OF KEY POINTS

- The National Lung Screening Trial has definitively shown a reduction in **lung cancer mortality** in a research setting but effective implementation of a lung cancer screening program needs to be evaluated in different health-care communities.
- **Selection** of high-risk participants for low-dose (radiation) computed tomography screening is improved by the use of multivariate risk prediction models.
- A range of **recruitment** strategies will be required based on available health infrastructure and the distribution of the high-risk population.
- Simplified management algorithms for **pulmonary nodules**, incorporating risk prediction models and image analysis techniques, will likely lead to reduction in downstream investigations and surgery for benign disease.
- **Overdiagnosis** represents an important potential harm for participants in any lung cancer screening program. Rates of overdiagnosis vary with histologic subtype of the screen-detected cancer and with the phenotype of the screened population.
- **Smoking cessation** is critical to the overall benefit and cost-effectiveness of a lung cancer screening program. The best strategy to optimize the intervention and integrate it into a program is not known.
- The precision and **cost-effectiveness** of a lung cancer screening program is likely to be improved with probabilistic risk modeling and protocol-driven nodule management. The cost-effectiveness of a program will likely be a key determinant in federal or national decision making to adopt a lung cancer screening program.
- **Biomarkers** have the potential to further refine a risk-based approach to screening through identification of high-risk phenotypes or following identification of an indeterminate nodule. At present, there are no molecular biomarkers approved for clinical practice in lung cancer screening.

Lung cancer is the most common cancer and the greatest cause of cancer death in our world.[1,2] According to GLOBOCAN, there were an estimated 1.8 million cases of lung cancer diagnosed in 2012 and there were 1.59 million lung cancer–related deaths.[2] The association between smoking and lung cancer was first described more than 50 years ago.[3] Worldwide, smoking accounts for 80% of lung cancers in men and for 50% in women. About 30% of the world population reaching adulthood will start smoking, and the majority will continue to smoke throughout their lives.[1] Although smoking rates are decreasing in most high-income countries, they are increasing or persistent in low- to middle-income countries.[1] In some high-income countries with lower current smoking rates, a greater proportion of lung cancer is occurring in former

smokers.[4,5] The excess risk of lung cancer in former smokers is influenced by the age of smoking cessation, where 90% of lung cancer risk can be avoided if cessation occurs before 40 years of age.[1,3,4]

The fatality rate (ratio of mortality to incidence) for lung cancer is high, estimated to be 0.87 in the GLOBOCAN report.[2] The 5-year survival rate is generally low at less than 15% with a relative lack of variability amongst different world regions.[1,2] Most patients have advanced and incurable disease at the time of diagnosis.[1] In the United States (US), 56% of patients have distant metastasis and 22% have regional spread of disease; 15% of lung cancers are localized at the time of initial diagnosis.[6] The reason for this low percentage of early-stage disease is that it is asymptomatic; most early-stage lung cancers are currently detected by chance imaging procedures performed for other reasons.[7]

Until recently, there has been no role for lung cancer screening. Screening trials in which chest radiography and sputum cytology were evaluated did not demonstrate a decrease in lung cancer–related mortality.[8–11] In the 1990s, single-arm screening trials with low-dose (radiation) computed tomography (LDCT) of the chest demonstrated an increase in sensitivity for detecting lung cancer compared with chest radiography.[12–14] Authors of the initial trials reported that 60% to 80% of detected lung cancers were stage I disease.[15–21] These studies led to a number of randomized screening trials to compare LDCT with either chest radiography or observation alone.

There are a number of European randomized control trials that include an LDCT screening arm and a control arm.[22–31] However, these trials are likely underpowered to detect a clinically plausible benefit in terms of lung cancer–related mortality.[32] Subsequently, two larger randomized studies have been undertaken, the National Lung Screening Trial (NLST) in the US and the Dutch-Belgian Randomised Lung Cancer Screening Trial (NELSON).[33–35] The NLST study has been published and determined that LDCT screening was associated with a 20% reduction in lung cancer mortality compared with chest radiography.[36] The NELSON study is nearing completion.

The NLST has definitively shown a reduction in all-cause and disease-specific mortality in a research setting but effective implementation of a lung cancer screening program needs to be clarified in different health-care communities. The International Association for the Study of Lung Cancer Strategic Screening Advisory Committee published position statements in 2012 and 2014 to inform the process of implementation of lung cancer screening. They have recommended incorporation of a multidisciplinary group of experts and identified a number of specific issues that need to be addressed for broader community implementation. These include identification of high-risk individuals, uniform radiology standards, standardized reporting and management of CT findings, and integration of smoking cessation programs.[37,38]

The US Preventive Services Task Force (USPSTF) published recommendations on LDCT screening for lung cancer in the US in 2014.[32,39,40] Following the final decision on February 5, 2015, by the Centers of Medicare and Medicaid Services to cover lung CT screening of Americans aged 55 years to 77 years who had smoked at least 30 pack-years, lung cancer screening is being implemented in the US health-care system.[39] Many other countries are evaluating the translation of LDCT screening into

clinical practice and implementation of coordinated programs in their respective health systems.[40–43]

In this chapter, we summarize the current knowledge for lung cancer screening with LDCT and discuss the issues that require ongoing clarification.

PARTICIPANT SELECTION

Rather than a population-based strategy, as exists for breast and colorectal cancer, proposed lung cancer screening programs involve screening identified high-risk groups. A significant proportion of our community are current or former smokers who may be eligible for screening. There are an estimated 1.1 billion smokers worldwide.[1,44] To develop cost-effective lung cancer screening programs, an improved definition of a high-risk individual to target screening efforts is needed.

It is also important to consider comorbidities in participants who are potential candidates for screening. To achieve the benefits of screening, both at an individual and at a community level, participants must be able to undergo curative treatments and have a reasonable life expectancy. Smokers are at an increased risk of other comorbidities that may limit curative therapy or life span.[45] USPSTF guidelines for screening in the US recommend discontinuing screening if a person develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery.[46]

Selection criteria for LDCT screening used in research trials have largely been based on age and smoking history, but lung cancer screening is most effective when applied to people at highest risk.[47] The identification of high-risk individuals using age and smoking criteria alone was used in the NLST and NELSON trials and is the basis of current eligibility criteria in the US (USPSTF criteria; Table 7.1).

Selection of individuals for lung cancer screening using risk prediction models is superior to selection using age and smoking criteria alone.[47–51] Multiple risk prediction models exist but one of the best studied is the prostate, lung, colorectal, and ovarian (PLCO) model that is based on prospectively collected data from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial.[11] The use of this model in analysis of NLST data showed improved performance compared with NLST enrollment criteria.[48] In 2014, Tammemagi and colleagues presented an evidence-based risk threshold based on the $PLCO_{m2012}$ model and NLST mortality outcomes.[49] At $PLCO_{m2012}$ risk of 1.51% or more over 6 years there was consistently lower lung cancer mortality in those NLST participants screened with LDCT compared with chest x-ray. This risk threshold performed better than USPSTF criteria. More lung cancers were detected and fewer were missed using the risk model. The number needed to screen to prevent one lung cancer death was 255 compared with 963 in the lower-risk category. Importantly, the use of USPSTF criteria alone resulted in the screening of a substantial number of low-risk individuals and exclusion of some high-risk individuals.[49]

External validation and comparison of four published risk prediction models were performed in 20,700 ever-smokers of the EPIC-Germany cohort (Bach model, Spitz model, Liverpool Lung Project, and $PLCO_{m2012}$). The results revealed that the $PLCO_{m2012}$ model showed the best performance. All of the models, except the Spitz model, showed better prediction and performance than screening trials eligibility criteria using age/smoking criteria alone.[50]

The use of multivariate risk prediction models to select participants who will most benefit from screening is likely to be the most cost-effective strategy. The IASLC High Risk Working Group has recommended the use of these prediction models in a coordinated program.[37,51]

Recruitment

The success of a screening program is dependent on uptake by the target population.[52,53] Recruitment research from other screening programs such as breast and colorectal cancers has shown that there are many different barriers to uptake of screening, particularly in some minority groups and deprived populations, and there is no universal approach.[52,54]

There is no disease-specific evidence available to advise on the best method of recruitment to a lung cancer screening program. Most published lung cancer screening trials used a combination of various media advertising, mailed invitations, and approach via general practitioners or primary practice databases to recruit participants. Analysis of eligible participants who declined LDCT screening in the trial setting revealed a variety of factors contributing to the decision. These included practical barriers (e.g., traveling, carer responsibilities, too difficult/too much effort), emotional barriers (e.g., fear of diagnosis, anxiety), fatalistic beliefs, avoidance, low perceived risk and/or benefits, knowledge barriers, and dislikes of health-care systems.[53,55,56]

In the community, current smokers generally have lower socioeconomic status and lower education levels compared with former smokers or never-smokers.[45,54,57] In the US they also were less likely to have a regular general practitioner and have reduced access to health care.[45] Respondents to lung cancer screening trials are more likely to be younger, former smokers, better educated, more health conscious, and have better access to medical care.[34–61]

Attitudes toward lung cancer screening vary in different cohorts. In the US, published surveys of different populations have highlighted some of these variations.[45,61–63] In one cross-sectional telephone survey of 2000 individuals from the general population, less than 25% of current smokers and 7.7% of former smokers believed they were at increased risk of lung cancer.[45] Current smokers were less willing to undergo surgery and had less perceived benefit of screening. Other cohorts have shown greater awareness of risk and willingness to undergo screening.[61,63] In a separate cross-sectional written survey of war veterans in the US, 80% of current smokers and 16% of former smokers believed they were at an increased risk of lung cancer.[61] The majority of participants were willing to take part in screening, have surgery, and had higher perceived benefits of screening. This cohort differed from the general population in that the majority had good access to health-care facilities.[61] In an ethnically diverse cohort recruited from a US primary care center uptake of screening was affected by fatalistic beliefs, sense of self-efficacy, understanding of impact of lung cancer, concerns about radiation effects, and mistrust of health-care workers.[62] Costs also play a role in screening uptake in health-care systems that are not fully publicly funded. It was noted in this cohort that a requirement to pay for a CT scan would be likely to reduce screening uptake.[45,62,63]

A cross-sectional survey in the United Kingdom specifically addressed smokers in socioeconomically deprived communities and also revealed complex attitudes to screening.[54] Participants

were positive in principle about screening, had high levels of fear of lung cancer but had low perceived benefits of screening, felt stigmatized, and held avoidant and fatalistic beliefs, particularly amongst current smokers.

These findings suggest that implementation of a lung cancer screening program in a general population may have some difficulty recruiting current smokers, would need to educate current and former smokers about their perceived risks of lung cancer and benefits of screening, and would need to design targeted education and recruitment strategies to allay fears and anxiety in certain community groups. CT costs likely need to be fully covered, and programs would preferably have multiple access points in the community (i.e., noncentralized LDCT access).[45,62]

A range of recruitment strategies will be required based on available health infrastructure and the distribution of the high-risk population in each country. National support and a centrally organized coordinated program are more likely to result in higher uptakes of screening. Approaches using invitations customized to the characteristics of the target group and involvement of the primary care team are also likely to have some benefit.[52] Therefore to target different high-risk populations in the community, to maximize uptake in a screening program, and to ultimately reduce lung cancer mortality, we face a variety of challenges both within and between countries.

SUMMARY OF RANDOMIZED SCREENING TRIALS

Published single-arm, observational screening trials since 1999 have established that lung cancer screening with LDCT is feasible.[13–21] The majority of cancers detected by LDCT are at an early stage, making them amenable to curative techniques. The NLST and the NELSON were established to assess the mortality benefit of lung cancer screening but had notable differences in design (Table 7.2). In addition, there are a number of smaller

randomized studies in Europe including the Discontinuation of Antihypertensive Treatment in Elderly People (DANTE),[22,24] Multicentric Italian Lung Detection (MILD),[25] Danish Lung Cancer Screening Trial (DLCST),[26,27] Italian Lung Cancer Screening Trial (ITALUNG),[28,29] UK Lung Cancer Screening (UKLS),[64] and German Lung Cancer Screening Intervention Trial (LUSI)[30,31] studies that are at varying degrees of follow-up and maturity (Table 7.2).[65–67] One particularly notable difference is that the NELSON and other randomized European studies have predominantly male participants compared with the NLST study (Table 7.2). This may influence the final mortality benefit, as subset analysis of the NLST data suggested greater mortality benefit for LDCT screening in women.[68]

The NLST was powered to show a mortality benefit of at least 20% and enrolled 53,456 participants with three annual screening scans (Fig. 7.1). The NELSON study was designed to show a mortality benefit of at least 25% but only enrolled about 15,822 participants with repeat screening scans at increasing intervals. The European CT screening trials collaborative group will pool the smaller randomized European studies with the NELSON study data for mortality evaluation (Table 7.2).[66,67]

Because the random assignment of eligible participants in the NELSON study took place from 2004 to 2006, 10 years of follow-up will be reached for all participants in 2016. To perform the mortality analyses, data linkages with national cancer and death registries must be undertaken and complete data will become available in early 2019. The final mortality analyses of NELSON and pooling of data with other trials within the European consortium will then be performed.[66]

PULMONARY NODULES

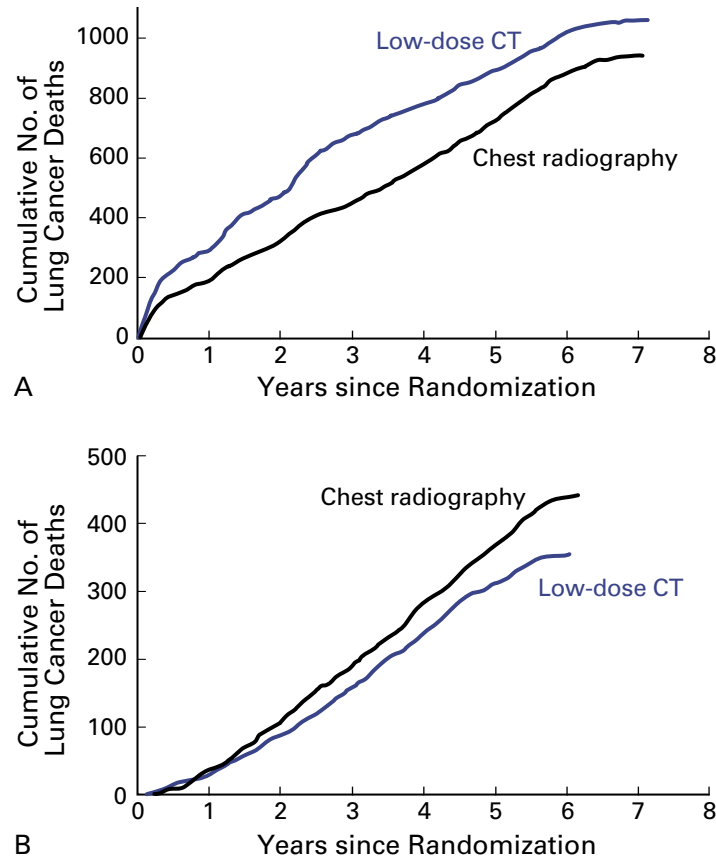
Screening LDCT scans in ever-smokers over 50 years of age frequently detects noncalcified pulmonary nodules.[65,73,74] A number


Fig. 7.1. Cumulative numbers of lung cancers and deaths from lung cancer in the National Lung Cancer Screening Trial. (A) The number of lung cancers includes lung cancers that were diagnosed from the date of randomization to December 31, 2009. (B) The number of deaths from lung cancer includes deaths that occurred from the date of randomization to January 15, 2009. *CT,* computed tomography. *(Reprinted with permission from National Lung Screening Trial Research Team, Aberle DR, Adams AM, et al. Reduced lung-cancer mortality with low-dose computed tomographic screening.* N Engl J Med. *2011;365(5):395–409.)*

of guidelines have been published to assist in the management of nodules found on the baseline LDCT and to minimize downstream investigations or unnecessary biopsy/surgery. The guidelines have used different nodule measurement techniques, action thresholds, and diagnostic algorithms and have become increasingly complex.[75–78]

In published studies, pulmonary nodules can be seen on the baseline LDCT in up to 70% of screened participants.[16,73,74] The majority of these nodules are in subcentimeters and only a small proportion will eventually be diagnosed as lung cancer, the remainder being benign. They require further surveillance or investigation because there is usually no prior imaging available to assist in nodule analysis and decision making. This may create additional work, further radiation exposure, investigations, anxiety for participants, and even unnecessary surgery.

The term "positive screen" and/or "indeterminate screen" has been used to define an action threshold that will prompt investigation before the next annual screening LDCT, that is, an "interval" assessment. The investigation may be only further radiologic follow-up at a short-term interval or could include positron emission tomography scan, biopsy, or surgery. The definition of a "positive or indeterminate screen" has varied between published studies but generally the definition uses nodule size or nodule volume thresholds and nodule appearance.[65,79] These varying definitions have caused some confusion in interpretation of different LDCT studies, and a "negative screen" did not necessarily mean an absence of pulmonary nodules. In the NLST and NELSON studies, a similar proportion of

participants had a baseline LDCT result that required a short-term interval repeat LDCT: about 19.6% and 19.2%, respectively; about 1.8% to 2.1% had biopsies, and 1.1% to 1.2% had surgery.[66,71,73,80] Surgery performed for benign disease varies between 10% and 29% with the NLST and NELSON results at the upper range of reported rates in the randomized studies (Table 7.2).

Baseline Probabilistic Nodule Risk Prediction

Although nodule size and type are important, in 20% of screening participants the largest nodule is not the malignant lesion.[80] A different approach to evaluation of pulmonary nodules detected on LDCT screening was described using the Pan-Canadian nodule prediction model.[80] This nodule risk prediction tool was based on prospectively collected longitudinal nodule data in a screened cohort of current or former smokers over 50 years of age and validated in a separate screened cohort. It utilizes both participant and nodule characteristics. The area under the curve was 0.97 and the performance persisted even when applied to nodules less than 10 mm in diameter.[80] Using this model, the number of participants with a "positive screen" requiring interval assessment after baseline LDCT can be reduced to 8% compared with 20% as seen in the NLST and NELSON trials.[79] This approach may assist in improved definition of low- and high-risk groups and simplifying the clinical decision algorithm when a nodule is detected on a baseline LDCT without the need for further imaging, investigation, or volumetric analysis.[79,80]

This risk model was subsequently validated in two independent cohorts and has been suggested to have superior performance to the American College of Radiology Lung Imaging Reporting and Data System (Lung-RADS) classification.[81–83] It has been recommended by the American College of Radiology Lung-RADS and the British Thoracic Society Guidelines. It is being prospectively evaluated in the International Lung Cancer Screening Study in Australia and Canada.[78,84]

The Lung-RADS (http://www.acr.org/Quality-Safety/Resources/LungRADS) was designed to facilitate uniform reporting of abnormalities seen on lung CT screening. The system has been validated using the NLST data and was reported to lower the false-positive rate from 27% for the NLST to 13% for Lung-RADS, and after baseline decreased to 5.1% for Lung-RADS compared with 21.8% for the NLST. A corresponding decrease in sensitivity for Lung-RADS was also noted.[85]

Prospective validation studies for this system, now that lung cancer screening is approved in the US, will help to define Lung-RADS's performance and possible integration with volumetric studies and nodule risk models.

Longitudinal Surveillance

For nodules that do not prompt immediate investigation, longitudinal assessment of behavior is the usual management, with growth or development of a solid component prompting intervention. Management of nodules detected at the baseline LDCT has been approached in different ways.[65,79,86] The majority have used maximum two-dimensional measurements and appearance of the lesion. More recently, the NELSON study and some other European studies have utilized three-dimensional nodule reconstruction, volumetric analysis of nodules, and calculation of tumor volume-doubling time (VDT) to evaluate the detection of nodule growth.[25,30,31,64] NELSON utilized a nodule protocol based on volumetric assessment, nodule growth (defined as a change in volume of ≥25%), and VDT.[87,88]

LDCT results were defined as follows: (1) negative, screened at next round (new nodules <50 mm^3 or previously detected nodule with growth <25% or growth ≥25% and VDT >600 days); (2) positive, referred to pulmonologist (new nodules >500 mm^3 or previously detected nodule with growth ≥25% and VDT <400 days); and (3) indeterminate, referred for a short-term follow-up CT (new nodules 50–500 mm^3 or previously detected nodule with VDT 400–600 days). The use of this nodule management strategy resulted in a higher positive predictive value (40.6% vs. 3.6%) and a substantially lower false-positive result (59.4% vs. 96.4%) than in the NLST.[86] The calculation of VDT, however, does require a second LDCT for comparison, and approximately 20% of NELSON participants therefore required further interval LDCT after a baseline LDCT using this algorithm. Volumetric analysis is currently limited to solid nodules and requires specific software.[89] The continued development of software systems to assist in nodule detection, automated risk calculation, or image analysis will likely significantly improve the workflow in an LDCT screening program.[90,91] Such programs are likely to include automated nodule risk assessment at baseline and volumetric analysis longitudinally in high-risk lesions (Figs. 7.1 and 7.2).

OVERDIAGNOSIS

Overdiagnosis refers to the detection of cancers that would not have led to death if untreated.[92] This includes patients who will die from another cause, for example, comorbidity or an unexpected event, even if the detected cancer becomes clinically significant.

The challenge for clinicians with overdiagnosis is that it can only be applied retrospectively and therefore it is very difficult to relate this population-based concept to an individual to assist with clinical decision making. It is important to note that overdiagnosis does not affect the known mortality benefit of LDCT screening for lung cancer, but does represent an important potential harm of screening, because it incurs additional cost, anxiety, and morbidity associated with (perhaps unnecessary) treatment.

Overdiagnosis is present in all screening programs, for any cancer type. The prevalence of overdiagnosed cancers in LDCT screening trials is certain, but the precise magnitude is not known. There are wide-ranging estimates of overdiagnosis from LDCT screening for lung cancer, dependent on statistical approach, the population being studied, accounting for lead time and length time bias, histopathologic cell type, the definition of a positive screen, and even the definition of overdiagnosis itself. Modeling studies by the Cancer Intervention and Surveillance Modeling Network estimate that 9.5% to 11.9% of screen-detected lung cancers are overdiagnosed.[46] Analysis of the 1089 lung cancers reported in the LDCT arm and 969 in the chest x-ray arm of the NLST suggested that the probability of overdiagnosis for any screen-detected lung cancer was 18.5% (95% confidence interval [CI], 5.4% to 30.6%).[93] Other modeling estimates with different approaches to account for length and lead time bias suggest that the proportion of overdiagnosed cases may be less than 10%.[94] For bronchioalveolar lung cancers (now considered in situ adenocarcinomas) in the NLST, this figure was estimated to be 78.9% (95% CI, 62.2% to 93.5%). Overdiagnosis may also relate to the phenotype of the screened population: after stratification of 18,475 individuals from the NLST by the presence, or absence, of spirometric-defined chronic obstructive pulmonary disease (COPD), the early-stage adenocarcinomas were almost exclusively found in the normal-spirometry group.[95] This suggests that overdiagnosis is more likely in individuals with no spirometric evidence of COPD.

From a clinical perspective, mitigating the possible harm of overdiagnosis requires careful use of terminology and perhaps even judicious use of terminology for a positive screen, for instance not regarding a lesion with long VDT of over 600 days, or a pure ground-glass opacity, as a true-positive screen.[96] Models developed from the NLST data suggest that only some lung cancers with low aggressive behavior (i.e., predominantly the in situ adenocarcinomas/atypical adenomatous hyperplasia) will become symptomatic, with 14% at 5 years and 27% at 10 years becoming clinically significant.[93,97] Similarly, long-term follow-up of pure ground-glass opacity lesions in a Japanese cohort indicated 16% demonstrating tumor growth after 3 years' follow-up.[98] Clinical decision making with consideration for the probability of a lesion becoming clinically relevant, in tandem with attention to age and comorbidities (with their associated risk), and personal preference, is required for individuals in whom such (possibly) indolent cancers are identified on LDCT.

SMOKING CESSATION

Aside from the clear impact of smoking cessation on all-cause mortality, the importance is highlighted following resection for lung cancer with a large systematic review reporting a 5-year survival rate of 77% in those able to quit and 33% in those continuing to smoke.[99,100] This study reported statistically significant increased hazard ratios for all-cause mortality, reoccurrence, and development of second primary with continued smoking after resection of early-stage nonsmall cell lung cancer.

Within lung cancer screening studies the proportion of current smokers has ranged from 47.3% to 76.1% at baseline.[22,26–28,30,36,101,102] Cessation rates of study participants have ranged from 6.6% to 29.0%,[27,103–111] which are likely to be higher than spontaneous quit rates in the general population (5% to 10%).[112,113] Increased numbers of quit attempts amongst participants likely lead to higher cessation rates in some, but not
Fig. 7.2. Example of assessment of nodule size using volumetric software in the NELSON trial. Baseline low-dose computed tomography shows a nodule with a volume of 302 mm^3 in the right upper lobe of a 66-year-old man. Three months later, the volume increased to 575 mm^3; the volume-doubling time was 98 days. On diagnostic workup, a pT1 N0 Mx squamous cell carcinoma was diagnosed.

all, studies.[103,105–110] It is not known whether the higher quit and cessation rate is a result of selection bias, of increased health awareness due to participation in a cancer screening trial, of the accompanying smoking cessation interventions, or perhaps related to the CT scan result itself.

The number of quit attempts by participants with an abnormal result on LDCT screening is higher than that by participants with a normal result.[103,105–110] The positive relationship of an abnormal CT scan and smoking cessation is present for any abnormal CT finding, but is stronger for abnormalities suspicious for lung cancer, with persistent effect for up to 5 years.[114] This observation suggests that the finding of an abnormality on CT screening may be a teachable moment for current smokers.

Some studies have demonstrated an initial low uptake of optional smoking cessation services, hence the need to integrate smoking cessation both at enrollment and also with repeated interventions over multiple time points.[111,115,116] Most guidelines now recommend integrated smoking cessation within a lung cancer screening program, and integrated smoking cessation is a requirement for Medicare-funded screening in the US.[37,46,117–119] There are recent data supporting the cost-effectiveness,[120] additional mortality benefit,[121] and a high sustained quit rate with such an approach,[114] although the best strategy to optimize smoking cessation and long-term abstinence in the context of LDCT screening is not known.[111]

Cost-Effectiveness

The cost-effectiveness of any screening intervention is one of the major considerations for national or federal policy.[122] There has been a wide variance of cost-effectiveness from different (observational) studies, with varying methods, outcomes, assumptions, and data sources.[123–126] Randomized controlled trial data on cost-effectiveness from the NLST report $67,000 per quality-adjusted life year gained (95% CI, $52,000–186,000) and £8466 (95% CI, £5542–12,569)

from the UKLS study.[64,127] As randomized controlled trial data, these reports provide invaluable "real-life" data, and these reports have different methodolgic assumptions and approaches to others (as well as differing health-care practices in the US compared with many other countries), making direct comparisons difficult and highlighting the continuing need for local data.

Cost-effectiveness modeling of the Pan-Canadian Early Detection of Lung Cancer (PanCan) study demonstrated that LDCT-detected early-stage cancers treated by surgical resection are cheaper than treating later-stage lung cancer and that the cost-effectiveness of any program is most sensitive to all-cause mortality and the annual costs of screening.[128] Importantly, the approach in the PanCan study utilized probabilistic prediction modeling (as did the UKLS study) and demonstrated that there are likely to be significant cost efficiencies from the use of risk-selection tools. This analysis also further highlighted the importance of smoking cessation influencing cost-effectiveness. In addition, in advanced lung cancer, targeted therapies and personalized approaches to treatment cost more than chemotherapy, further highlighting the potential importance of early detection and treatment.[129]

In the NLST, screening with LDCT was much more cost-effective in women than in men and among the groups with a higher risk of lung cancer, which demonstrates the importance of identifying high-risk groups and enhancing pretest probability.[127] Identifying the most appropriate means of recruitment of high-risk individuals,[130] the size of the potential population at risk,[128] development of an accurate risk prediction model,[48] nodule management algorithms minimizing repeat scans for false-positive nodules,[80] and effective smoking cessation interventions[131] are key factors in determining the cost of a lung cancer screening program. The challenge for policy makers is assessing unique federal or national conditions, health-care systems, and costs to judge if a lung cancer screening program will be cost-effective, and thus appropriate for local populations.

BIOMARKERS

Since the publication of the NLST data, there has been renewed interest in the development of biomarkers that might assist in improving pretest probability of a positive result for screening (i.e., better identification of a high-risk group, with reduction in number needed to treat) and/or to improving specificity for diagnosis following identification of an indeterminate nodule.

A molecular biomarker could come from a variety of sources including sources that are tissue based (dependent on accessibility) or biofluid based (including peripheral blood, urine, sputum, and breath). Such biofluid-based markers include circulating tumor cells, cell-free DNA and RNA, proteins, peptides, metabolites, microRNA, antibodies to tumor-associated antigens or tumor microenvironment, and exhaled breath condensate.[132] Despite hundreds of biomarkers reaching Food and Drug Administration phases I and II of development, few have reached phase III (the capacity of the biomarker to longitudinally detect preclinical disease) and currently four are in phase IV (prospective evaluation: summarized in Table 7.3). At present, no biomarkers are currently used in clinical practice.[133,134]

Arguably, the most informative biomarker available at this time is the measurement of spirometry (forced expiratory volume over 1 second and forced vital capacity), which in turn can identify individuals with airflow obstruction and COPD. The presence of COPD improves risk selection for lung cancer screening, including a subanalysis from the CT arm of the NLST, demonstrating that spirometric airflow limitation was associated with a doubling of lung cancer risk, no apparent overdiagnosis, and a more favorable stage shift.[48,95,135–137,139]

TABLE 7.3 Biomarkers Under Prospective Evaluation

Autoantibody signature[135]	The EarlyCDT-Lung test performs an assay for seven autoantibody signatures. Undergoing evaluation as a pre-CT screening tool.
Serum miRNA[136]	A 34-miRNA signature capable of stratifying risk in early and advanced NSCLC, benign lesions, and other tumor types. Evaluation as part of the COSMOS study.
Plasma miRNA[137]	A 24-miRNA signature for the detection of NSCLC with stratification of low, intermediate, and high risk. Evaluation as part of the MILD study.
Prosurfactant B[138]	The integration of plasma pro-SFTPB levels into a lung cancer risk prediction model (using phenotypic information) significantly improves lung cancer prediction in a high-risk cohort. Evaluated as part of the PanCan study.

CT, computed tomography; *MILD,* Multicentric Italian Lung Detection; *miRNA,* microRNA; *NSCLC,* nonsmall cell lung cancer; *SFTPB,* surfactant protein B.

It is widely anticipated that personalized care will increasingly influence clinical decision making in the future. As such, the drive to identify and develop biomarkers that can assist in discrimination of high or low risk of lung cancer, or benign or malignant tumor will continue. A future biomarker will need to gain sufficiently high sensitivity (to rule out disease), or high specificity (to rule in disease), or alter clinical decision making, as well as being acceptable to patients, and contribute to the cost-effectiveness of any lung cancer early detection program.

CONCLUSION

LDCT screening for lung cancer has produced a significant reduction in lung cancer–specific and all-cause mortality in the NLST study. Screening programs have now commenced in the US, and many other countries are evaluating implementation in their individual health-care systems. Further mortality outcome data from the NELSON trial and other pooled European studies will become available in the near future.

In the interim, we anticipate continued efforts to help improve the selection of individuals who will benefit most from screening by using risk prediction models to characterize the highest risk groups in our communities. In addition, further improvements in the management of screen-detected pulmonary nodules by utilizing prediction models, volumetric and CT image analysis, and incorporation of biomarkers are needed to reduce unnecessary investigations and surgery for benign disease and maximize cost-effectiveness.

The future implementation of lung cancer screening will require coordinated programs with multidisciplinary team management, integrated smoking cessation, quality assurance/accreditation, and standardized algorithms to maximize the benefits and minimize the harms of screening. It is paramount that these endeavors continue in parallel with efforts to reduce smoking prevalence.

8 Preclinical Biomarkers for the Early Detection of Lung Cancer

Jun-Chieh J. Tsay, Alissa K. Greenberg, William N. Rom, and Pierre P. Massion

SUMMARY OF KEY POINTS

- This chapter provides a review of some of the most promising recent studies of diagnostic biomarkers in lung cancer.
- We discuss the challenges and the importance of biomarker validation. Current guidelines recommend a study design to include prospective collections of specimens and retrospective blinded evaluation.
- A novel multiomics approach to biomarker discovery has greatly advanced the field of early lung cancer detection.
- Noninvasive biomarkers in the blood, sputum, airway epithelium, or exhaled breath can be combined with imaging to detect early stage lung cancer and improve mortality.

Lung cancer is the leading cause of cancer deaths in the United States and worldwide.[1] This statistic is largely due to the persistent poor survival of patients diagnosed with lung cancer. In the United States as of 2009, the overall 5-year survival for nonsmall cell lung cancer (NSCLC) remained at only 16.6%.[2] However, if the cancer is detected at an early stage, the 5-year survival exceeds 50%.[3] For this reason, in the last decade, the quest for an effective means of early diagnosis has intensified. In 2011, the results of the randomized multicenter National Lung Screening Trial (NLST) were published, confirming that early diagnosis of lung cancer can improve survival.[4] Screening for lung cancer in the high-risk group studied in the NLST now has the support of the US Preventive Services Task Force (grade B recommendation).[5] However, low-dose computed tomography (CT) of the chest for lung cancer screening has significant drawbacks, including cost, radiation exposure, high false-positive rates, and a risk of overdiagnosis of indolent cancers. Thus the results of NLST have sparked even greater interest in developing more practical and more specific means of early detection of lung cancer, using noninvasive biomarkers of early disease.

Biomarkers for lung cancer have several potential clinical uses in addition to early detection (Fig. 8.1). They may be used for risk stratification, optimal treatment selection, prognostication, and monitoring for recurrence. Markers of risk can help identify a population to be screened. At this preclinical stage, the marker identifies individuals without disease but with factors that may predispose them to lung cancer. Given the high false-positive rate with CT screening, a marker that could more clearly define the at-risk population could decrease the number of screening CT scans conducted and also improve the specificity of CT screening, thus decreasing patient anxiety and the need for repeated CT and invasive procedures induced by false-positive nodules.

Markers are currently used for treatment selection, prognostication, and monitoring for recurrence in patients with known disease. A variety of markers, reflecting the biology of lung cancer

progression from premalignant lesions to invasive lung cancer, may prove to be more useful for each of these roles. In this chapter, we focus on current and potential biomarkers for the early detection of lung cancer. Markers of risk and prognosis are not reviewed.

EARLY DETECTION

For the foreseeable future, CT will undoubtedly remain an important part of any program for the early detection of lung cancer. CT can detect the small noncalcified nodules that may represent early lung cancers. However, as a stand-alone screening tool, this technique is problematic. First, it has poor specificity because of the high prevalence of nonspecific benign pulmonary nodules.[4-6] Second, CT is costly, and the necessity for repeated CT to determine growth rates over time can expose patients to potentially harmful radiation.[7] Lastly, we cannot predict which early lung cancers will progress and which will remain indolent for prolonged periods.

The ultimate goal of lung cancer early detection biomarker research is to develop a marker that identifies early stage lung cancer (or even preneoplasia) and prompts a change in clinical practice that saves lives. A more obtainable target may be a marker that can be used in conjunction with chest CT to help distinguish malignant from benign nodules found on CT images or identify aggressive or indolent phenotypes of early lung cancers found by imaging.[8] Depending on the selected size cutoff, 15% to more than 50% of individuals in CT screening programs have nodules.[4,9–14] NLST demonstrated that more than 96% of the nodules identified were thought to be benign based on stability on follow-up CT. Of nodules that are ultimately surgically resected, up to 30% are found to have benign pathology.[15] In the NLST, 24% of patients who underwent an invasive diagnostic procedure were found to have nodules of benign etiology. To address the issue of large numbers of false-positive findings on CT, experts have suggested using a larger nodule size cutoff of 7 mm or 8 mm, which would decrease the number of positive CT results to 5% to 7%,[16] or narrowing the definition of high-risk individuals who would be eligible for screening.[17] An effective biomarker would also be an invaluable aid in the management of these indeterminate pulmonary nodules. Depending on their assay performance characteristics, biomarkers could guide the clinician toward reassurance, watchful waiting, or immediate biopsy or resection, and thus decrease the anxiety, cost, and uncertainty of lung cancer screening.

Lung cancer biomarkers may also reduce the problem of overdiagnosis in lung cancer screening. Although the NLST demonstrated that screening can decrease lung cancer mortality, a percentage of cancers diagnosed are likely indolent malignancies that may not progress if disregarded. At the New York University screening program, one-third of the cancers diagnosed were indolent adenocarcinomas, which were followed for a prolonged period before resection and were still stage I at the time of surgery.[14] A biomarker that could a priori identify these indolent cancers may spare older patients or patients with other medical problems unnecessary surgeries.
Fig. 8.1. Lung cancer biomarkers have many potential clinical uses, depending on the marker and the clinical stage. Four clinical contexts for biomarker use include the following: (1) During the period before lung cancer is detectable, markers may be used for risk assessment and to identify populations that may benefit from lung cancer screening or chemopreventive measures. (2) When lung cancer is in the preneoplastic stage, it is generally not clinically detectable. Biomarkers that identify preneoplasia would lead clinicians to recommend close monitoring and chemoprevention if available. (3) Early stage disease can be detected by thoracic imaging, but this technique is nonspecific, and indeterminate nodules are frequent. Lung cancer biomarkers may be used either to identify individuals who should undergo computed tomography (CT) screening or to differentiate benign from malignant nodules. At this stage, biomarkers may also be used for prognostication and treatment selection if they can distinguish indolent from aggressive disease. (4) After lung cancer has been treated, biomarkers may be useful for monitoring for recurrence or to determine prognosis and select patients for adjuvant chemotherapy or tertiary chemoprevention.

The Biology of Lung Carcinogenesis

Continued progress in understanding the sequence of molecular changes underlying the progression from preneoplasia to invasive lung cancer has galvanized research into discovery and validation of lung cancer biomarkers for early detection. It has also raised the possibility of personalizing lung cancer treatment using biomarker profiles. The World Health Organization defines the various preneoplastic lesions of the bronchial epithelium as squamous dysplasia and carcinoma in situ, which progresses to squamous cell carcinoma; atypical adenomatous hyperplasia, which may precede adenocarcinoma; and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, which may progress to carcinoid. Small cell lung cancer (SCLC) is believed to arise from extensively molecularly damaged epithelium without going through recognizable preneoplastic stages.[18–20]

Alterations in gene expression and chromosome structure known to be associated with malignant transformation have been demonstrated in these preneoplastic lesions, and the changes appear to be sequential; in particular, their frequency and number increase with increasing atypia. Some of the alterations found in preneoplastic lesions include hyperproliferation and loss of cell cycle control; abnormalities in the p53 pathway, the RAS genes, and genes in the genomic region of 3p14.2 and 3q26-29;[21] aberrant gene promoter methylation;[22] increased vascular growth; altered extracellular matrix; decreased retinoic acid and retinoid X receptor expression;[23] and many other genetic and epigenetic changes.[18,19]

Biomarker Validation

The validation of a biomarker for clinical use is challenging. Any biomarker considered for use in a clinical setting must satisfy a host of criteria related to ease of use and performance. The biomarker must be relatively noninvasive, require only small amounts of material needing a minimum of preparation, be quantifiable and reproducible in multiple populations and laboratories, have a proven clinical use with acceptable sensitivity and specificity for this use, be acceptable to the target population, and be cost-effective and reimbursed by health insurers.[24] No markers have yet made it through these rigorous requirements, although many are in the pipeline.[25] Appropriate study design will be crucial to bringing any of these markers to clinical use.

Guidelines for biomarker study design and statistical evaluation suggest that validation should be conducted using a prospective specimen collection retrospective blinded evaluation design.[26] In this approach, specimens are collected prospectively from a longitudinal cohort that represents the target population. After the outcome status is determined, a nested case–control study can be designed. Cases and controls are selected randomly for biomarker studies, with the investigators blinded to the case–control status. Random sampling of cases and controls from within a well-defined cohort provides validity to the case–control design. An important element of this study design is that the validation population must be representative of the population in which the biomarker will be used, to minimize false positives. In the case of lung cancer, this means that individuals with a history of tobacco use and its related morbidities, including chronic

obstructive pulmonary disease, cardiovascular disease, and other malignancies, must be included in the validation cohort. Ideally, the biomarker can be tested in longitudinal samples to ensure its accuracy in detecting early, preclinical disease. Measures of validity include sensitivity, specificity, negative predictive value, and positive predictive value (which can be summarized with a receiver operating characteristic [ROC] curve).[27] The prevalence of the disease influences these measures, thus it is important that the biomarker validation process be applied to all possible populations in which the marker would be used. Lastly, when a potential marker has been validated as effective for early diagnosis, it should be evaluated in a screening trial with lung cancer mortality as the end point to prove that use of the biomarker decreases mortality and the validation studies were not hampered by problems of overdiagnosis, lead-time bias, or length bias. The Early Detection Research Network of the US National Cancer Institute has established guidelines for cancer biomarker development and validation.[28]

Advances in Techniques for Biomarker Discovery

Currently, we see a profusion of potential biomarkers for lung cancer. Different histologic types, different stages of disease, and a variety of molecular pathways to transformation contribute to making the process of biomarker discovery for lung cancer complex. New high-throughput technologies allow researchers to look for and validate multiple biomarkers simultaneously. Microarrays are used to evaluate thousands of potential markers concurrently.

For example, circulating DNA (cDNA) microarrays identify thousands of genes that are differentially expressed in lung cancers, preneoplasias, and normal lung; antibody arrays evaluate multiple antigens or antibodies at once; and methylation arrays identify methylation of many different gene promoters simultaneously. Proteomics is the study of protein profiles in tissues and body fluids. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) and surface-enhanced laser desorption/ionization have been used to describe protein profiles and to identify individual protein markers in lung cancer. The ability to accurately measure quantitative transcriptome in individual cells with relatively small number of sequencing read makes single-cell RNA sequencing a popular technology for biomarker discovery. In recent years, important advances in the development and validation of these and other high-throughput technologies have raised the potential for great strides in biomarker discovery.

Specimen Types

One of the most important criteria for a successful biomarker is that the testing material be easily accessible. Current markers use multiple biologic sources. Tissue-based assays are generally the most invasive, but may be acceptable in some circumstances. The concept of field cancerization supports the theory that surrogate tissues—such as bronchial, buccal, and nasal brushings; endobronchial biopsy specimens; or even exhaled breath—may be used as markers of increased risk for lung cancer. Genetic and epigenetic changes in the bronchial epithelium or perhaps the nasal or buccal epithelium may mirror changes in the lower respiratory tract and suggest that a lesion seen on CT images represents malignancy. Although obtaining the tissue may require bronchoscopy, pairing molecular markers obtained from the airways with a high-risk profile and a lesion on CT images may increase the specificity of lung cancer screening. The potential use of tissue-based biomarkers is highly dependent on the accessibility of the specimens and the robustness of the assay offered. It may take additional time to refine airway epithelium-based biomarkers because banked samples are not as readily available as they are for tumor tissues or blood. Blood-based assays are attractive due to the ease of acquisition. This simplicity aids in the discovery process, the validation process, and the acceptance into clinical practice. Altered or methylated DNA, overexpressed messenger RNA (mRNA), microRNA (miRNA), proteins, peptides, metabolites, and even circulating tumor cells (CTCs) can all be detected in the circulating blood; however, there are significant challenges as well. Blood is a dynamic medium, which reflects various physiologic and pathologic states that can overwhelm the detection of an early stage, preclinical cancer.

Other biofluids—exhaled breath condensate, sputum, and urine—are also easily accessible samples for biomarker analysis. Each type of sample has its own appeal and its challenges. Exhaled breath is easily and painlessly obtained, and large volumes can be collected without detriment to the patient. Theoretically, the use of exhaled breath analysis may allow for a more specific lung cancer diagnosis. However, only volatile compounds can be detected and genetic material is sparse or absent. Sputum has the advantage of perhaps giving results specific to lung cancer, as it contains both bronchial epithelial cells and other secretions reflecting the local milieu of the lung.[29,30] However, it is difficult to obtain adequate sputum samples from the lower airways, and samples are frequently exclusively saliva. Urine is an easily accessible biofluid, but it may be less specific to lung cancer. Lung cancer biomarker research using urine as the biologic sample is still in its infancy.

LUNG CANCER BIOMARKERS FOR EARLY DETECTION

Given the many different genetic and epigenetic changes involved in malignant transformation in lung cancer, it is not surprising that innumerable potential biomarkers exist. With progress in understanding the biology of lung carcinogenesis, the development of high-throughput techniques for biomarker discovery, and increased focus on early detection of lung cancer, the field of lung cancer biomarker research has expanded at a phenomenal rate. As yet, no biomarker has been shown to have adequate sensitivity, specificity, reproducibility, and ease of use to be validated as a biomarker for the early detection of lung cancer. However, many studies of biomarkers for the early diagnosis of lung cancer have shown promising results (Table 8.1).

Cytology

Sputum contains bronchial epithelial cells from the central airways and theoretically may provide a means to detect a central malignancy or changes reflecting field cancerization, which suggest a high risk that the lungs may harbor a malignancy. However, trying to detect early lung cancer by sputum cytology has not been particularly successful. Bronchial epithelial cells comprise less than 5% of sputum samples, and even after using techniques to enrich for these cells, detecting morphologic changes is subjective and therefore unreliable. Studies have shown that sputum cytology has very low sensitivity and specificity and is a particularly poor method for detecting adenocarcinoma.[35] However, when sputum cytology is combined with some other markers described here (including genetic abnormalities,[36] chromosomal aneusomy,[37,38] DNA methylation,[39,40] or miRNA[41,42]), sensitivity increases. Automated cytometry for more objective and quantitative cytopathologic assessment may also help address the issues of subjectivity and low sensitivity. In some reports, an automated system quantifying the DNA content improved the sensitivity of sputum cytology to the range of 75% to 80% in heavy smokers.[43,44]

Buccal epithelium is easily obtained, may be used as a surrogate for bronchial epithelium, and reflects the field cancerization effect. Backman et al.[45] reported the ability to detect abnormal nanostructure architecture in microscopically normal-appearing buccal

epithelial cells, using partial wave spectroscopic microscopy. They evaluated 63 smokers with lung cancer and compared the findings with those for 72 individuals without lung cancer, including 50 smokers and 22 nonsmokers, and reported an area under the ROC curve (AUC) ranging from 0.81 to 0.88 depending on the control group used. Modification in the protocol with the introduction of low-coherence enhanced backscattering spectroscopy directly applied to the buccal mucosa also generated an excellent diagnostic tool with 94% sensitivity, 80% specificity, and 95% accuracy in distinguishing lung cancer patients from smoker controls.[46]

Circulating Tumor Cells and Circulating Tumor DNA

Liquid biopsy as a noninvasive method to detect tumors has generated excitement in the field of circulating biomarkers. CTCs are cells that originate from a malignancy and circulate in the peripheral blood. Research indicates that in patients with known malignancy, these cells may shed into the circulation and, even at early stages of cancer, can be detected. CTCs can be captured by immobilized antiepithelial cell adhesion molecule (EpCAM or tumor-associated calcium signal transducer 1 [TACSTD1]) antibodies, using a chip or bead platform.[31–34] The presence of "sentinel" CTCs detected by the International Symposium on Endovascular Therapy filtration-enrichment technique in combination with CT scan in chronic obstructive pulmonary disease patients has the potential for early detection of lung cancer.[47] This research is in its early stages but clearly holds appeal, as the test detects actual tumor cells rather than less-specific markers.

Circulating tumor DNA (ctDNA) is composed of small fragments of nucleic acid that are cell free (not associated with cells or cell fragments) and can be collected from different bodily sources. Levels of circulating cell-free DNA in plasma and serum are generally reported to be higher in patients with cancer than in healthy controls.[48–49] The circulating DNA in patients with lung cancer exhibits genetic and epigenetic changes typical of the tumor (chromosome loss, oncogene activation, and tumor-suppressor gene inactivation by methylation).[50,51] A novel ultrasensitive method for quantitating ctDNA using cancer personalized profiling by deep sequencing (CAPP-Seq) is a promising technique for the development of a ctDNA biomarker for early detection of lung cancer.[53] In NSCLC, CAPP-Seq was able to identify somatic alterations in over 95% of tumors, with ctDNA levels highly correlating with tumor volume. Measurement of ctDNA levels has the potential to monitor treatment response as well as for early lung cancer screening. When combined with integrated digital error suppression, CAPP-Seq was able to profile epidermal growth factor receptor (EGFR) mutations in NSCLC with 90% sensitivity and 96% specificity.[54]

Mitochondrial DNA

The mitochondrial genome has an increased mutation rate compared with that of the nuclear genome, and DNA repair is less efficient. Because mitochondrial DNA lacks introns, mutations are also more likely to accumulate in coding regions. Mutations in the mitochondrial genome—including point mutations, deletions, and admixtures—are associated with cancer and other disorders. Sequence variants in mitochondrial DNA can be rapidly detected using high-throughput resequencing microarrays.[52] Using this method, Jakupciak et al.[55] analyzed blood, tumor, and body fluids from 26 patients with early stage cancer (lung, bladder, kidney), compared the results with those for 12 smokers without cancer, and found that patients with cancer had a significantly higher incidence of mitochondrial DNA mutations.[55]

Noncoding RNAs

Noncoding RNAs (ncRNAs) are functional transcripts that do not code for proteins, but play an important role in regulating gene expression. Of these, several small ncRNAs have been studied for their roles in carcinogenesis and as possible biomarkers for cancer.[56] The most extensively studied so far are the microRNAs (miRNAs). These are small, ncRNA segments that are thought to regulate gene expression. miRNAs are abnormally expressed in several types of cancer,[57] but have tissue specificity as well,[55] making them ideal for biomarker research. Furthermore, miRNAs are generally stable and well preserved in formalin-fixed tissue. They are also present in the circulation, both intracellularly and extracellularly, where they can be detected by reverse transcription-polymerase chain reaction (RT-PCR), thus allowing for noninvasive testing. It is thought that extracellular miRNAs are released into the circulation by all cells in the body and therefore may reflect the body's systemic response to the presence of cancer, perhaps including changes in miRNA expression in circulating blood cells.

Changes in miRNA profiles have been identified in the blood of patients with lung cancer, and this is an active field of research, with multiple studies examining miRNA expression profiles as possible lung cancer biomarkers. As an example, a recent study of miRNA profiles in plasma from two independent cohorts of patients showed that a signature of 15 miRNAs in the blood identified patients at high risk for the development of lung cancer with 80% sensitivity and 90% specificity.[59] In another study, investigators described a panel of 34 serum miRNAs that could identify high-risk, asymptomatic patients with early stage NSCLCs with 80% accuracy.[60] Other investigators identified two miRNAs that distinguished early stage lung cancer from normal controls with 100% sensitivity and 84% specificity.[61] In patients with solitary pulmonary nodules on CT images, a panel of miRNAs was promising as a tool to distinguish benign from malignant nodules.[62,63] In another approach, miRNA profiles in whole blood were studied to capture intracellular miRNA.[69] This approach has had promising results.[61–66] A serum-based four-miRNA (miR-193b, miR-301, miR-141, and miR-200b) panel signature was able to discriminate lung cancer patients from noncancer individuals in an independent cohort with an AUC of 0.993 (95% confidence interval [CI], 0.979–1.000, $p < 0.001$).[70] miRNAs can also be detected in sputum samples, and several studies have demonstrated success in identifying both squamous cell and adenocarcinoma using a panel of miRNA markers in sputum samples.[42,67,68,71,72] Using quantitative RT-PCR, a panel of three sputum-based miRNA (miR-21, miR-31, and miR-210) was studied in patients with solitary pulmonary nodules; the sensitivity and specificity of the test for detecting lung cancer were 81% to 82% and 86% to 88%, respectively, in two independent cohorts.[74]

Another type of small ncRNA is small nucleolar RNA (snoRNA). Although snoRNAs are the largest group of ncRNAs, we are just beginning to understand the diverse functions of these molecules. Recent studies have indicated that snoRNAs may play a role in the development and progression of malignancy. One study of snoRNA expression signatures found that certain snoRNAs were significantly upregulated in both tumor tissue and plasma from patients with lung cancer compared with controls.[73] Like miRNA, snoRNA was shown to be stable and readily detectable in the plasma by quantitative RT-PCR.

Genetic Changes

Microsatellite instability (MSI) and loss of heterozygosity (LOH) are two allelic alterations that have been investigated as potential biomarkers for lung cancer. Microsatellites are segments of DNA in which a short motif is repeated multiple times.[75] These areas are prone to mutations during replication due to the transient split of the two helical strands and slippage of the DNA polymerase complex at reannealing, which generates an insertion or deletion loop. MSI occurs when these mutations result in a somatic change in length. MSI is associated with an impaired DNA repair mechanism. Changes in microsatellite repeats correlate with altered gene expression. LOH is the loss of one allele of a gene when the other allele is already inactivated, resulting

in loss of function of the gene. LOH can be caused by numerous genetic mechanisms.

Numerous instances of LOH and MSI exist throughout the human genome. LOH and MSI at particular chromosomal regions seem to be more common in different tumor types. Losses of genetic material from chromosomes 3p and 9p are two of the earliest genetic changes occurring during bronchial carcinogenesis, and multiple lung cancer tumor suppressor genes are located on these chromosomes, including RBSP3, NPRL2, RASSF1A, and FHIT on 3p and CDKN2A and CDKN2B on 9p. Several studies have evaluated whether MSI and LOH in these regions could be found in circulating DNA69 or sputum of patients with lung cancer.[76–78] However, this technique can be problematic, because the proportion of circulating DNA derived from the cancer cells is likely to be low. In general, genetic alterations (LOH or MSI) were found in circulating DNA of 27% to 88% of patients with lung cancer.[79] When multiple markers are combined, the sensitivity can be increased, but often at the cost of specificity. Again, combining MSI or LOH with other markers, such as methylation and sputum cytology, may increase accuracy.[80,81]

Individual Genetic Mutations

We have long understood that lung carcinogenesis is associated with an accumulation of genetic mutations, and this was one of the first areas of focus for biomarker discovery. Mutations in the *KRAS* gene can result in constitutive activation. *KRAS* mutations occur in a limited number of hot spots, making mutations in this gene easier to detect through screening. *KRAS* mutations in circulating DNA are present in 20% to 30% of patients with lung cancer,[82,83] and *KRAS* mutations were found in bronchoalveolar lavage fluid in over 50% of patients with adenocarcinoma.[84,85] p53 mutations in circulating DNA have been found in 27% of patients with lung cancer.[82] EGFR is a receptor tyrosine kinase that is involved in cellular signaling in the mitogen-activated protein kinase (MAPK), phosphoinositide 3-kinase (PI3K), and signal transducers and activators of transcription (STAT) pathways. Mutations in the *EGFR* gene can result in constitutive activation and uncontrolled downstream signaling. *EGFR* mutations are more common in adenocarcinomas and in nonsmokers with lung cancer, and therefore this may be a more useful biomarker in nonsmokers.

Genomics

Genomic techniques allow for high-throughput detection of multiple mutant alleles simultaneously and the identification of gene expression profiles associated with the presence of malignancy.

Gene expression profiling in the sputum, bronchial epithelium, and peripheral blood is being studied as a method for early detection. Genomic techniques have been used to develop panels of genetic changes that could be used to screen sputum. In one study, the investigators identified a panel of six genes that could distinguish patients with early stage lung cancer from controls with 86.7% sensitivity and 93.9% specificity.[86]

Spira et al.[87] reported that an 80-gene microarray signature from the right main stem bronchial epithelium achieved 80% sensitivity and 84% specificity for distinguishing smokers with and without lung cancer. Bronchial-airway gene-expression classifier was validated in two multicenter prospective studies, AEGIS-1 and AEGIS-2, with an AUC of 0.78 (95% CI, 0.73–0.83) and 0.74 (95% CI, 0.68–0.80), respectively.[88] Another group developed a 14-antioxidant gene panel for the bronchial epithelium that achieved an AUC of 0.82 for discriminating patients with lung cancer from controls.[89]

Showe et al.[90] have proposed that gene expression profiling in peripheral blood mononuclear cells may be useful for early detection of lung cancer. They postulate that the immune response to the presence of malignant cells results in a change in the gene expression profile of circulating mononuclear cells. They initially analyzed gene expression in peripheral blood mononuclear cells in 137 patients with NSCLC compared with 91 controls with benign disease (including benign nodules) and found a 29-gene signature that identified patients with lung cancer with 91% sensitivity and 80% specificity.[90] In their validation set, they reported 78% accuracy. They also demonstrated that the gene signature was significantly reduced after tumor resection. In a subsequent study, they reported that resection of early lung tumors significantly changed the expression of more than 3000 genes. They also identified five miRNAs whose expression level decreased significantly after tumor removal.[91]

Gene Hypermethylation

Methylation of promoters in many different tumor suppressor genes occurs early in the development of lung cancer. DNA methylation involves the addition of a methyl group to the fifth position of the cytosine located 5′ to a guanosine in a CpG dinucleotide. A CpG island is a stretch of DNA that contains high CpG contents. Hypermethylation of CpG islands in gene promoter regions results in a conformational change of the chromatin, preventing RNA polymerase and other regulatory proteins from accessing the region, and thus silencing of gene transcription. Silencing by hypermethylation affects genes involved in all aspects of normal cell function and is a critical trigger for malignant transformation and progression. Methylation can be detected by methylation-specific PCR analysis. With this analysis, bisulfite is used to convert all unmethylated (but not methylated) cytosines to uracil. Amplification is then done with primers specific for methylated versus unmethylated DNA. In modified methylation-specific PCR, a two-step nested PCR improves the sensitivity of the assay.

Gene hypermethylation has become a very active area of research. In previous studies, aberrant methylation of p16INK4a, APC, TMS1, CDH1, RARβ-2 RASSF1, MGMT, DCC, AIM1, DAPK, and others has been reported in lung cancer.[92–97] Belinsky et al.[98] found that hypermethylation of the promoter region of many different genes in the blood and sputum is associated with lung cancer and may even precede the clinical diagnosis of lung cancer. Other lung cancer studies have demonstrated aberrant promoter methylation of PRSS3 (serine protease family member-trypsinogen IV, a putative tumor-suppressor gene),[99] human DAB2 interactive protein gene,[99] and apoptosis-associated speck-like protein containing a caspase and activation and recruitment domain (ASC).[101] Hypermethylation of p16 and FHIT genes may be associated with an increased risk of lung cancer recurrence after therapy.[102,103] In 2010, Ostrow et al.[104] used quantitative methylation-specific PCR to evaluate the frequency of promoter methylation of five candidate tumor-suppressor genes (kif1a, NISCH, RARβ, DCC, and B4GALT1) in the plasma of individuals with abnormal CT findings. They reported that 73% of patients with malignancy had methylation of at least one gene, whereas only 29% of controls had methylation. In a follow-up study, this group focused on the *NISCH* gene, a tumor suppressor located on chromosome 3p21 (frequently lost in lung cancer) that codes for the protein Nischarin.[105] Nischarin inhibits cell migration and possibly transformation. Hypermethylation of *NISCH* was found in 68% of heavy smokers without disease and 69% of light smokers with lung cancer and was absent in light smokers without disease. These data suggest that *NISCH* methylation may be a marker of risk for lung cancer.

Investigators have also evaluated methylation in other body fluids and tissues. In bronchoalveolar lavage, methylation of p16, RASSF1A, H-cadherin, and RARβ was associated with the presence of lung cancer, whereas FHIT methylation seemed to be related to tobacco exposure.[106] Using bronchial aspirates, RASSF1A promoter hypermethylation was found in 88% of patients with SCLC and in 28% of patients with NSCLC. No

hypermethylation was found in patients with benign lung disease.[107] In other studies, this group found aberrant promoter methylation of APC,[108] p16, and RARβ2[109] in bronchoalveolar lavages from patients with lung cancer. They reported a sensitivity of 69% and specificity of 87% for the detection of lung cancer using this combination of genes.

A high-throughput global expression profiling approach has been used to identify new cancer-specific methylation markers. Using this technique, applied to multiple lung cancer cell lines, 132 genes that had been suppressed by methylation were identified. The investigators confirmed that these genes are expressed in normal lung,[110] but often not in companion primary lung cancers. They also found that seven of these loci were also commonly methylated in breast, colon, and prostate cancers. Ehrich et al.[111] reported the use of quantitative DNA methylation analysis technology to complete a large-scale cytosine methylation profiling study and thereby perhaps identify new methylation markers.[111] They analyzed methylation at 47 different gene promoter regions in lung tumor tissue and adjacent normal lung from 96 patients with lung cancer. Using a technique that combines MALDI-TOF MS of methylation-dependent sequence changes introduced by bisulfite treatment, they were able to identify six genes with significant differences in methylation in lung cancer tissues compared with normal tissues. These studies demonstrate that with the use of new techniques, high-throughput analysis of methylation status at multiple different promoter regions is possible.

Protein Markers

Protein markers have the advantage of reflecting phenotype rather than genotype and therefore theoretically may be more accurate than genetic markers as means for early detection of disease, rather than risk of disease. Several individual protein markers are currently used for monitoring or prognostication in lung cancer, and many of these have also been investigated as potential biomarkers for early detection, although none have adequate accuracy for this clinical use.[79] Carcinoembryonic antigen (CEA), CYFRA 21-1, and squamous cell carcinoma antigen (SCCA) have been evaluated for the diagnosis of squamous cell lung cancer.[112-114] Neuron-specific enolase, progastrin-releasing peptide, and neural cell adhesion molecule may have some utility in the detection of SCLC.[115–117]

Osteopontin is a ubiquitous extracellular phosphoprotein that interacts with cell-surface receptors to stimulate a variety of downstream processes. It is an important bone matrix protein and a mediator of immune cell recruitment, wound healing, and tissue remodeling, but has also been associated with tumor progression or cellular transformation. Overexpression of osteopontin has been found in both tissue and serum in lung cancer patients, but decreases after resection of the tumor and may be associated with more aggressive disease.[118,119] In an intriguing, small, case-controlled study, investigators evaluated osteopontin levels over time in longitudinal samples obtained from a lung cancer screening program.[120] They found that the rate of increase of osteopontin levels was significantly higher in patients in whom incidence lung cancers developed than in those in whom these did not. These data suggest that monitoring osteopontin levels may be useful in conjunction with CT to aid in distinguishing benign from malignant nodules.

Ciz1 is a nuclear matrix-associated DNA replication factor that promotes initiation of DNA replication and helps coordinate the sequential functions of cyclin E- and A-dependent protein kinases. It influences both DNA replication and cell proliferation. Normally Ciz1 is attached to the nuclear matrix. Recently, Higgins et al.[121] reported the identification of a stable Ciz1 variant, which lacks part of the C-terminal domain involved in nuclear matrix attachment and seems to be present only in tumor cells. Using a polyclonal antibody specific to this variant and Western blot analysis, the investigators were able to identify the presence of variant Ciz1 in the plasma of patients with lung cancer. In two independent sets, the presence of variant Ciz1 in the serum distinguished patients with cancer from controls with extremely high accuracy (AUC, 0.905–0.958). These results warrant the pursuit of further validation studies.

Many other proteins have been investigated as biomarkers for lung cancer. hnRNP B1, an RNA-binding protein involved in mRNA transportation and RNA mutation, is common in squamous cell carcinoma of the lung. Expression in the sputum has been correlated with risk of lung cancer development in certain populations, and the protein has been found to be overexpressed in early stage lung cancer.[122] Human telomeres function as a protective structure capping the ends of chromosomes. Dysfunction plays an important role in cancer initiation and progression. Human telomerase catalytic component is known to be elevated in cancers, and the copy number of human telomerase catalytic component mRNA in serum may correlate with lung cancer stage and risk of metastasis or recurrence.[123]

Some other proteins investigated, with variable results, include survivin, a protein that inhibits apoptosis and promotes mitosis;[124,125] Fas-associated death domain, which inactivates nuclear factor-kappaB, and is associated with overexpression of cyclins D1 and B1, thereby affecting the cell cycle;[126] and soluble e-cadherin, which plays a role in cell–cell adhesion.[128] Functional polymorphisms of matrix metalloproteinase 9 have been associated with risk of lung cancer and recurrence.[129]

A recent study indicates that a degradation product of complement activation, C4d, may serve as a biomarker for early diagnosis and prognosis of lung cancer.[129] This candidate biomarker was studied in the tumors, bronchoalveolar lavage, and blood of individuals with and without lung cancer, including patients diagnosed with preclinical disease in the context of a screening program. This biomarker had remarkable performance and deserves further validation.

It is unlikely that any single protein will serve as a biomarker for early detection of lung cancer, but perhaps a panel of proteins, identified through traditional or proteomic techniques, may achieve adequate sensitivity and specificity.

Proteomics

In the earliest clinical proteomics studies to identify markers for lung cancer, investigators used MALDI-TOF MS and identified proteins such as serum amyloid A and macrophage migration-inhibitory factor as being increased in lung cancer.[130] In a follow-up study, enzyme-linked immunosorbent assay (ELISA) analysis confirmed that serum amyloid A was increased in patients with lung cancer, but macrophage-inhibitory factor levels did not differentiate patients with lung cancer from those with other diseases.[131] Some of these investigators then used a combination of proteomics techniques and literature search for known tumor-associated proteins to establish a panel of serum protein markers: CEA, retinol binding protein, α1-antitrypsin, and SCCA.[132] Combining an assay of three of these proteins (CEA, α1-antitrypsin, and SCCA) with measurement of nodule size on CT images resulted in 80% sensitivity and 89% specificity for distinguishing malignant from benign nodules.[133]

Serum proteomic profiling has also identified peptide signatures that may be used to discriminate lung cancer from matched controls.[134] Investigators further evaluated the same MALDI MS signature in a population with indeterminate pulmonary nodules. They demonstrated that peptide signatures may add to the diagnostic accuracy of chest CT.[135] More recently, investigators used multiple reaction monitoring MS to measure the concentration of 13 candidate proteins identified in the literature and in freshly resected lung tumors and in plasma of patients with lung cancer and controls from three different sites. They reported a negative

predictive value of 94% using this classifier. Importantly, the classifier score obtained was independent of other risk factors for malignancy, such as nodule size, smoking history, and age, indicating that this test may provide complementary information when evaluating pulmonary nodules.[136] In a follow-up study, the investigators performed a validation of the protein classifier that prioritizes sensitivity and negative predictive value to rule out patients with benign nodules. The result was a 90% negative predictive value at 92% sensitivity and 20% specificity.[137]

In one of the largest clinical proteomic biomarker studies to date, investigators used proteomic technology to analyze serum from 1326 tobacco-exposed individuals, including 291 lung cancer cases, from four different lung cancer screening trials.[136] In that study, the investigators used a highly automated technique that used DNA aptamers as extremely specific protein-binding reagents to measure levels of 813 different human proteins. In the training set, 44 candidate biomarkers were identified, and the most highly discriminatory proteins were used to create a 12-protein panel (cadherin-1, CD30 ligand, endostatin, HSP90α, LRIG3, MIP-4, pleiotrophin, PRKCI, RGM-C, SCF-sR, sL-selectin, and YES). In the validation step, this panel was able to discriminate NSCLC from controls with 89% sensitivity and 83% specificity. The proteins identified—six of which were upregulated and six of which were downregulated in the lung cancers—are known to play roles in cell movement and growth, cell–cell adhesion, inflammation, and immune monitoring. These investigators further analyzed the effect of variations in blood collection to improve reproducibility across populations. After adjusting for confounding proteins through sample mapping vectors, a seven-marker protein panel resulted in an AUC of 0.85, which was validated in two independent cohorts.[138]

Another proteomic technique is to use MS to identify protein markers in lung cancer tissues and then screen for these in patient serum, differentiating benign from malignant nodules.[136] MS can identify protein biomarkers that can then be screened in patient serum using ELISA.[137]

Autoantibodies and Tumor-Associated Antigens

As mentioned, the presence of malignant cells can activate the immune system, and cancer has been shown to induce autoimmunity to autologous cellular antigens.[140] Many of the target antigens are cellular proteins, whose deregulation, aberrant expression misfolding, truncation, or proteolysis could lead to or result from tumorigenesis. These changes may result in loss of immunologic tolerance. A systemic response to these tumor-specific antigens provides an opportunity to detect cancers at an early stage. Numerous immunogenic tumor-associated antigens have been identified in human sera using high-throughput analysis, such as recombinant cDNA expression libraries, phage display, and protein microarrays.[141,142] Autoantibodies to some of these antigens have been found in patients with lung cancers.[143,144] Several studies have identified autoantibody panels as markers of lung cancer. In some of these studies, protein microarray and phage display techniques were used.[145–148] In others, autoantibodies against known lung cancer–associated proteins (e.g., p53, c-Myc, HER2, Muc1, CAGE, GBU4-5, NY-ESO-1, annexin 1, PGP9.5 and 14-3-3 theta, LAMAR1, IMPDH, PGAM1, and ANXA2) were investigated.[149–152] Sensitivity and specificity approaching 90% have been reported, although validation studies are needed. In one study, the investigators used microarrays to identify autoantibodies in sera from patients prior to the clinical diagnosis of lung cancer and were able to show that levels of autoantibodies to annexin I, 14-3-3 theta, and LAMR1 were elevated prior to clinical diagnosis in patients in whom lung cancer subsequently developed compared with patients in whom it did not.[152] This same group has further developed a five-autoantibody classifier (tetratricopeptide repeat domain

14 [TTC14]; B-Raf proto-oncogene, serine/threonine kinase [BRAF]; actin-like 6B [ACTL6B]; MORC family CW-type zinc finger 2 [MORC2]; and cancer/testis antigen 1B [CTAG1B]) to differentiate lung cancers from smoker controls with a specificity as high as 89%.[153] The EarlyCDT-Lung test (Oncimmune LLC, De Soto, Kansas, USA) is the first clinically available biomarker test marketed for the early detection of lung cancer. The assay is an ELISA measuring autoantibody reactivity to a panel of six tumor-associated antigens (p53, NY-ESO-1, CAGE, GBU4–5, annexin 1, and SOX2). In 2010 and 2011, the technical feasibility and clinical utility of the test were reported,[154–156] and approximately 40% of lung cancers could be detected using the assay, with 90% specificity. The test is now available, and subsequent studies have confirmed these results in independent samples.[157] Adding additional autoantibodies to the panel may improve the assay.[159] Its performance in clinical practice was evaluated in 1600 patients. It had a sensitivity of 41%, with positive EarlyCDT-Lung test result associated with a 5.4-fold increase in lung cancer incident. Over 50% of positive results were of early stage lung cancer (stages I and II).[157]

Because of the heterogeneity of the immune system, as well as of lung cancer, it is unlikely that reactivity to any single tumor-associated antigen will identify all lung cancers. Microarray analysis allows for the evaluation of multiple different tumor-associated antigens simultaneously. The microarrays can be spotted with tumor proteins and then hybridized to the sera of patients with lung cancer. Using this technique, Qiu et al.[160] found reactivity patterns that may identify patients with lung cancer. Alternatively, the microarray can be spotted with antibodies to known tumor antigens and then hybridized to patients' sera to identify circulating tumor-associated antigens. Using this technique, Gao et al.[161] identified a distinctive serum protein profile in patients with lung cancer compared with controls.

Metabolomics

Metabolomics, measurements and quantification of end products of cellular metabolism, is a relatively new research area in oncology. It has the potential to be an attractive noninvasive biomarker, because metabolites in blood are end products of cellular processes in disease and cancer states. There are two common ways to measure metabolites: mass spectroscopy and nuclear magnetic resonance spectroscopy. In one study, investigators used gas chromatography TOF MS to analyze metabolome, including 462 lipid, carbohydrate, amino acid, organic acid, and nucleotide metabolites, in serum and plasma to develop classifiers to distinguish NSCLC from a control. Cancer-associated biochemical changes were identified as decrease in glucose levels, change in cellular redox, increase in nucleotide metabolites 5,6-dihydrouracil and xanthine, increase in de novo purine synthesis, and increase in protein glycosylation. A validated classifier using a multimetabolite model yielded an AUC of 0.885 with 92.3% sensitivity and 84.6% specificity.[162,163] Another group used proton nuclear magnetic resonance spectroscopy and was able to discriminate adenocarcinoma of the breast from adenocarcinoma of the lung with an AUC of 0.96.[164] Further, proton nuclear magnetic resonance was able to detect metabolic phenotype of blood plasma in 233 lung cancer patients and 226 controls. A validated classification model discriminated between the two groups with an AUC of 0.88.[165]

Volatile Organic Compounds

An intriguing idea is the use of markers in the exhaled breath to diagnose lung cancer. Studies have reported that dogs are able to distinguish breath samples from patients with lung cancer from healthy controls with great accuracy.[166] Tumor cell growth is accompanied by alterations of protein expression patterns, which

lead to peroxidation of the cell membrane, and the emission of volatile organic compounds (VOCs). Studies have indicated that VOCs, mainly alkanes and aromatic compounds, are preferentially produced and exhaled by patients with lung cancer. Poli et al.[167] reported that the measurement of a combination of 13 VOCs in the exhaled breath allowed correct classification of lung cancer in 80% of cases. Several studies have used gas chromatography combined with mass spectrometric analysis of VOCs.[168–172] The colorimetric sensor array signature of exhaled breath volatile organic compounds was able to distinguish lung cancer patients from control with an AUC between 0.794 and 0.861.[173] In one study, Phillips et al.[174] measured the alveolar gradient of C4–C20 alkanes and monomethylated alkanes in patients with lung cancer compared with controls. They developed a model using nine VOCs to predict the presence of lung cancer and in their test set achieved a sensitivity of 85% and specificity of 81%. Subsequently, they reported similar sensitivity and specificity using a weighted digital analysis model that included 30 breath VOCs.[175] Other groups have designed nanosensors to detect changes in electrical resistance from the identified organic compounds in patients' exhaled breath.[176] These assays are sensitive to humidity and other environmental factors. In addition to VOCs, investigators have tried to identify volatile proteins and peptides in exhaled breath condensate that could be used for the early detection of lung cancer.[177,178] The lack of interinstitutional reproducibility in studies of exhaled breath biomarkers is troubling. Validation of a standardized exhaled breath collection device is needed if markers identified through these studies are to be useful.

CONCLUSION

The development of noninvasive lung cancer biomarkers for early detection could have a dramatic impact on lung cancer outcomes. The development of lung cancer biomarkers may allow us to identify populations that would benefit from CT screening, could distinguish individuals with benign pulmonary nodules from those with early malignancies, may differentiate patients with indolent versus aggressive tumors, and will allow for personalization of lung cancer treatment based on tumor characteristics. Significant advances in our understanding of the molecular and genetic changes involved in lung carcinogenesis have provided the basis for many investigations into possible lung cancer biomarkers. The development of new and improved high-throughput technologies raises the potential for great strides in biomarker discovery. Over the last few years, there has been a proliferation of research on lung cancer biomarkers, and a large number of potential diagnostic biomarkers have been identified. The slow progress through the validation pipeline can be attributed to many factors. First, current discovery methods are inefficient and lack reproducibility. In addition, many of the technologies have limited power to detect low-abundance cancer markers against a high background of high-abundance molecules in the complex matrices of biologic samples. Further, we have limited capacity to verify and validate candidate markers due to the novelty of the technology and the insufficient availability of biosamples from prospective studies and early stage disease. The reproducibility of biomarker data has also been flawed because of inconsistent study design, model overfitting, changing technologies, and lack of cross-validation and independent validation. Many studies report high sensitivity and specificity. However, these studies are often troubled by small size, a lack of reproducibility, or inconsistent controls between studies. All of the biomarkers identified so far must be validated in larger independent clinical cohorts.

The discovery of lung cancer biomarkers is progressing rapidly. A high volume of data from multiple high-throughput

techniques has been accumulating at an exponential rate in the last few years, generating a large number of biomarker candidates. Standardization of validation studies and the development of high-quality longitudinal cohorts for testing of promising markers should usher in a new age of biomarker validation. A biofluids-based molecular test can improve the selection of individuals for CT screening, distinguish malignant from benign nodules, and differentiate indolent from more aggressive cancers. Low-dose CT screening for lung cancer can detect 18% to 33% indolent cancers that may be considered overdiagnosed.

9 Chemoprevention of Lung Cancer and Management of Early Lung Cancer

Swati Gulati, James L. Mulshine, and Nico van Zandwijk

SUMMARY OF KEY POINTS

- Most chemoprevention research is focused on natural products and is not amenable to traditional pharmaceutical development.
- Robust research and development for lung cancer chemoprevention by the pharmaceutical industry is largely lacking.
- The traditional model of developing drugs for advanced disease and then backing successful agents into early disease application is not working.
- Safety is coequal to efficacy in developing a successful chemopreventive agent.
- Lung cancer screening with spiral computed tomography is being implemented, and as a result more stage I curative cases will be found.
- Individuals followed after successful management of their initial lung cancer will experience a high rate of metachronous second primary lung cancer (1% to 3% cumulative), and this will be a growing new cohort of patients that would benefit from successful chemoprevention management.
- Locoregional delivery of potential chemoprevention drugs by "aerosolized approaches" may reduce cost and improve safety.
- Systematic study of resected early-stage lung cancers and surrounding injured bronchial tissues may provide insight into the molecular drivers of (early) lung cancer using the precedent of Vogelstein and coworkers' mapping of colon carcinogenesis.

In a recent editorial published in the *Lancet*, advances in lung cancer treatment outcomes were reviewed and it was concluded that simple preventive measures, such as banning advertising, blank cigarette packaging, and increasing awareness of the harms of smoking, might result in more reductions in mortality than all new promising agents combined.[1] For the tens of millions of tobacco-exposed individuals, including former smokers, who will remain at increased risk of lung cancer for most of their remaining life, this is a grim message.[2] At the same time, there is clear progress in early detection of lung cancer and computed tomography (CT) screening, which has been endorsed and is being implemented in the United States, and endorsed in Canada and China with pilot screening evaluations being implemented in a number of other countries.[3] Screening will result in finding more early-stage cancers, which in many instances can be cured by surgery, but as outlined in the discussion of field carcinogenesis reviewed in this chapter, many of the surgically cured individuals at a frequency of 1% to 3% per year will manifest a second primary lung cancer.[4] The net effect of this lung cancer screening dynamic is that before too long, we will have tens of thousands of people in follow-up for metachronous primary lung cancer.

In a perfect world that would mean the pharmaceutical industry would be focusing on developing drugs that would target the mechanisms driving field carcinogenesis and short circuit the development of these metachronous lung cancers. A comprehensive recent review of chemoprevention relates that for lung cancer there are no new (approved) products and the studies that are being done in this space are generally small, investigator-driven studies of plant-derived agents with little prospect for evolution to a full-fledged pharmaceutical product.[5] Although many studies continue to demonstrate the importance of anti-inflammatory agents, the lung cancer prevention field is remarkably free of major pharmaceutical investment. In this most innovative time in the history of biomedicine, for the world's most lethal cancer, we have no lead compound and no obvious serious, commercially viable effort to find one. Publications have noted for decades that the incentives for major pharmaceutical involvement in the field of chemoprevention are inadequate, but no structure fix has been implemented.[6]

In a recent chemoprevention review it has been suggested that the process to develop chemopreventive agents mirrored the steps in developing drugs for advanced lung cancer. This position seems to reflect conventional wisdom, but is that really the optimal way to develop a drug to stop or delay the occurrence of early lung cancer? Late drug development failures are often the consequence of off-target drug effects.[7] In considering the application of chemoprevention drugs in asymptomatic target populations, the issue of off-target toxicity is vitally important and more an issue than off-target effects of drugs for symptomatic late-stage lung cancer. Chemopreventive agents have to be effective and safe at the same time. Further, target identification of potential drugs to arrest carcinogenesis of lung cancer has to be derived from tissue that is representative for early carcinogenesis. A model for this would be the comprehensive mapping that Vogelstein and colleagues[8] have conducted in mapping molecular events with colon carcinogenesis. Finally, lung cancer arises principally from the aerosolized delivery of tobacco combustion products to the airway. The epithelial lining of the airways represents a remarkably small volume of cells that can be targeted economically and safely using established methods. Many successfully approved aerosolized products exist for obstructive pulmonary and infectious disease.[9,10] Chemoprevention for lung cancer presents an exceptionally strategic opportunity for making a major impact in the War on Cancer and generating a new class of lung cancer drugs. It is time to get serious about bringing such tools into being.

Lung cancer is by far the leading cause of cancer-related deaths worldwide. In the United States alone, 158,080 deaths were projected for 2016, accounting for about 27% of all cancer deaths.[11] Median survival in all stages of disease has improved during the past decades, but the likelihood of obtaining a cure, even with optimal modern therapy, is low because most cases are detected after the development of symptoms from respiratory cancer, and these occur when the disease is in a regional or distant metastatic stage. Lung cancer is usually related to exposure to carcinogens that occurred over 10 years to 20 years and requires multiple molecular genetic changes before the development of

invasive lung cancer.[12,13] Consequently, a strong rationale exists for detecting lung carcinogenesis before the development of invasive metastatic cancer. This detection includes prudent implementation of lung cancer screening as a high-quality service to identify early, curable lung cancer.

After an exhaustive review of the evidence, the US Preventive Services Task Force (USPSTF) endorsed low-dose lung cancer screening as an early-detection approach with the potential to significantly reduce deaths from lung cancer.[14] Prospective detection of lung cancer in high-risk cohorts in the absence of symptoms mandates a clinical management approach that differs significantly from the routine management of lung cancer detected on the basis of symptoms. As with other cancer screening services, this screening service must be delivered with high quality, low cost, and ready accessibility. This chapter reviews strategies that contribute to routinely achieving that level of proficiency, and this information may constitute a useful reference for clinicians communicating about the merits and limitations of this service to high-risk individuals who are considering participation in lung cancer screening. As early detection becomes more successful, more patients will survive lung cancer. As a byproduct of this success, more patients with cured lung cancer, especially those with heavy exposure to tobacco products, will have a high risk of the development of new primary lung cancers. This outcome produces a strong demand for new tools to manage this earliest form of lung cancer. Chemoprevention is the term used for the process of implementing drugs to interfere with carcinogenesis.

Tobacco smoking is estimated to account for at least 80% of the attributable risk for lung cancer.[15] Smoking cessation, especially before middle age, is associated with significantly lower tobacco-attributable cancer risk.[15] Clearly, we must continue our efforts in tobacco control, which have substantially reduced smoking prevalence in several countries. However, 1.3 billion people worldwide still smoke, and the multinational tobacco companies continue to introduce cancer-causing products designed to entice teenagers into a lifetime of nicotine addiction. In addition, despite a significant reduction in the prevalence of smoking among US adults, from 42% to 19% between 1965 and 2011, lung cancer incidence has not decreased because of the growing number of aging people.[11,16] Despite smoking cessation, lung cancer risk remains elevated and never reaches the level of risk among nonsmokers.[15] A significant percentage of newly diagnosed lung cancer occurs in former smokers.[17] Thus in certain individuals, the carcinogenic process elicited by tobacco smoke continues to evolve despite smoking cessation. These observations underline why strategies to slow, halt, or even reverse carcinogenesis continue to gain great interest and why it is of interest to explore the evolution and progress of chemoprevention efforts.

In early chemoprevention studies, researchers evaluated vitamins or micronutrients in an attempt to reduce cancer incidence as the primary end point. A challenge with this approach was cost, because such studies required thousands of participants and many years of follow-up to detect a significant chemoprotective benefit. Interpreting results from these trials may also have been complicated by the comingling of study participants who continued to smoke with individuals who had stopped smoking.[18] More recently, study designs have focused on cancer incidence as the primary end point in populations who are at high risk for lung cancer. An example is to exclude individuals with a 20-pack/year history who do not have more than a 10% to 15% lifetime risk of lung cancer. Intermediate marker end points can be used to quickly designate risk strata to select trial populations in whom lung cancer is more likely to develop so that smaller trials can be more informative. Chemoprevention of lung carcinogenesis remains a highly attractive concept, especially in targeting trials on agents that are involved in downstream effects of multiple carcinogens, tumor promoters, and inflammatory compounds in cigarette smoke.[19]

Lung cancer is strongly associated with direct consumption of tobacco products, and 87% of all lung cancers are detected in individuals who are active or former smokers. An additional 6% to 7% of lung cancer occurs in partners of smokers or their offspring. The second and third most common known causes of lung cancer are radon and asbestos, and epidemiologic evidence from the 2000s points to a clear association between lung cancer and air pollution.[20,21] Despite the high degree of certainty that a link exists between tobacco smoke and lung cancer, establishing the causal link between tobacco exposure and lung cancer took several decades. The discovery that tobacco smoke was capable of producing identical p53 mutations both in patients with lung cancer and in mice exposed to tobacco smoke added incontrovertible evidence for a strong epidemiologic association.[22]

The original description of so-called field of cancerization dates back to the pioneering work of Slaughter et al.,[23] who showed that multiple foci of epithelial hyperplasia, hyperkeratinization, atypia, dysplasia, and carcinoma in situ occurred in otherwise normal-appearing epithelium adjacent to cancers of the oral pharynx in smokers. This empiric evidence suggested that carcinogen exposure has widespread effects throughout the epithelial field subjected to carcinogen damage. Auerbach et al.[24] reported that the same pattern of heterogeneous, multifocal histologic changes occurred throughout the bronchial epithelium of smokers who had lung cancer, consistent with the concept of field of cancerization. Translated into contemporary biologic terms, field of cancerization means that areas of histologically normal-appearing tissue adjacent to neoplastic lesions display molecular abnormalities, some of which are the same as in the tumors.[24] Several studies have shown the field of injury created by cigarette smoke, and molecular studies support the stepwise model of lung carcinogenesis, with genetic and epigenetic alterations occurring in the cells.[25] Field carcinogenesis also forms the basis for the observation that among individuals who survive a first cancer, a second malignancy is likely to develop in the region of the tobacco-exposed epithelium.[26–29]

Among the earliest molecular findings in the aerodigestive tract of chronic smokers are loss of heterozygosity in chromosomes 3p, 9p, and 17p; p53 mutations; and changes in promoter methylation and in telomerase activity of noncancerous epithelial cells.[13,30–35] Loss of heterozygosity is a crucial event. For example, loss of the short arm of chromosome 3, which is often the earliest loss and is demonstrated occasionally even in early hyperplasia,[30] results in the loss of a region rich in tumor suppressor genes. Evidence also indicates loss of the short arms of chromosomes 9 and 17, resulting in loss of tumor suppressor genes in p16 and p53, both of which are important to the cell's ability to repair DNA damage elicited by tobacco smoke. Gene p53, in particular, acts as a transcription factor in the control of G_1 arrest and apoptosis, or programmed cell death, thereby allowing the cell to repair any existing DNA damage or induce apoptosis once the cell is too far damaged for repair. The gene p16, found on chromosome 9p, negatively controls cyclin-dependent kinase–cyclin activity by overexpression of cyclin-D1. Inhibiting cyclin-D1/cyclin-dependent kinase prevents the damaged cell from entering into mitosis and proliferating with damaged DNA. Studies have proved that methylation of the p16 gene in the oral epithelium induced by tobacco smoke is an independent risk factor for lung cancer in current and former smokers.[36]

The loss of these and other tumor suppressor genes in lung cancer seems to be augmented by the activation of several crucial proto-oncogenes. For example, Ras, myc, and the epidermal growth factor receptor (EGFR) are all tumor-promoting genes that are activated progressively during lung carcinogenesis. Mutations of Kirsten rat sarcoma (KRAS) are particularly common in

adenocarcinomas of the lung; some studies have shown that 30% of lung adenocarcinomas in smokers contain KRAS mutations.[37]

Other mechanisms of lung carcinogenesis are also relevant, such as amplification of EGFR.[38] Mutations have been detected in the EGFR tyrosine kinase (TK) binding domain, which confer sensitivity to small-molecule EGFR TK inhibitors (TKIs).[39–41] Both KRAS mutations and EGFR mutations have been found in the airways of smokers and nonsmokers in regions distant from the primary tumor, suggesting that both play a role in field carcinogenesis.[37,42]

Gene mutations and rearrangements have also been mapped to specific histologic and clinical characteristics among the lung cancer subtypes. This discovery has led to the development of target-specific chemotherapeutic drugs, which have revolutionized the treatment of lung cancer.

Rearrangements of the anaplastic lymphoma kinase (ALK) gene, which result from an inversion in the short arm of chromosome 2, have been identified in a subset of patients with nonsmall cell lung cancer (NSCLC). This subset causes distinct clinical and pathologic features and usually affects younger patients with no history or a light history of smoking.[43,44] ALK TKIs such as crizotinib and alectinib have been shown to increase progression-free survival rates. Similarly, rearrangements of the c-ros oncogene 1 (ROS1) and ret proto-oncogene (RET) genes have been isolated in adenocarcinoma and in some subsets of advanced NSCLC. These patients, too, are mostly young with little or no history of smoking.[45–49]

Some mutations are mutually exclusive of each other, such as EGFR and KRAS mutations. Amplification of fibroblast growth factor receptor 1 is seen in patients with squamous cell lung cancer. This mutation is associated with cigarette smoking in a dose-dependent fashion and is an independent negative prognostic factor.[50]

Global messenger RNA and microRNA (miRNA) expression profiles have been described in the bronchial epithelium of so-called healthy smokers, and cancer-specific gene expression profiles have been reported in smokers with and without lung cancer.[51,52]

GENE SILENCING

Another mechanism of lung carcinogenesis is loss of function of tumor suppressor genes. A growing body of evidence suggests that gene silencing through epigenetic means is crucial in lung carcinogenesis. For example, the tumor suppressor gene in NSCLC known as RASSF1A, which is also located in the region of chromosome 3p rich in tumor suppressor genes, encodes a protein that heterodimerizes with Nore-1, an important RAS effector with a proapoptotic effect.[53] Evidence suggests that in NSCLC, RASSF1A can be inactivated by hypermethylation.[54,55]

Another important gene that can be inactivated by epigenetic means is the retinoic acid receptor-β (RAR-β), which also maps to chromosome 3p. RAR-β is a nuclear retinoid receptor with vitamin A–dependent transcriptional activity.[56] The RAR-β gene is gradually lost during lung carcinogenesis,[57] and this may be caused by loss or hypermethylation.[58,59] The maintenance of RAR-β in mature tumors is a risk factor for poor prognosis,[60] and the RAR-β gene is differentially regulated in current as opposed to former smokers. For example, a retrospective study on methylation status and the occurrence of second primary tumors (SPTs) in patients with completely resected NSCLC showed an association between RAR-β2 hypermethylation in the development of SPTs only in former smokers.[61] In current smokers, hypermethylation was associated with a protective effect, pointing to the value of context with regard to smoking status in understanding the biologic effects of retinoid receptors in lung cancer.[61,62]

The role of miRNAs may also prove to be crucial. These small noncoding RNA molecules have been recognized as important in epigenetic control by altering the translation of proteins from messenger RNAs. miRNAs are able to target a multitude of messenger RNAs and have emerged as key posttranscriptional regulators of gene expression involved in cell proliferation, apoptosis, and stress resistance. miRNAs are also located in cancer-associated genomic regions or in fragile sites, suggesting that differences in miRNA expression may be induced by genomic alterations and play either a tumor suppressor or oncogenic role.[63]

Cigarette smoke is a potent source of such molecular injury, and recent studies have shown that the components in cigarette smoke affect miRNA levels in the respiratory tract.[64,65] An emerging notion is that smoking may lead to downregulation of miRNAs in the airway. The mechanistic understanding of the link between these miRNA changes and early lung carcinogenesis is just beginning to emerge. The fact that miRNA dysregulation is an early event in lung carcinogenesis may offer opportunities for chemopreventive approaches (i.e., reversing aberrant miRNA expression induced by smoking).[66] For example, miRNA changes were found in biopsy specimens obtained in a phase II trial comparing iloprost (a prostacyclin analog) with placebo in high-risk patients, and these changes were related to histologic findings at baseline.[67] Proteomic analyses of preinvasive lesions in the bronchial tree have uncovered patterns clearly different from those in normal epithelium,[68] supporting the rationale for chemopreventive strategies.

SUSCEPTIBILITY TO LUNG CANCER AND BALANCING OF ANTAGONISTIC PATHWAYS

The risk of the development of lung cancer, even among the heaviest smokers, varies widely, perhaps because of genetic and even dietary factors. In fact, 85% of heavy smokers will not develop lung cancer, which suggests important differences among individuals in susceptibility to lung cancer. Several prediction models for lung cancer have been proposed. The Bach model uses variables related to age, smoking, and asbestos exposure in black populations, whereas the Spitz model and Liverpool Lung Project include family history and other occupational exposures in addition to age and smoking history in white populations.[69–71] Although these models are easy to administer and calculate, their discriminatory power is only moderate, which is not surprising because the models fail to account for many comorbidities and other epigenetic factors. In 2012, Hoggart et al.[72] proposed a prediction model that includes more variables, including biomarker exposure; socioeconomic status; comorbidities including pneumonia, chronic obstructive pulmonary disease (COPD), and emphysema; and body mass index for current smokers, former smokers, and nonsmokers.[72] Despite researchers' best attempts, a prediction model cannot assimilate all possible epigenetic and genetic factors to make consistently accurate predictions.

Accumulating evidence suggests that genetic and epigenetic factors are crucial in modulating individual susceptibility to lung cancer.[73] An example is the identification of a susceptibility locus for lung cancer at 15q25 in a large genome-wide association study.[74,75] Locus 15q25 contains nicotinic acetylcholine receptor subunit genes and seems to be involved in carcinogen metabolism. The two major carcinogens from cigarette smoke, benzo[a] pyrene and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, require metabolic activation before they can exert full carcinogenic effects.

Various activation pathways compete with detoxification pathways, and the balance between the two is crucial in modulating cancer risk. Cytochrome P450s serve as carcinogen-metabolizing enzymes, whereas glutathione transferases serve as detoxification enzymes. Both sets of these important genes are known to have significant polymorphisms that correlate with variations in lung cancer risk.[76–78] Gene polymorphisms in microsomal epoxide hydrolase and their patterns of expression in the respiratory

epithelium also influence the activity of antioxidant enzymes, skewing the balance between the two redox pathways.[79]

Moreover, many researchers believe that DNA repair capacity may play an important role in susceptibility to lung cancer.[80] CYP1A1, an enzyme of the cytochrome P450 family, plays a role in the development of EGFR mutations, hence altering the risk profile of lung cancer among smokers.[81] Other modulators of risk in lung cancer include diet and gender. Dietary factors function as epigenetic modulators of lung cancer susceptibility. In several case–control studies, defective detoxification and defective repair of genetic damage were associated with increased individual susceptibility to lung cancer.[82,83] Food constituents, such as those found in fruits and specific vegetables, appear to afford marked protection to individuals with limitations in their detoxification capacity.[84] This relationship between diet and lung cancer has been explored extensively and is being used as a basis for the development of preventive approaches to lung cancer.

VITAMINS AND MICRONUTRIENTS

Specific micronutrients have been associated with a lower risk of lung cancer, including vitamin E, selenium, isothiocyanates, polyphenols, betaine, and choline. A number of large randomized trials have sought to delineate which compounds in the human diet may be responsible for the protective effects.[85–87] Among heavy smokers, a diet high in red meat consumption and with low adherence to the so-called Mediterranean diet has been found to be associated with increased risk of lung cancer.[84] Conversely, a diet high in vegetable fats and fiber was shown to reduce lung cancer incidence among heavy smokers.[88] The role of selenium has been investigated for preventing lung cancer among patients with selenium deficiency. A trial that sought to prevent SPTs after primary skin cancer in a selenium-poor population in Arizona showed a 34% reduction in lung cancer incidence,[86] and because of this success, the role of selenium as a chemoprotective agent was explored in other malignancies. The Selenium and Vitamin E Cancer Prevention Trial[89] was conducted to study the effect of selenium on prostate cancer incidence. In this trial, 32,400 men were randomly assigned to receive oral selenium, vitamin E, or selenium plus vitamin E as compared with placebo in a double-blind fashion and were monitored for a median of 5.46 years. The trial showed no benefit of selenium or vitamin E, or the combination, to confer any protection against prostate cancer. A phase III prevention study was published in 2013 by the Eastern Cooperative Oncology Group in which patients with resected stage I NSCLC were randomly assigned in a 2:1 ratio to receive selenium methionine at 200 μg/day or placebo. In this trial, selenium failed to demonstrate any objective benefit compared with placebo in protecting against the development of lung SPTs.[90]

However, the Eastern Cooperative Oncology Group study was initiated without preliminary studies, and the recommendation must be to continue to build biomarker-driven, targeted, phase II approaches that appropriately pursue modulation of a crucial biomarker, followed by confirmation, before proceeding with large-scale studies.

Initially, researchers found considerable epidemiologic evidence for the potency of carotenoids and retinoids in reducing cancer risk in general, and lung cancer risk in particular. In fact, the original definition of chemoprevention as "attempts to reverse, suppress, and prevent carcinogenic progression to overt cancer" was based on experimental work showing that vitamin A analogs were capable of reversing or preventing epithelial carcinogenesis in animal experiments.[91]

Early chemoprevention trials included broad populations of individuals who were at risk because of their exposure to tobacco and/or asbestos. Others trials focused on specific high-risk populations, such as uranium miners. Thus, with several decades of epidemiologic and dietary investigation augmented by various experimental systems, a number of compounds, including retinoids and carotenoids, were found to be capable of reversing cell damage. Considerable effort was invested in testing this approach in human populations. The trials focused on broad patient populations, including individuals at very high risk. In other words, studies included individuals with known premalignancy of the airway and patients who already had a primary tobacco-related cancer, because these cohorts were known to have extraordinary risk for developing an SPT and therefore offered a more efficient approach for evaluating candidate chemoprevention agents.

STATUS OF LUNG CANCER SCREENING AND ITS RELATIONSHIP TO CHEMOPREVENTION

After decades of disappointing results, a robust approach to detect and cure early lung cancer has finally emerged. The National Lung Screening Trial (NLST)—the most expensive screening trial ever conducted by the National Cancer Institute—found that the use of low-dose CT (LDCT) in at-risk populations was associated with a significant reduction in lung cancer mortality.[92] Based on this finding and related data, LDCT screening is now recommended by the USPSTF. Humphrey et al.[12] outlined the underpinnings of the USPSTF draft statement on lung cancer screening in individuals at high risk of lung cancer and summarized the benefits and potential harms of this new screening approach.[12] From a review of this synthesis, a number of evidence-based conclusions emerge that clarify important issues about this new public health service as we begin national dissemination of LDCT screening.

To begin, no strict definition of LDCT exists; it is typically considered to use 10% to 30% of the dose of radiation applied in a standard, noncontrast CT. LDCT has been demonstrated to be as accurate as standard-dose CT for detecting solid pulmonary nodules in most adults. In the NLST, acceptable chest CT screening was accomplished at an overall average effective dose of less than 2 millisievert (mSv), which is considerably less than the average effective dose of 7 mSv used for a typical standard-dose chest CT.[93]

The use of low-dose radiation for screening reflects the context of this imaging application. In a physician's office, an individual presenting with the appropriate history combined with signs or symptoms of lung cancer is much more likely to have lung cancer than is an asymptomatic individual participating in a lung cancer screening effort. With screening, the balance of risks and benefits is much narrower than in the standard setting of symptom-detected cancer, and so defining the optimal approach to the LDCT process with the greatest efficiency and quality while minimizing costs and harms is the fundamental challenge as we move toward national implementation of lung cancer screening.

The National Comprehensive Cancer Network (NCCN) has provided a useful source of information about how to approach this LDCT screening process.[94] An example of the management and follow-up for one set of findings after LDCT screening is shown in Fig. 9.1.

NCCN proposes that LDCT screening requires sophisticated multidetector CT scanners and analytic software, professional physicists and staff who can certify equipment and perform studies to a consistent standard at acceptable radiation exposures, qualified radiologists who use standardized terminology and standardized interpretation, appropriate guidelines, reliable communication with primary care physicians, medical environments that can absorb patients who require ongoing management, and the responsibility of tracking screened individuals and documenting outcomes.

NCCN has stratified risk groups that may be eligible for LDCT screening (Table 9.1).[94] The highest-risk group mirrors the eligibility criteria of the NLST, but the lower-risk strata still

Lung Cancer Screening

EVALUATION OF SCREENING FINDINGS   FOLLOW-UP OF SCREENING FINDINGS

Solid nodule on initial screening LDCT[m]

<6 mm[c] → Annual screening LDCT until patient is no longer a candidate for definitive treatment[a,b]

6 to <8 mm[c] → LDCT in 6 mo[a]

8 to <15 mm[c] → LDCT in 3 mo[a] or Consider PET/CT

≥15 mm[c] → Chest CT ± contrast and/or PET/CT

See Evaluation LCS-7

Chest CT ± contrast and/or PET/CT →
- Low suspicion of lung cancer[r] → LDCT in 3 mo[a]
- High suspicion of lung cancer → Biopsy[d] or surgical excision[d] →
  - No cancer → Annual screening LDCT until patient is no longer a candidate for definitive treatment[a,b]
  - Cancer confirmed → See appropriate NCCN Guidelines

Solid endobronchial nodule → LDCT[a] in 1 mo (immediately after vigorous coughing) → If no resolution → Bronchoscopy

A

NCCN National Comprehensive Cancer Network®

NCCN Guidelines Version 1.2017
Lung Cancer Screening

EVALUATION OF SCREENING FINDINGS   FOLLOW-UP OF SCREENING FINDINGS

Part-solid nodule on initial screening LDCT[m,v]

<6 mm[c] → Annual screening LDCT until patient is no longer a candidate for definitive treatment[a,b]

≥6 mm with solid component <6 mm[c] → LDCT in 6 mo[a]

≥6 mm with solid component 6 to 8 mm[c] → LDCT in 3 mo[a] or Consider PET/CT

See Evaluation LCS-8

Solid component ≥8 mm[c] → Chest CT ± contrast and/or PET/CT →
- Low suspicion of lung cancer → LDCT in 3 mo[a]
- High suspicion of lung cancer → Biopsy[d] or surgical excision[d] →
  - No cancer → Annual screening LDCT until patient is no longer a candidate for definitive treatment[a,b]
  - Cancer confirmed → See appropriate NCCN Guidelines

B

Fig. 9.1. Algorithm recommended by the NCCN for the management of solid (A) or part-solid nodules (B) detected by low-dose computed tomography (LDCT) screening. *CT,* computed tomography; *NCCN,* National Comprehensive Cancer Network; *PET,* positron emission tomography. All screening and follow-up CT scans should be performed at low dose (100 kVp to 120 kVp and 40 mAs to 60 mAs or less), unless evaluating mediastinal abnormalities or lymph nodes, where standard-dose CT with intravenous (IV) contrast might be appropriate (see Table 9.2). There should be a systematic process for appropriate follow-up. [a]There is uncertainty about the appropriate duration of screening and the age at which screening is no longer appropriate. [b]For nodules less than 15 mm: increase in mean diameter over 2 mm in any nodule or in the solid portion of a part-solid nodule compared with baseline scan. For nodules over 5 mm: increase in mean diameter of over 15% compared with baseline scan. [c]Rapid increase in size should raise suspicion of inflammatory etiology or malignancy other than nonsmall cell lung cancer. [d]Tissue samples need to be adequate for both histology and molecular testing. Travis WD, Brambilla E, Noguchi M, et al. Diagnosis of lung cancer in small biopsies and cytology: implications of the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society Classification. *Arch Pathol Lab Med.* 2013;137:668–684. *Note:* All recommendations are category 2A unless otherwise indicated. *Clinical Trials:* NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged. *(Adapted from the NCCN Guidelines for Lung Cancer Screening V.1.2017. 2014 National Comprehensive Cancer Network, Inc. All rights reserved. TABLE 9.1 Guidelines of the NCCN on Eligibility for Low-Dose Computed Tomography Screening[a]

Risk Level			Risk Factors
High risk[b]	Age 55–74 years and 30-pack/year history of smoking and smoking cessation <15 years (category 1)[c]	or	20-pack/year history of smoking and one additional risk factor (including radon exposure, cancer history, family history of lung cancer, history of lung disease, and occupational exposure to lung carcinogens such as asbestos and diesel fumes; category 2B)[c]
Moderate risk[d]	Age 50 years and 20-pack/year history of smoking	or	Second-hand smoke exposure (no additional risk factors)[e]
Low risk[d]	Age <50 years	and/or	<20 pack/year history of smoking

[a]Moderate-risk and low-risk patients are not recommended for screening.
[b]Screening is recommended for the high-risk groups in the NCCN Guidelines for Lung Cancer Screening.
[c]Category 1: Based on high-level evidence, there is uniform NCCN consensus that the intervention is appropriate. Category 2B: Based on lower-level evidence, there is NCCN consensus that the intervention is appropriate.
[d]Screening with LDCT is not recommended for the moderate-risk and low-risk groups in the NCCN Guidelines for Lung Cancer Screening.
[e]Risk factors include radon exposure, cancer history, family history of lung cancer, history of lung disease, and occupational exposure to lung carcinogens (e.g., asbestos, diesel fumes).

include people who may develop lung cancer but in whom the cost-to-benefit ratio may be narrower. NCCN also has a patient summary for lung cancer screening, which is an excellent source of objective information for the clinician to guide discussions with potential screening candidates on topics such as who is an appropriate candidate for LDCT screening and what the likely risk is relative to benefit.[95]

An important topic that frequently arises when considering the benefits of screening is the concept of overdiagnosis. Overdiagnosis occurs when a cancer detected during screening does not behave in a lethal fashion, such that an individual may die with, not from, a screen-detected cancer. The USPSTF recently commented on the extent of overdiagnosis with chest x-ray screening in the Prostate, Lung, Colorectal, and Ovarian (PLCO) screening trial. Chest x-ray screening was the initial basis of concern for overdiagnosis in lung cancer screening.[96] In the PLCO trial, among participants at risk for lung cancer due to heavy tobacco exposure, the cumulative incidence of lung cancer after 6 years of follow-up was the same in both the chest x-ray and usual-care groups (606 per 100,000 person-years vs. 608 per 100,000 person-years, respectively; relative risk, 1.00; 95% confidence interval [CI], 0.88–1.13). These results indicate a very small influence of overdiagnosis in this setting, and the PLCO findings suggest that overdiagnosis is not a major confounder in evaluating the benefit of lung cancer screening.[97]

However, many other questions remain unanswered as we consider the implementation of LDCT screening because many misconceptions exist about this new service. One of the most important concepts is understanding the difference between providing screening care for a patient at risk for lung cancer and the more typical situation of treating a symptomatic patient suspected to have lung cancer. The risk–benefit considerations in these two settings are very different, and these differences mandate distinct management approaches.

Regarding other misconceptions, the core design assumption of the NLST, which evaluated more than 53,000 current or former smokers at a cost in excess of $250 million, was widely vetted. The consensus that emerged was that a target reduction in mortality of 20% with LDCT compared with chest x-ray outcomes would constitute compelling evidence of an objective screening benefit. An analysis of the full benefit of LDCT would have been much more expensive and require considerably more time to complete. Therefore it is not surprising that a more recent analysis of NLST outcomes with a rederived eligibility

risk model constructed from PLCO case outcomes resulted in a more efficient rate of lung cancer detection.[98] In that report, the mortality reduction was 30%, compared with the 20% benefit reported in the NLST.[98] This example demonstrates how the LDCT screening process can be improved, and the reanalysis of the NLST data set underscores how valuable this data resource is in allowing process improvement for LDCT screening. As screening becomes implemented, it will be essential to continue to build screening registries from the data of as many screening individuals as possible so that continuous process improvement can be sustained.[98]

LDCT screening does entail a range of possible harms. A 2012 review article from a joint society initiative communicated reservations about the balance of risks and benefits of lung cancer screening.[99] The investigators reported that "uncertainty exists about the potential harms of screening and the generalizability of results."[99] By contrast, a comprehensive synthesis of the issues with screening management was published by the USPSTF in 2013 and conveyed a more optimistic perspective regarding how refined management approaches have improved the process of lung cancer screening. The USPSTF provides an excellent resource for guiding discussions to inform potential screening individuals about risks and benefits of this service.[12,97]

Results of the NLST and Other Clinical Trials Are Not Equal

Although disparate views exist regarding the strength of the evidence supporting LDCT, data synthesis from the comprehensive USPSTF analysis helps clarify this dialogue with its clear support for the strengths of this new approach. At the time of publication, the NLST was the only completed, fully powered, randomized, lung cancer screening trial reported,[92] and no comparable, adequately powered trial was currently under consideration. Comparisons of the mortality reduction reported in the NLST relative to the results of two small, randomized, European trials are not helpful because the latter studies were not adequately powered to give a reliable assessment of the mortality reduction of LDCT.[99] Although ongoing trials will generate interesting and important cost-related and other data that are complementary to those of the NLST, no existing trials will have sufficient study power to supersede the positive conclusion of the NLST relative to the end point of mortality reduction. The largest of the ongoing trials is the Dutch-Belgian Randomized Lung Cancer Screening Trial

TABLE 9.2 Summary Results of Large Clinical Trials Relative to Cancer Detection and Frequency of Stage I Lung Cancer

Study	No. of Cancers/Total Screened (%)		Stage I/All Detected Cancers (%)	
	Round 1	Round 2	Round 1	Round 2
NLST	168/24,715 (0.67)	211/24,102 (0.87)	104/165 (63)	141/204 (69)
NELSON	40/7289 (0.5)	57/7289[a] (0.8)	42/57 (73.7)	—

[a]NELSON round 2/3 data were presented together, reflecting the study design.[100]

NLST, National Lung Screening Trial; *NELSON,* Dutch acronym for Dutch-Belgian Randomized Lung Cancer Screening Trial.[101]

(Dutch acronym NELSON), a study being conducted by a consortium of Dutch and Belgian investigators.[100] Preliminary data from NELSON can be compared with follow-up data from the NLST91 (Table 9.2). As shown, the cancer detection rates are comparable and the stage I detection rates are similar as well, so a major reduction in benefit with LDCT in the NELSON trial is not expected.

From the perspective of US national policy, the NLST data represent the standard criterion showing that LDCT screening can reduce mortality from lung cancer. In the wake of the additional NLST follow-up results, the most relevant contribution of the NELSON trial may be the quality of the ancillary studies, such as the eventual economic analysis. The NELSON investigators embedded more advanced clinical screening management provisions because this trial started several years after the start of the NLST.

Meeting or Exceeding the Favorable Outcomes Reported in the NLST

Going forward, a crucial issue is whether the reported benefits of LDCT screening can be met or exceeded when LDCT is implemented nationally as a routine clinical service. This is a complex issue involving a number of variables that are all crucial in determining the overall benefit of this approach. For example, the risk of lung cancer after heavy smoking persists, despite smoking cessation, and remains elevated as long as the former smoker lives.[2] Therefore ongoing screening beyond the two rounds evaluated in the NLST could further improve the mortality benefit of lung cancer screening beyond the 20% threshold.[92] Two reports have suggested that sustained annual screening may reduce mortality from lung cancer by 40% to 60% under different screening scenarios.[103,104] LDCT has several robust features that enhance its performance as a cancer screening tool. Indeed, the rapid refinement of CT image resolution has resulted in routine detection of progressively smaller primary lung cancers. This evolution improves patients' outcomes for two reasons. First, smaller tumors are associated with better cancer-specific outcomes.[105] Second, smaller tumors are likely to be amenable to treatment with minimally invasive thoracic surgery, a new surgical approach associated with a better quality of life, better compliance with adjuvant therapy, and fewer postoperative complications.[106,107]

In the NLST, surgical clinical care was not specified by any optimized protocol and was typically not delivered in a center selected for excellence in thoracic surgical care. At the time of the NLST, minimally invasive surgery was used in only a minority of the cancers detected during the study. For these reasons, thoughtful national implementation coupled with current best practice could mean that LDCT screening meets or even exceeds the favorable results reported in the NLST. Definitive data for the optimal approach to surgical management in the screening setting do not exist. However, many centers of excellence have

reported favorable surgical outcomes using minimally invasive approaches, generally with video-assisted thoracoscopic surgery.[106,107] A retrospective review of 347 thoracic resections performed in the setting of a lung cancer screening program demonstrated that long-term (10-year) results of sublobar resection were equivalent to those of lobectomy for clinical stage 1A lung cancers.[108] In addition to these excellent results, sublobar resection preserves greater amounts of well-functioning lung tissue.

The Lung Cancer Alliance, an advocacy group, has proposed the mechanism of the Lung Cancer Screening Framework, which encourages institutions providing screening services to employ best practices for screening, including minimally invasive surgical techniques, so that the quality of screening services is maintained at a high level. To validate that institutions are successful in their screening management services, the framework process also mandates that participating institutions routinely report relevant screening outcomes and complication rates, so that potential screening individuals can make informed decisions about where they choose to receive their screening care.[109]

SCREENING INTERVAL AND SELECTION OF CANDIDATES

Questions regarding the optimal interval for the frequency of LDCT screening have been cited as a justification for delaying national implementation. A more efficient approach for defining candidates for LDCT would address much of the uncertainty cited with regard to candidate selection while providing timely access for patients most likely to benefit from LDCT screening. Given the complexity of predicting lung cancer risk, it is unlikely that a one-size-fits-all screening recommendation would suffice moving forward; however, new risk-stratification tools have been shown to provide more robust discrimination of lung cancer risk.[110]

The context for lung cancer screening is unique because tobacco exposure is such a powerful determinant of risk. In 2012, a large British meta-analysis that included data from more than 250,000 individuals resulted in the development of a tool that was very robust in stratifying risk using only the patient's history of tobacco exposure.[111] This approach is consistent with a report by Tammemägi et al.[98] that modeled a better screening outcome when using a more refined tool for cohort identification. Although more comprehensive molecular or genetic models are being developed, the risk tool based on tobacco exposure history would be a logical candidate to use when starting the national screening process and evaluating the generalizable benefit of LDCT screening.[110] Professional societies have suggested that it would be logical to extend LDCT screening to other target cohorts whose level of risk is similar to that of the NLST target population.[112,113] For example, screening could be recommended for individuals based on age, history of tobacco exposure, and other factors as determined by that risk tool, all of which might define a screening cohort equivalent to the validated risk strata found among NLST participants. Perhaps further work with the PLCO risk model could prospectively classify risk of lung cancer relative to the risk strata studied in the NLST as a normative tool for comparing new risk-stratifying tools going forward.[98]

OPPORTUNITIES TO IMPROVE LDCT SCREENING

Since the start of the NLST in 2002, substantial improvements have been made in several areas, including the imaging resolution of LDCT, tools to discriminate high-risk populations, efficiency of diagnostic workup algorithms, and the morbidity of curative thoracic surgical procedures.[12,97] The dose of medical radiation required for LDCT has also decreased.[92]

The LDCT screening setting, which, for now, involves annual follow-up, provides an opportunity to manage tobacco cessation at each annual encounter. The intensity of the cessation strategy can be tailored for the persistent smoker, and this new screening management setting therefore offers a new platform for personalized efforts at smoking cessation. More effective integration of screening and smoking cessation could enhance the public health benefit of this new service. The strength of this growing body of information supporting the safety and effectiveness of LDCT screening, as well as the growing number of endorsements by professionals, has led insurers, such as WellPoint and Anthem, to provide LDCT as a covered service. Third-party coverage through Medicare in the United States was adapted in 2015.

IMPROVEMENTS IN THE APPROACH TO SCREENING AND LDCT IMAGING

Since the inception of the NLST a decade ago, the approach to lung cancer screening that was built into the NLST protocol has improved substantially, yet these improvements—which could facilitate LDCT implementation by reducing potential harms and costs—have not been considered in evaluating the efficacy of CT screening. For example, multidetector scanners were used in the NLST because they are faster than earlier scanners and allow full visualization of lung fields within a single breath hold. The use of such scanners results in fewer CT image artifacts and allows more comprehensive analysis of the lung than that achievable with chest x-rays. However, recently developed CT scanners offer faster image acquisition, which may translate into technically better-quality studies with less motion artifact, and the image quality has continued to improve. These improvements lower both the risks and costs of imaging. All of these factors are pertinent in the public health implementation of LDCT as a national screening resource.

CHANGES IN NODULE EVALUATION AND DIAGNOSTIC WORKUP

Awareness is variable on the importance of the new findings regarding the approach to nodule evaluation.[99] Published reports have outlined considerable refinement in the clinical management of the screening process since the initiation of the NLST, which did not mandate a specific approach to nodule evaluation. Yankelevitz et al.[114] were the first to report that clinically important lung nodules could be identified by restricting the diagnostic workup to suspicious nodules that showed significant growth over a defined period. This interval-growth approach to the diagnostic workup was incorporated into the design of the NELSON trial and resulted in a favorable workup rate of 12% for the diagnosis of invasive nodules, with a diagnostic sensitivity of 95% and a specificity of 99% for LDCT.[100] More recently, this interval-growth criterion for suspicious nodules was used prospectively in a cohort of 4700 patients undergoing screening at the Princess Margaret Hospital; only 3% of the patients were required to undergo an invasive workup, and the false-positive diagnostic rate was 0.42%.[115] The validity of these findings is supported by a recent retrospective analysis of baseline lung cancer cases accrued in the International Early Lung Cancer Action Project. In this analysis, changing the threshold of nodule size for a lung cancer diagnostic workup from 4–5 mm to 7–8 mm was associated with timely diagnosis of early-stage lung cancer while significantly reducing the frequency of false-positive results.[116] Implementation of this approach could improve the efficiency of LDCT screening by reducing the costs and harms of invasive diagnostic workups within the baseline screening process. The NCCN has been integrating the evolving research information into its management recommendations

for screening (see Fig. 9.1). This information will allow more consistent management of LDCT, with expectations of more favorable outcomes.

FURTHER OPPORTUNITIES ASSOCIATED WITH LDCT SCREENING

A crucial opportunity to optimize the benefit of screening is to integrate smoking cessation into lung cancer screening.[117,118] Although integration of LDCT screening into smoking cessation has been reported with mixed success, to date little research has been done to optimize smoking cessation within the setting of recurrent screening. Some authors have characterized the screening encounter as a so-called teachable moment for a dialogue about smoking cessation, and the cost efficiency of this integration is projected to be extremely favorable.[119,120] Furthermore, every subsequent annual LDCT screening for a persistent smoker is an opportunity to explore more personalized or intensive measures for smoking cessation. Increasing success with smoking cessation would not only improve the inherent cost efficiency of the LDCT screening process relative to lung cancer outcomes, but would also accrue to the other well-validated health and economic benefits related to smoking cessation. Through new mechanisms required by the Centers for Medicare and Medicaid Services, reimbursement for LDCT screening services could be linked to demonstrating compliance with national quality measures for these services, especially with regard to risk stratification and smoking cessation.[121]

A related consideration with LDCT is the unprecedented potential to evaluate the status of other tobacco-related diseases. For example, recent reports have shown that coronary calcium analysis can be derived from LDCT images and may be a useful stratification tool for the risk of coronary artery disease.[122,123] Furthermore, an LDCT assessment of lung injury could serve as a metric of risk for progression of COPD.[124,125] Indeed, patients with tobacco exposure participating in lung cancer screening are known to experience a significant comorbid risk of COPD and cardiovascular disease. With further research, the opportunity exists to simultaneously evaluate for the three major host consequences of tobacco exposure—coronary artery disease, COPD, and cardiovascular disease—with only LDCT. These diseases represent three of the leading causes of premature death in our society.[126] The emerging setting of LDCT screening can therefore provide a useful window into the preclinical phase of three major chronic diseases, so the time is ripe to explore this important opportunity.

CHEMOPREVENTION TRIALS

Risk categories differ across the spectrum of lung carcinogenesis, from individuals exposed to carcinogens, to individuals with known premalignant lesions, to individuals who have already had cancer as a result of tobacco smoke exposure. Reducing the frequency of cancer in these three categories of at-risk individuals (carcinogen-exposed individuals) is the focus of chemoprevention. Specific terms are used to describe the various approaches to cancer prevention. The first is known as primary cancer prevention. Primary prevention involves intervening in patient populations who have only an increased risk, such as with tobacco control measures, to reduce exposure to tobacco combustion products. The purpose of primary prevention is to reduce the incidence of and mortality from lung cancer.

Secondary prevention applies to individuals with evidence of lung premalignancy and involves attempts to prevent the progression of that premalignancy or, ideally, to reverse it to an earlier stage of carcinogenesis. Chemoprevention falls into this category. An efficient way to study the benefit of chemoprevention drugs is to evaluate populations at the highest risk for cancer, meaning

TABLE 9.3 Primary Randomized Trials of Chemoprevention in Lung Cancer

Study	Intervention	End Point	No. of Patients	Outcome
ATBC20	β-carotene, α-tocopherol	Lung cancer	29,133	Negative/harmful
CARET[129]	β-carotene, retinol	Lung cancer	18,314	Negative/harmful
Physician's Health Study[130]	β-carotene	Lung cancer	22,071	Negative
Women's Health Study[131]	β-carotene, aspirin, vitamin E	Lung cancer	39,876	Negative

patients who have already had a first tobacco-related malignancy and have a very high risk of an SPT developing. Many of the early trials focused on using retinoids and carotenoids as chemoprevention agents because of the strong epidemiologic and experimental evidence for the activity of these compounds.

Primary Chemoprevention

Several large, randomized studies were conducted in populations deemed to be at increased risk of lung cancer because of exposure to tobacco smoke or asbestos, or their occupation as uranium miners. The hypothesis that dietary β-carotene could lower the incidence of epithelial cancers was first proposed by Peto et al.[127] Later, three major studies, the Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) Study, the Beta-Carotene and Retinol Efficacy Trial (CARET), and the Physician's Health Study, were carried out using increasingly high doses of the carotenoid β-carotene (Table 9.3).[128–130]

None of the three studies showed significant reductions in lung cancer risk using these compounds. In fact, the secondary end point in two of these studies, ATBC and CARET, showed an increase in the incidence of lung cancer associated with β-carotene supplementation. Both of these trials, which were 2 × 2 factorial studies, also involved a second agent, as an intervention. In these cases, neither the second agent nor vitamin A itself was found to be associated with an increased risk of lung cancer, but neither were they protective against lung cancer. Both of these studies showed that the risk of lung cancer was increased only among smokers.

The ATBC was a randomized, 2 × 2 factorial, double-blind, placebo-controlled, primary prevention study in which 29,143 Finnish male smokers received α-tocopherol (50 mg/day alone), β-carotene (20 mg/day), both α-tocopherol and β-carotene, or a placebo.[128] The enrolled participants were 50 years to 69 years of age, and all of them smoked five or more cigarettes per day; they received follow-up observation for 5 years to 8 years. Although the incidence of lung cancer, the primary end point, was not modified by supplementation with α-tocopherol alone, both groups that received β-carotene supplementation, either alone or with α-tocopherol, had an 18% increase in the incidence of lung cancer and an 8% increase in lung cancer mortality. This study showed a stronger adverse effect from β-carotene in men who smoked more than 20 cigarettes per day and was the first to raise the concern that pharmacologic doses of β-carotene could be harmful in active smokers. However, a follow-up analysis suggested that the excess risk among β-carotene recipients was no longer evident after 4 years to 6 years, and a continued, slight excess in total mortality was attributable to cardiovascular diseases.[132]

The results of CARET were consistent with the results of the ATBC trial. This was also a randomized, double-blind,

placebo-controlled trial testing the combination of β-carotene (30 mg/day) and retinyl palmitate (25,000 IU) in 18,314 men and women aged 50 years to 69 years who were considered to have an increased risk of lung cancer. Most participants had a smoking history of 20 or more pack-years and were either current smokers or recent former smokers. Significant or extensive occupational exposure to asbestos was noted in 4060 men in this trial.[133] The trial was terminated prematurely because of concern about possible harm, consistent with the findings of the ATBC study. Lung cancer incidence, the primary end point, was increased by 28% in the active intervention group, and overall mortality was increased by 17% in this group.[129]

This finding was different from those of the Physician's Health Study,[130] a randomized, double-blind, placebo-controlled trial that included 22,071 healthy male physicians. Half of the participants received 50 mg/day of β-carotene on alternate days, and the other half received placebo; no adverse effect of β-carotene supplementation was noted. The use of supplemental β-carotene in this study, which included mostly nonsmokers, showed no adverse or beneficial effects on cancer incidence or overall mortality rate during a 12-year follow-up.[130] Similarly, the Women's Health Study evaluated the effect of β-carotene supplementation and found no evidence of either benefit or harm. However, only 13% of the women were smokers in both the treatment and placebo groups.[131]

Subsequent subgroup analyses of the ATBC and CARET studies indicated that an excess of cancers was found only in the β-carotene study arms including high-risk heavy smokers or individuals with previous exposure to asbestos.[134]

A recent metabolomic analysis has proposed that increased mortality in the ATBC study could be related to dysregulation of glycemic control induced by β-carotene and induction of cytochrome P450 enzymes, leading to interactions with cardiovascular drugs.[135] This hypothesis must be considered in light of the emerging understanding that a high percentage of smokers died prematurely from cardiovascular causes, and this confounding factor can play a major role in the increased overall mortality rate in these chemoprevention trials. Tobacco is known to upregulate cytochrome P450 enzymes, and this effect can accelerate the metabolism not only of chemopreventive drugs, but also of other classes of therapeutic drugs, such as cardiovascular drugs.

The role of inhaled steroids as possible chemopreventive agents has been reported. Inhaled budesonide was associated with a dose-dependent reduction in the risk of lung cancer in a cohort of patients with COPD.[136] A phase II trial from 2011 studied the effects of oral budesonide on the size of CT-detected pulmonary nodules in current and former smokers. Treatment for 1 year did not significantly affect the size of peripheral lung nodules, but a trend toward regression of nonsolid and partially solid nodules was noted.[137] At least some of these ground-glass nodules are suspected to be cancer precursor lesions. Epithelial-directed drug delivery may be advantageous because it could result in high drug concentrations in areas of high tobacco-related injury in the airways, yet achieve nontoxic drug levels in the systemic circulation. Oral administration of these agents may not result in sufficient drug concentrations at the bronchial epithelium. Experimental studies in animal models with aerosolized 13-*cis*-retinoic acid and retinyl palmitate have shown significant improvements in histologic changes in the bronchial epithelium.[138] This pharmacologic approach has a strong theoretic appeal, and the preliminary positive results require further research.

Secondary Chemoprevention

Although authorities disagree about which premalignant markers most consistently predict the development of cancer, the success in studying patients with premalignancy has been limited. To date, randomized trials have used various end points, including

TABLE 9.4 Secondary Randomized Trials of Chemoprevention in Lung Cancer

Study	Intervention	End Point	No. of Patients	Outcome
Lee et al.[142]	Isotretinoin	Metaplasia	40	Negative
Kurie et al.[143]	Fenretinide	Metaplasia	82	Negative
Arnold et al.[144]	Etretinate	Metaplasia	150	Negative
McLarty et al.[145]	β-Carotene, retinol	Sputum atypia	755	Negative

reversal of sputum atypia, reduction in DNA micronuclei, and reversal of dysplasia or hyperplasia (Table 9.4). Some of these trials have used retinoids and have shown that in the absence of smoking cessation, retinoids are incapable of reversing premalignant lesions. By contrast, some biomarker-driven studies using pan-retinoids, such as 9-*cis*-retinoic acid, or atypical retinoids, such as fenretinide, have shown that these agents can modulate biomarkers such as RAR-β or expression of human telomerase reverse transcriptase, respectively.[139,140] Little evidence is available to suggest that any of the compounds listed in Table 9.4 are capable of consistently reversing premalignant lesions. To date, one of the most positive studies has been the one that used folate and vitamin B12, which showed some improvement in metaplasia of the bronchial epithelium in smokers.[141] Given the difficulty in validating end points, however, even these positive results must be viewed with caution. Larger trials using biologic end points are needed to confirm efficacy.

The findings of Lee et al.[142] are interesting because they indicated that retinoids could be effective in conjunction with smoking cessation. No evidence of benefit was found in active (continuing) smokers, but that raises the issue of accelerated drug metabolism in current smokers due to induction of metabolizing enzymes. However, more recent studies using novel retinoids have indicated the potential for significant benefit. Kurie et al.[139] reported the results of a randomized controlled trial in former smokers who received either 9-*cis*-retinoic acid or 13-*cis*-retinoic acid with α-tocopherol. The end point of this trial was

upregulation of RAR-β, which may inhibit the process of pulmonary carcinogenesis. Of 177 evaluable participants, patients treated with 9-*cis*-retinoic acid were found to have restoration of RAR-β expression ($p < 0.03$), and this finding also correlated with a reduction of bronchial metaplasia ($p < 0.01$).[139] No significant effect was found among patients receiving 13-*cis*-retinoic acid with α-tocopherol, so this group of investigators planned to move forward with 9-*cis*-retinoic acid, a pan-retinoid agonist, targeting former smokers.

Ki-67, a biomarker for cell proliferation, has been used as an end point for changes in bronchial dysplasia in various secondary chemoprevention trials. For example, a phase II trial was conducted to study the effects of enzastaurin, a serine/threonine kinase inhibitor, to reduce the Ki-67 labeling index in former smokers. The patients were randomly assigned to receive oral enzastaurin (500 mg/day) or placebo daily for 6 months. The results failed to show any significant difference in changes in the Ki-67 labeling index between the experimental and placebo arms. However, in a subgroup analysis restricted to metaplastic and dysplastic samples, almost one-fifth of the participants had a 50% reduction in Ki-67 expression in the experimental arm compared with none in the placebo arm.[152]

A phase III trial evaluated the effect of 13-*cis*-retinoic acid (50 mg/day) in high-risk patients as measured by changes in the Ki-67 labeling index of the bronchial epithelium. The study included patients with more than a 30-pack/year history of smoking, evidence of airflow obstruction, or surgically cured stage I or II NSCLC. Results after 12-month follow-up failed to show any change in the Ki-67 labeling index,[153] but dosage reductions in 13-*cis*-retinoic acid were frequent because of adverse drug effects.

Sulindac was studied as a potential chemopreventive agent in a randomized, placebo-controlled phase II trial. However, results from this trial of squamous cell lung cancer chemoprevention failed to demonstrate sufficient benefits from sulindac as documented by changes in the Ki-67 labeling index.[156]

This result raises the question of whether Ki-67 is the appropriate biomarker. Data are conflicting as to whether Ki-67 expression is related to smoking status and degree of dysplasia or whether it predicts the eventual development of lung cancer.[157–159]

Various other natural agents, including curcumin, deguelin, bovine lactoferrin, *myo*-inositol, and epigallocatechin gallate, have been studied in animal models as potential agents to block tumor carcinogenesis, but these agents are in the very early stages of evaluation.[160–163]

The cyclooxygenases (COXs) have been reported to be involved in carcinogenesis. Inhibition of this enzyme, particularly COX-2, is a potential chemopreventive approach. In population-based cohort studies, the use of nonsteroidal anti-inflammatory drugs for more than 1 year was associated with a reduction in the relative risk of lung cancer and conferred chemoprotective effects in smokers.[164–166] In a phase IIb study, celecoxib, another COX-2 inhibitor, significantly reduced the Ki-67 labeling index and other secondary end points in former smokers.[164] However, these agents can be used only in specific populations with a low cardiovascular risk, which limits their utility in terms of chemoprevention of smoking-associated diseases.

Iloprost is another agent that modulates the COX cascade and has effects similar to those of the COX-2 inhibitors. Oral iloprost was shown to significantly improve endobronchial dysplasia in the epithelia of former smokers in a phase II trial. Confirmatory trials linking the administration of these agents to improvements in clinical end points are required before recommending broader use of these agents.[155]

Neoadjuvant window-of-opportunity trials entail the administration of specific drugs to patients with newly diagnosed lung cancer just before (typically 2 weeks before) lung cancer resection. In this manner, the expression analysis can be evaluated in

comparison with postdrug exposure to define the signaling pathways that are active and influenced by the drug exposure. This approach gives a more precise signature of actual drug impact than is possible with conventional drug-development approaches for lung cancer and potentially identifies useful intermediate markers of drug effect. This class of trial also allows direct evaluation of the respiratory epithelium for mapping the extent of carcinogenic injury along with the drug response at those sites. Three such trials have been conducted in patients with stage I NSCLC. Chemotherapy is administered during the preoperative window, and then disease is assessed for response in terms of tumor load reduction and biomarker profiling. The first of these trials was conducted to explore the use of gefitinib in patients with stage I NSCLC to assess response in terms of tumor burden and to identify predictors of response.[167] Thirty-six patients received gefitinib (250 mg/day) for up to 4 weeks before surgical resection in this single-arm study. Tumor shrinkage was more common among nonsmokers and women, and the strongest factor to predict response was EGFR mutation; this finding supports gefitinib as part of a neoadjuvant regimen for early-stage NSCLC in selected populations (with EGFR mutations). These trials also serve as biomarker trials by identifying markers that are predictive of response and their potential use to select a target population for chemopreventive and therapeutic approaches. Another phase II trial explored the use of pazopanib, an oral antiangiogenesis agent that inhibits vascular endothelial growth factor, in early-stage NSCLC. These investigators also conducted extensive biomarker profiling of cytokines and angiogenic factors (CAFs) to investigate the relationship between CAFs and tumor shrinkage. Levels of 11 CAFs were found to be associated with tumor shrinkage, notably interleukin-12 and interleukin-4. The authors proposed the use of CAF profiling to select target populations for pretreatment with pazopanib.[168]

Another trial used a combination of bexarotene and erlotinib in early-stage NSCLC. This combination was found to be active in KRAS-driven lung cancer cells and also in clinically active, chemorefractory mutant KRAS cancers, which was interesting because the presence of KRAS mutations was hypothesized to be a marker of resistance to gefitinib treatment.[169]

Linkage Chemoprevention and Future Research

Patients with tobacco-related cancers remain at a substantially elevated risk for subsequent tumors in the tobacco-damaged epithelium.[27,28,170–174] Although treatment of the initial cancer can often be successful, these patients have a high risk of an SPT.[175] The lifetime risk of an SPT in the head and neck region is approximately 20%. Although estimates have varied between 3% and 7% per year, the evidence remains very strong that SPTs are the major cause of death after curative surgical procedures for head and neck cancer.[173–178]

Given the high likelihood of both recurrence and SPTs in patients with advanced oral, oropharyngeal, or laryngeal squamous cell cancers, Hong et al.[179] launched a randomized, placebo-controlled study of 103 patients with stages I–IV head and neck squamous cell cancer (Table 9.5). The patients were randomly assigned to receive either high-dose 13-*cis*-retinoic acid (100 mg/m^2/day) or placebo for 1 year after definitive local therapy. The dosage of 13-*cis*-retinoic acid was reduced to 50 mg/m^2/day after 13 of the first 44 patients experienced intolerable adverse effects. The primary end points were recurrence of the primary tumor and development of an SPT. No difference was found between the treatment arms in local recurrence or distant metastases. However, the patients treated with 13-*cis*-retinoic acid had a dramatically lower incidence of SPTs. Of the 103 patients followed for a median of 42 months, SPTs developed in 6% (3/49) in the 13-*cis*-retinoic acid arm compared with 28% (14/51) in the placebo arm.

TABLE 9.5 Prevention Studies on Lung and Aerodigestive Secondary Primary Tumors (Tertiary Chemoprevention)

Study	Intervention	End Point	No. of Patients	Outcome
Pastorino et al.[180]	Retinyl palmitate	SPT	40	Positive
EUROSCAN[181]	Retinyl palmitate, *N*-acetylcysteine	SPT	82	Negative
Lippman et al.[182]	13-*cis*-Retinoic acid	SPT	150	Negative
Khuri et al.[183]	13-*cis*-Retinoic acid	SPT	755	Negative
Hong et al.[179]	Isotretinoin	SPT	73	Positive

SPT, secondary primary tumor.

A large-scale follow-up to this trial using a much lower dose of 13-*cis*-retinoic acid was published in 2006. In this randomized, double-blind, placebo-controlled study, launched in 1991, more than 1382 patients were registered and 1192 were randomly assigned to either low-dose 13-*cis*-retinoic acid (30 mg/day) or placebo. These patients were definitively treated for stage I or II head and neck squamous cell cancer. After a median follow-up of 7 years, no effect was seen with the low-dose retinoid for reducing the incidence of SPT in the lung or aerodigestive tract.[183] No pharmacologic assessment was done in this trial to demonstrate the adequacy of retinoid delivery into the bronchial epithelial tissue despite the major dosage reductions due to adverse effects (skin dryness, cheilitis, hypertriglyceridemia, conjunctivitis, etc.) encountered in the trial by Hong et al.[179]

Several phase III trials have been launched in an attempt to prevent SPTs in patients with lung cancer. The first of these was a trial by Pastorino et al.,[180] who randomly assigned more than 300 patients with early-stage lung cancer to retinyl palmitate or placebo. This study showed a significant reduction in the development of lung SPTs in the retinyl palmitate arm. A subsequent study by Bolla et al.[184] using a different synthetic retinoid, etretinate, failed to show a reduction in SPTs.

Two large follow-up phase III trials reported in the past decade include the EUROSCAN study and the US Intergroup 91-0001 trial.[181,182] EUROSCAN, a randomized study of adjuvant chemoprevention from the European Organisation for Research and Treatment of Cancer, studied the effects of vitamin A (retinyl palmitate) and *N*-acetylcysteine in patients with early-stage head and neck and lung cancer.[181] In this trial, 2592 patients with cancers of the larynx (TIS-T3 and 0-N1), oral cavity (TIS-T2 and 0-N1), or NSCLC (T1-T2 and 0-N1) received retinyl palmitate 300,000 IU/day in year 1 and 150,000 IU/day in year 2, *N*-acetylcysteine 600 mg/day for 2 years, both drugs, or placebo. No significant differences were seen for the three active treatment arms compared with placebo in terms of recurrence rates, SPT development, or survival. Of note, more than 90% of the patients were current smokers, with 43 median pack-years of tobacco exposure.

The US Intergroup 91-0001 trial was a randomized, double-blind, placebo-controlled study of low-dose (30 mg) 13-*cis*-retinoic acid administered after complete resection of stage I NSCLC.[182] This trial completed accrual in 1997 after enrolling 1486 participants. The study objective was to evaluate the efficacy of low-dose 13-*cis*-retinoic acid for 3 years at 30 mg/day compared with placebo in the prevention of SPTs. Patients were required to have complete resection of primary stage I NSCLC (postoperative T1 or T2 and 0) and to be registered between 6 weeks and 3 years after completion of therapy. After a median follow-up of 3.5 years, no significant differences were seen between placebo and 13-*cis*-retinoic acid with respect to time to SPT development, recurrence rate, or mortality. Multivariate analyses showed that the rate of SPTs was not affected by any stratification factor, and

the recurrence rate was affected only by treatment stage, with evidence for a treatment-by-smoking interaction (hazard ratio for treatment by current smoking vs. never-smoking status, 3.11; 95% CI, 1.00–9.71). Therefore low-dose 13-*cis*-retinoic acid was not shown to affect overall survival rates or SPTs, recurrence rates, or mortality in patients with stage I NSCLC. Subsequent subset analyses have indicated that 13-*cis*-retinoic acid was associated with a higher rate of metastatic progression among current smokers and a suggestion of benefit among never-smokers.

FUTURE STRATEGIES

After more than two decades of unsuccessful chemopreventive interventions for patients with NSCLC, the accumulated evidence suggests that approaches relying exclusively on the development of epidemiologic guidance for selection of compounds are not sufficient to identify effective interventions across broad and disparate populations. Although clues continue to emerge from the epidemiologic literature suggesting that dietary constituents or specific medications, such as green tea polyphenols, curcumin, statins, and metformin, significantly reduce lung cancer risk,[185,186] few experts have suggested moving prevention approaches forward without further testing of these concepts in well-designed, biomarker-driven trials.

To date, substantial evidence shows that overexpression of EGFR occurs throughout lung carcinogenesis.[38,187,188] Furthermore, mutations of the EGFR TK binding domain can be seen diffusely across the normal-appearing airway in patients with resected adenocarcinomas who are nonsmokers and whose primary tumor harbors this mutation. This discovery of EGFR TK mutations in apparently normal-appearing airways not damaged by tobacco exposure, despite the absence of an identifiable carcinogen leading to EGFR mutations, represents a new and as yet poorly understood type of field effect.[42] Chemoprevention approaches using the EGFR TKI in high-risk patient populations have been proposed, and so-called window-of-opportunity trials have been conducted with pazopanib, gefitinib, and erlotinib, as elaborated earlier.[158,189–191]

EGFR inhibitors have also been examined in pilot studies in combination with bexarotene.[169] The incidence of EGFR TK mutations in adenocarcinomas of the lung is most prominent among Asian nonsmoking women; however, the identification of individuals at greatest risk is the biggest challenge.

Important data also indicate a progressive upregulation of COX-2 in lung carcinogenesis, and trials of suppression of COX-2 with selective COX-2 inhibitors have shown promising preliminary results.[147,192] Another approach has been to upregulate prostacyclin, thereby downregulating prostaglandin E2, potentially the crucial downstream effector pathway for COX-2.[193] These COX-directed chemopreventive strategies merit further evaluation.

Another targeted approach is based on experiments in vitro and on epidemiologic data. Govindarajan et al.[194] showed that thiazolidinediones, which stimulate the peroxisome proliferator-activated receptor (PPAR), are able to induce cell cycle arrest. These investigators performed a large cohort study of 87,678 male veterans 40 years and older and showed a 33% reduction of lung cancer risk among the 11,289 thiazolidinedione users. One caveat, however, is that this study failed to account for variations by smoking status. PPAR expression has been found to be more prevalent in squamous cell cancers than in adenocarcinomas. In squamous cell cancer, it is associated with bcl and c-myc positivity, whereas in adenocarcinoma it is associated with size of the tumor. These findings suggest the potential of PPAR expression as a prognostic marker and may have implications for chemotherapy and treatment.[195] Other researchers have used corticosteroids, both inhaled and oral, or inhaled retinoids, all of which have shown promise. Two randomized phase II pilot studies in high-risk patients failed to show a trend in favor of inhalational corticoids, but these trials had methodologic limitations, such as a focus on central airway changes and sample sizes that were not large enough to allow definitive conclusions.[150,151] Larger studies using more efficient delivery devices to target deep respiratory epithelium, thereby mirroring the deposition of tobacco-containing products, seem warranted.

Notwithstanding the negative outcomes of several large comparative trials, a considerable number of epidemiologic, experimental, and clinical observations continue to provide evidence that antioxidants, anti-inflammatory agents, EGFR TKIs, and phytochemicals may block various modes of carcinogenesis. However, the modes of action of several of these agents at the level of gene transcription are not yet completely understood. Thanks to new molecular biologic techniques, this insight is rapidly increasing, and after many years with meager results of chemoprevention studies, we may have entered a more positive era in this area of research.

CONCLUSION

The expanding understanding of the pathologic and genetic basis of lung carcinogenesis provides a foundation for chemopreventive research. The emergence of lung cancer screening with more frequent detection of early-stage lung cancer also will provide impetus for defining effective chemopreventive agents. Increased numbers of potentially cured early-stage lung cancers will result in many patients being followed with concerns of field of cancerization resulting in the development of second primary lung cancers. Despite concerted efforts, no successful chemopreventive strategy has been validated to date. New trial designs such as those with small trial cohorts including only a very "high-risk population" defined with biomarkers may allow for more rapid and economically chemopreventive drug development. Candidate intermediate biomarkers have been identified and have been used in trials with preliminary positive results. In addition, neoadjuvant, window-of-opportunity trials may also provide a valuable tool for better defining the mode of chemoprevention drug action, and the tissue specimens obtained before and after drug exposure in these window trials may help identify candidate companion diagnostic or therapeutic biomarkers to assess the response of the drug for use in subsequent drug development trials. Considering the ever-increasing burden of lung cancer worldwide, it is imperative to continue our efforts to identify effective chemopreventive agents to arrest early lung carcinogenesis. With increasing insight into the molecular basis coupled with a better screening strategy, the road is paved for more successful studies in the at-risk population.

10 Copy Number Abnormalities and Gene Fusions in Lung Cancer: Present and Developing Technologies

Marileila Varella-Garcia and Byoung Chul Cho

SUMMARY OF KEY POINTS

- Lung cancers commonly have structural chromosome aberrations and aneuploidy, with many of them associated with carcinogenesis.

- Gene amplification is a common mechanism of oncogenic activation in nonsmall cell lung cancer (NSCLC) involving genes such as *MYC*, *EGFR*, *ERBB2*, *MET*, *PIK3CA*, and *FGFR1*. Gene amplification is also associated with resistance to drugs, for instance, to epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors when the T790M *EGFR* allele or the *MET* gene is amplified.

- More recently, genes such as *ALK*, *ROS1*, *RET*, and *NTRK1* were found to be activated in NSCLC by fusions with gene partners subjected to constitutive transcription or carrying specific domains inducing phosphorylation.

- Novel therapeutics have been developed to target those specific molecular drivers, and several drugs have succeeded in substantially improving survival and quality of life of patients carrying such molecular changes.

- NSCLC tumor profiling is achieved by numerous technologies focusing on different levels such as DNA (e.g., sequencing, fluorescence in situ hybridization [FISH]), RNA (e.g., reverse transcription-polymerase chain reaction), and protein (e.g., immunohistochemistry [IHC]). Technologies using in situ (FISH, IHC) and extraction (PCR based, sequencing) platforms have distinct advantages and limitations.

- Single tests and test panels are available, with the latter being most effective due to the low incidence of the rearrangements in the overall NSCLC population, the lower cost per gene tested, and the scarcity of tumor tissue in patients with advanced stage disease. Molecular drivers have been detected more commonly in lung adenocarcinomas than in squamous cell carcinomas (SCCs) but a strong effort is ongoing to better define potential therapeutic targets in SCC. Very little is known regarding markers for therapy in small cell lung cancer.

Lung cancer is a group of diseases displaying a high level of genomic instability and complex molecular changes. This chapter reviews the impact of molecular events detectable by cytogenetic techniques, such as instability, at the DNA and chromosome levels in lung cancer patients. In addition, the chapter also examines two of the major molecular mechanisms leading to the nonviral activation of oncogenes: gene amplification and gene fusion. Overexpression of proteins in conditions in which they are normally absent is commonly driven by an increase in gene copy number or the release of a specific gene from the ligand binding control, thus having its active domain under the control of the promoter or of the active domain of a constitutively activated gene. Amplification of genes in lung cancer was discovered in the mid-1980s for v-myc avian myelocytomatosis viral oncogene homolog (*MYC*) and Kirsten rat sarcoma viral oncogene homolog (*KRAS*).[1,2] Conversely, fusion proteins are a much newer phenomenon in lung cancer. Despite being common and well-known in leukemia and lymphoma as causal factors and targets for therapy, gene fusions were not described in lung cancer research before the start of the 21st century. However, with the progress of genomic technology, the number of activated gene fusions discovered mainly in NSCLC has increased rapidly, as will be detailed here.

GENETIC INSTABILITY IN LUNG CANCER

Accumulation of multiple genetic abnormalities is known to be associated with lung cancer initiation and progression. Genetic instability, which may cause these abnormalities, is a general term that refers to both chromosomal instability (CIN) and microsatellite instability (MSI).[3] Instability involving whole or partial regions of chromosomes (CIN) includes deletion, duplication, insertion, and translocation. CIN may induce loss of heterozygosity (LOH) of tumor suppressor genes or DNA repair genes when deletions occur, and amplification of oncogenes by multiple duplications of focal chromosome regions. Consequently, compelling evidence has supported the role of CIN in the pathogenesis of lung cancer.[4–7] In addition to alterations at the chromosomal level, instability at the nucleotide level, frequently referred to as MSI, is usually connected to mismatch repair (MMR) defects.[8,9] MSI may cause missense mutations that facilitate the inactivation of tumor suppressor genes, such as *p53*, which may contribute to the development and progression of lung cancer.[10,11] Both phenomena—CIN and MSI—obviously contribute to the phenotype instability and versatility of cancer cells. Therefore an understanding of the molecular mechanisms leading to genetic instability holds promise for the development of novel therapeutic strategies in lung cancer.

Microsatellite Instability

Microsatellites, also known as simple sequence repeats, are tandem repeats of short (fewer than 10 bp) DNA sequences, which are useful markers for genetic mapping and LOH of defined chromosomal loci. The most common microsatellite in humans is a dinucleotide repeat of CA, which occurs tens of thousands of times across the genome. Although the length of these microsatellites is highly variable from person to person, each individual has microsatellites of a set length. MSI, a hallmark of genetic instability, generally occurs because of abnormalities of the MMR genes, such as *hMSH2* and *hMLH1*, impairing the correction of errors that spontaneously occur during DNA replication.[12] The loss of MMR function renders tumor cells susceptible

to the acquisition of somatic mutations throughout the genome, and microsatellites are particularly susceptible to mutations in the absence of MMR. MSI was initially identified in colorectal cancer and was immediately clinically significant because of its association with hereditary nonpolyposis colon cancer (HNPCC).[13] In HNPCC, the MSI of MMR genes due to germline alterations is an essential molecular basis of its development. By contrast, in lung cancer, CIN plays a more important role in carcinogenesis, as homozygous and heterozygous deletions of certain chromosomal loci or amplification of oncogenes frequently occur, as will be described.[6,14,15]

There are conflicting data on the relevance of MSI in lung cancer. The frequency of MSI has been reported to range from 0% to 69% in NSCLC and from 0% to 76% in small cell lung cancer (SCLC).[8,10,14,16–19] Interestingly, several studies of NSCLC have demonstrated a higher frequency of MSI in tetranucleotide-repeating regions than in traditional mononucleotide-repeating or dinucleotide-repeating regions, and the term "elevated microsatellite alterations at selected tetranucleotide" (EMAST) has been proposed to designate the phenomenon.[8,10,16,20] Furthermore, EMAST was reported to be associated with SCC with lymph node metastasis.[16] The molecular mechanisms leading to EMAST, distinct from traditional MSI, were not associated with defects in MMR, but it was suggested that p53 alterations may be involved.[10,16,20]

Aneuploidy and CIN

Most cancer cells possess an abnormal number of chromosomes, often in the triploid or tetraploid range.[3] In addition to the altered number of chromosomes, cancer cells commonly have structural chromosome aberrations, such as inversions, deletions, duplications, and translocations. Aneuploidy, defined as numerical and structural abnormalities of chromosomes, commonly results from CIN.[21] Aneuploidy and CIN can mediate the evolution of cancer cell populations under selection pressure and are associated with poor prognosis and distinctive histopathologic features in many tumors. CIN plays an important role in lung carcinogenesis by accelerating homozygous and heterozygous deletions of tumor suppressor genes and effectively amplifying oncogenes.[6,14,22] Therefore a better understanding of the causes and effects of aneuploidy and CIN may lead to new therapeutic venues for solid malignancies, including lung cancer.[23]

Early studies have shown that lung cancer frequently exhibits marked LOH as a result of CIN when genome-wide or specific regions such as chromosomes 12p, 14q, and 17q were investigated.[4,5,24] Moreover, LOH at 3p loci containing genes associated with antioxidant defenses (e.g., glutathione peroxidase I) is not only associated with the development of lung cancer but also with higher responsiveness to DNA damaging agents (e.g., radiation).[25]

Multiple mechanisms during cell cycle progression have been implicated in the advent of CIN and aneuploidy in lung cancer. These include failure at the mitotic checkpoint, mutations and amplifications in the kinetochore (protein structure on chromatids where the spindle fibers attach during cell division) and centrosome components, and mutations in DNA repair genes.[23] The mitotic checkpoint, also called the spindle assembly checkpoint, is activated when the kinetochore is not attached to the spindle, lacks microtubules, or has poor or inadequate tension, thereby deregulating metaphase–anaphase progression.[26] Loss-of-function mutations, or reduced gene expression of the mitotic checkpoint genes (mitotic arrest deficient-like 1 [*MAD1/MAD2*] and mitotic checkpoint serine/threonine kinase [*BUB1, BUBR1*]), lead to chromosomal missegregation and contribute to aneuploidy.[27,28] Given that loss of mutations in mitotic checkpoint genes were rarely detected in lung cancers (less than 3%) in the recent comprehensive genome-wide sequencing data collection, development of lung cancer and CIN is more closely related to their

dysfunction due to phosphorylation or cytoplasmic location.[29–32] Interestingly, a study in MAD2+/−p53+/− and MAD1+/−MAD2+/− p53+/− mice suggested a cooperative role of *MAD1/MAD2* and *p53* genes in generating increased aneuploidy and tumorigenesis.[33] Furthermore, the mitotic checkpoint has also been linked to DNA-damage response, and a defective mitotic checkpoint confers cancer cells' resistance to certain DNA-damaging anticancer drugs.[23,34] The centrosomes are thought to maintain genomic stability through the establishment of bipolar spindles during cell division, ensuring equal segregation of replicated chromosomes to two daughter cells.[35] STK15, encoding aurora kinase A (AURKA), is amplified and overexpressed in diverse types of human tumors, leading to centrosome amplification, CIN, and tumorigenesis.[36] Aurora kinases are serine/threonine kinases that function as key regulators of the mitosis process. Their dysfunction interferes with cell cycle checkpoints and allows genetically aberrant cells to enter mitosis and undergo cell division. Overexpression of aurora kinases can lead to aneuploidy, resulting in the failure to maintain chromosomal integrity.[37]

In one study, AURKA was highly overexpressed in 50% of NSCLC, and its overexpression was significantly upregulated in tumor samples compared with matched lung tissue ($p < 0.01$), suggesting a role as a tumor marker.[38] Moreover, AURKA was principally upregulated in moderately and poorly differentiated lung cancers, as well as in SCCs and adenocarcinomas, compared with the noninvasive bronchioloalveolar subtype.[38] The frequency of AURKA amplification in NSCLC ranges from 1% to 6% and seems to be more common in lung adenocarcinomas than in lung SCCs.[29,30] In comparison, aurora kinase B (AURKB) plays a less clear role in tumorigenesis.[37] However, many studies now support an association between AURKB and malignant transformation, with the involvement of additional factors. Although AURKB overexpression alone did not transform rodent fibroblast cells, increased kinase activity did facilitate Harvey rat sarcoma viral oncogene homolog (*HRAS*)-induced transformation, which led to the production of aneuploid cells.[39] In an IHC analysis of 160 NSCLC samples, 78% of tumors were found to overexpress AURKB, and its overexpression was also associated with adverse tumor features and poor prognosis in lung adenocarcinomas.[40] Contrary to AURKA, the overexpression of which is associated with gene amplification,[41] AURKB overexpression was associated with aberrant transcriptional regulation in primary lung carcinoma.[42]

Therefore overexpression and amplification of aurora kinases have been associated with neoplastic transformation, serving as attractive targets for cancer therapy.[43] A growing number of inhibitors of aurora kinases have been developed and, at the time of publication, were being evaluated in clinical trials to assess the therapeutic potential of aurora-based targeted therapy. These inhibitors include AMG900 (Amgen, Thousand Oaks, CA, USA), AT9283 (Astex Therapeutics, Dublin, CA, USA), AZD1152 (Astra Zeneca, London, UK), and PF03814735 and BI811283 (Boehringer-Ingelheim, Ridgefield, CT, USA).[44] Some of these drugs have selective activity against one aurora kinase subtype, whereas others exhibit pan-inhibitory effects.

In addition to mitotic checkpoint proteins and centrosome components, CIN may be caused by defects in the DNA double-strand break repair genes—ataxia telangiectasia mutated (*ATM*), *BRCA1*, *BRCA2*, x-ray repair complementing defective repair in Chinese hamster cells (double-strand-break rejoining; *XRCC5*)— or DNA-damage response.[5,45–47] Interestingly, the chromosomal regions at 2q33–35 and 13q12.3, which included loci encoding the *XRCC5* and *BRCA2* genes, showed a high frequency of LOH in NSCLC.[5] More recently, it was reported that low messenger RNA and protein expressions in *BRCA1/BRCA2* and *XRCC5* genes occur in lung adenocarcinoma and SCC and that promoter hypermethylation is the predominant mechanism in deregulation of these genes.[45] Given that BRCA1/BRCA2 proteins are central to p53-dependent elimination of tetraploid or aneuploid (often

preceded by tetraploid state) cells, it is not surprising that these proteins are frequently inactivated or downregulated in NSCLC, synergizing with p53 inactivation to establish an atmosphere of tolerance for a nondiploid state.[48] Although unrepaired or incorrectly repaired DNA lesions may give rise to cancer-initiating mutations, one way to efficiently tackle cancer is to take advantage of such biologic differences between cancer and normal cells and exploit the defects of tumor-associated DNA-damage response in smart therapeutic strategies.[46]

AMPLIFICATION AS A MECHANISM OF ONCOGENESIS

Gene amplification refers to the expansion of gene copy number in a restricted region of a chromosome arm. It is prevalent in some tumors and is often associated with overexpression of the amplified gene, causing cancer cells to grow or become resistant to anticancer drugs.[49] Often, although not necessarily, gene amplification is seen as karyotypic abnormalities including the extrachromosomal, acentric structure known as double minutes and the homogeneously staining regions (Fig. 10.1).[50] High-throughput genomic analyses of thousands of cancer specimens showed that the majority (approximately 75%) of the gene amplifications were focal in nature (50 kb to 300 kb) and targeted primarily oncogenes, encoding signaling proteins crucial for cellular proliferation and survival.[51] This finding strongly supports the notion that gene amplification promotes tumor formation, tumor maintenance, and drug resistance. The preponderance of focal amplification targeting oncogenes contrasts sharply with large genomic deletions, which are mostly passenger mutations with only a few exceptions, such as cyclin-dependent kinase inhibitor 2A/B (*CDKN2A/B*), retinoblastoma 1 (*RB1*), and FAT atypical cadherin 1 (*FAT1*) tumor suppressor genes.[51] The contributing factors to CIN, including common chromosomal fragile sites, errors in DNA replication, and telomere dysfunction, are causally linked to amplification and large genomic deletions.[49]

Gene amplification is a common mechanism of oncogenic activation in NSCLC and, on a whole genome scale, has a strong effect on the level of protein expression.[15] Given the potential role of gene amplification in lung tumorigenesis and tumor progression, this event is commonly associated with unique clinicopathologic features and aggressive tumor behavior. Not surprisingly, amplifications of the EGFR, v-erb-b2 avian erythroblastic leukemia viral oncogene homolog 2 (*ERBB2*), met proto-oncogene (*MET*), *MYC*, and fibroblast growth factor receptor 1 (*FGFR1*) genes have been reported to be significantly associated with poor prognosis in NSCLC (as will be discussed). In addition, amplification has been identified as a mechanism of resistance to therapy.[49,52]

Because the tumor can become dependent on overexpression of the oncogenes for its survival and proliferation, amplifications of oncogenes usually define unique subsets of lung cancer and support their use as therapeutic targets. As best illustrated by the example of the success of trastuzumab in ERBB2-amplified breast cancer, amplification of specific oncogenes may provide diagnostic utility based on their impact on therapeutic response and patient outcome. In lung cancer, however, although the results of several studies have clearly demonstrated the clinical usefulness of testing for EGFR mutations and anaplastic lymphoma kinase (ALK) fusions to guide treatment and improve patient outcomes, selection of therapy based on gene amplification is yet to be approved.[53]

This chapter focuses on the most relevant examples of gene amplifications that have shown diagnostic usefulness because of prognostic and predictive values.

EGFR Amplification

Determination of EGFR gene copy number by fluorescence in situ hybridization (FISH) has prognostic and diagnostic usefulness in NSCLC (Fig. 10.1A). Based on a retrospective study of patients with advanced NSCLC who were treated with gefitinib, tumors are considered to have a high *EGFR* gene copy number (EGFR FISH+) if they show a high copy number or amplification of the *EGFR* gene.[54] Overall, tumors with a high *EGFR* gene copy number represent approximately 30% of NSCLC. Unlike *EGFR* mutations, which are more frequently found in Asian, female, and never-smoking patients, and in patients with adenocarcinoma histology, the distribution of *EGFR* copy numbers is mostly independent of these clinicopathologic characteristics.[55,56] Lung cancers with a high *EGFR* gene copy number seem to be associated with a worse prognosis than cancers with a low *EGFR* gene copy number, in both early and advanced stages. EGFR amplification usually coexists with mutations in lung adenocarcinoma, suggesting that the mutation occurs first, then induces gene amplification during tumor progression and metastasis. This hypothesis was clearly illustrated in a biomarker analysis of Iressa Pan-Asia Study (IPASS) that showed a concordance between EGFR mutation and high gene copy number in almost 90% of patients.[57] Interestingly, in an analysis from the Iressa Survival Evaluation in Lung Cancer phase III study in which patients were predominantly of non-Asian origin, the concordance rate between these two biomarkers seemed much lower, suggesting that the mechanism of the genomic gain of EGFR may have ethnic differences.[58]

Although *EGFR* gene copy number has been evaluated as a predictive biomarker for sensitivity to *EGFR* tyrosine kinase inhibitors (TKIs) in several studies, its predictive role remains controversial. Early studies showed that patients with EGFR FISH+ tumors were most likely to benefit from treatment with EGFR TKIs. However, in IPASS, patients with tumors with a high *EGFR* gene copy number had significantly longer progression-free survival with the *EGFR* inhibitor gefitinib only in the presence of an *EGFR* mutation, whereas patients with an *EGFR* mutation had longer progression-free survival with gefitinib irrespective of the *EGFR* gene copy number.[57,59] These findings suggest that the predictive value of the *EGFR* amplification was driven by coexisting *EGFR* mutations. The robust predictive value of *EGFR* mutations has been confirmed in subsequent phase III studies comparing first-line *EGFR* TKIs with chemotherapy in advanced NSCLC with activating *EGFR* mutations.[60–63]

Nevertheless, similar to the case of *EGFR* mutations, amplification of the *EGFR* gene can fully activate EGFR tyrosine kinase and trigger downstream oncogenic pathways. Therefore it seems reasonable to assume a correlation between an abnormality in the *EGFR* copy number and *EGFR* TKI sensitivity. In support of this hypothesis, it was reported that a high *EGFR* gene copy number may be used as a predictive marker in patients with advanced squamous cell lung carcinoma, in which activating *EGFR* mutations are very rare.[64] In addition to its effect on the prognosis and response to *EGFR* TKIs, focal amplification of *EGFR* that preferentially involves the T790M-containing allele confers resistance to the irreversible *EGFR* TKIs (e.g., dacomitinib).[65]

ERBB2 Amplification

ERBB2 is also a member of the family of EGFR tyrosine kinases, but it is not activated by a known cognate ligand and instead serves as a preferred dimerization partner to other family members. Amplification of the *ERBB2* gene, mapped at 17q11.2–q12, was reported to occur in approximately 2% of unselected NSCLCs, with a rise in frequency to 11% in poorly differentiated adenocarcinomas.[29,30,66,67] It was also reported that approximately 40% of ERBB2-amplified tumors had concurrent amplification and/or mutation of EGFR.[68] Therefore it is not surprising that ERBB2 amplification (Fig. 10.1B) was more frequently associated with female gender and never-smoking status, characteristics that are associated with the presence of EGFR mutation and amplification. ERBB2 amplification correlates well with protein overexpression and is associated with higher tumor grade, higher disease stage, and shorter survival, all of which provide evidence
Fig. 10.1. Gene amplifications in lung adenocarcinomas. (A) EGFR *(red signal)* and centromere 7 *(green signal)*. (B) ERBB2 (HER2) and centromere 17. (C) MET *(red signal)* and centromere 7 *(green signal)*. Amplification of EGFR and MET occurred in large and tight clusters of gene signals while amplification of ERBB2 occurred in smaller and looser clusters. *EGFR,* epidermal growth factor receptor; *ERBB2,* Erb-B2 receptor tyrosine kinase 2.

supporting this receptor as a useful molecular target in the treatment of NSCLC.[69,70] Unfortunately, the addition of trastuzumab to gemcitabine and cisplatin did not appear to provide any benefit for patients with advanced NSCLC with ERBB2 overexpression or amplification.[71] However, because very few patients had ERBB2 3+/ amplification in this trial, further evaluation of trastuzumab in this specific subset of patients with lung cancer is desirable. Given the high intratumoral heterogeneity of ERBB2 amplification and discrepancies between primary tumors and their metastases, careful testing should be considered in the assessment of patients with NSCLC as candidates for ERBB2-targeted therapy.[66]

Of note, a high *ERBB2* gene copy number (ERBB2/FISH+) had a positive additive effect on the efficacy of *EGFR* TKI in the presence of EGFR mutation and/or amplifications, suggesting that testing of the ERBB2 gene copy number may have a complementary role for selection of patients who gain the greatest benefit from *EGFR* TKIs.[68] By contrast, ERBB2 amplification is an example of an acquired resistance mechanism to the EGFR inhibitor cetuximab. In the HCC827 NSCLC cell, aberrant ERBB2 activation leads to persistent extracellular signal-regulated kinase 1/2 signaling in the presence of cetuximab, thus preventing cetuximab-mediated growth inhibition.[72]

MET Amplification

MET, a proto-oncogene located on 7q31, encodes a transmembrane tyrosine kinase receptor for hepatocyte growth factor (HGF).[73] Binding of HGF to MET induces receptor dimerization and transphosphorylation, triggering conformational changes that activate MET tyrosine kinase activity. Preclinical findings also suggest that lung cancer cell lines harboring MET gene amplification are dependent on MET for growth and survival.[74] HGF stimulation of MET gene amplification leads to the activation of a number of signaling pathways, including phosphatidylinositol 3-kinase/v-akt murine thymoma (PI3K)/AKT, RAS/mitogen-activated protein kinase (MAPK), and phospholipase C-γ pathways.[73]

The frequency of MET amplification is rare and has been reported to be 1.4% to 7.3% among patients with NSCLC not previously treated with *EGFR* TKIs.[29,30,75–81] MET gene amplification, or MET FISH+ (Fig. 10.1C), has not been associated with gender, histology, or smoking status, but has been significantly associated with higher tumor grade and advanced stage.[77,78,82] Interestingly, albeit mutually exclusive with mutations in *EGFR*, *ERBB2*, and *KRAS* genes, MET FISH+ status was significantly associated with EGFR FISH+ status, likely because both genes are located in chromosome 7.[77,81,82] This finding may support the early preclinical demonstration of interaction between EGFR and MET signaling pathways.[83] For patients who had surgical resection, survival was shorter for those with MET FISH+ tumors (5 or more copies per cell) than for those with MET FISH– tumors.[77]

The rarity of MET amplification in NSCLC, particularly at the high levels found in *EGFR* TKI–resistant cell line models (MET gene copy number greater than 12), suggested that this event plays a limited role in primary resistance to *EGFR* TKIs.[78] Instead, HGF-stimulated MET signaling activation is more likely to be responsible for primary resistance to *EGFR* TKIs. Autocrine or paracrine secretion of HGF results in MET activation, reactivation of the MAPK, and PI3K/AKT signaling pathways and immediate resistance to EGFR inhibition.[84,85] Indeed, HGF and MET have been reported to participate in paracrine tumorigenic pathways in several other malignancies.[86]

By contrast, MET amplification is present in approximately 20% of tumors with acquired resistance to *EGFR* TKIs.[87] Engelman et al.[52] reported that NSCLC overcomes inhibition of *EGFR* TKIs by amplifying the MET oncogene to activate ERBB3, a member of the EGFR family, and the PI3K/AKT cell survival pathway. In another study, Bean et al.[79] showed MET amplification in 21% of patients with acquired resistance to gefitinib or erlotinib and in only 3% of untreated patients, confirming that MET could be a relevant therapeutic target for some individuals with acquired resistance to *EGFR* TKIs.[79]

PIK3CA Amplification

PI3K signaling is a major oncogenic pathway that functions in cancer cell growth, survival, motility, and metabolism.[88] Amplification of the phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (*PIK3CA* gene), mapped at 3q26.3 and encoding the p110 catalytic subunit, was more frequently found in men, smokers, and patients with SCC.[89,90] Overall, the incidence of *PIK3CA* gene amplification has been reported to be 33.1% to 70% in squamous cell lung carcinoma and 1.6% to 19% in lung adenocarcinoma, suggesting that this genetic alteration mainly targets squamous cell lung carcinoma.[29,30,88,90–92] Furthermore, a high level of PIK3CA copy gain was present exclusively in SCCs.[92] Amplification of PIK3CA (Fig. 10.2A) occurs at higher frequencies than genomic mutations in lung cancer and they occur independently of each other, implying that either molecular event has equivalent oncogenic potential.[90–92]
Fig. 10.2. Gene amplifications in squamous cell adenocarcinomas. (A) *PIK3CA (green signal)* and centromere 3 *(red signal)*. (B) *FGFR1 (red signal)* and centromere 8 *(green signal)*. Amplification of these genes occurred as numerous small clusters of gene signals diffusely spread. *FGFR1,* fibroblast growth factor receptor 1; *PIK3CA,* phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha.

The functional importance of PIK3CA gene amplification is shown by increased PI3K activity and phosphorylated AKT.[92] Knockdown of PIK3CA inhibits anchorage-dependent and anchorage-independent growth in PIK3CA-amplified NSCLC cells, but has no effect in cells harboring wild-type PIK3CA.[92] Interestingly, coexistence of PIK3CA gene amplification and *EGFR* or *KRAS* mutation in a single tumor was less frequent in SCC than in adenocarcinoma. This finding suggests that PIK3CA copy gain may play a pivotal role in pathogenesis of lung SCCs, further providing a rationale for targeting the PI3K pathway in this disease. The significance of the PI3K pathway as a therapeutic target in squamous cell lung carcinomas has been highlighted in the most recent study by the Cancer Genome Atlas Research Network.[29] In that study, alterations in the PI3K/AKT pathway were found in 47% of tumors and, more important, approximately 38.2% of tumors (68 of 178) had PIK3CA amplifications. This finding is of particular interest because targeted agents have been successful for the treatment of only lung adenocarcinoma. The functional dependence of squamous cell lung carcinoma on the PI3K pathway should be validated by the successful treatment with targeted PI3K inhibitors, and such trials are underway.[80]

FGFR1 Amplification

The FGFR tyrosine kinase family comprises four kinases (FGFR 1–4) and plays a crucial role in cancer cell growth, survival, and resistance to chemotherapy.[80] Amplification of the FGFR1 locus at chromosome 8p12 has been described in several tumor types, particularly SCC of the lung (Fig. 10.2B) and SCLC.[93–100]

FGFR1 gene amplification is more commonly found in squamous cell lung carcinoma than lung adenocarcinoma, with a relatively high incidence of up to 24.8%, and has recently been reported to be a novel druggable target in this specific histologic subset.[94–100] Interestingly, Kim et al.[96] reported that the incidence of FGFR1 amplification was also associated with smoking status in a dose-dependent manner (current smoker, 28.9% vs. former smoker, 2.5% vs. nonsmoker, 0%; $p < 0.0001$), suggesting that FGFR1 gene amplification is an oncogenic aberration caused by cigarette smoking. FGFR1 gene amplification drives downstream activation of PI3K/AKT and RAS/MAPK signaling, and a selective FGFR inhibitor caused downstream inhibition and induction of apoptosis in FGFR1-amplified squamous cell lung carcinomas, strongly supporting the utility of FGFR1 gene amplification as a relevant therapeutic target in this disease.[100]

FGFR1 gene amplification also has been reported to hold a significant prognostic value. Kim et al.[96] found that FGFR1 amplification is a negative prognostic factor for patients with resected SCC of the lung, whereas Heist et al.[97] reported there was no significant difference in overall survival by FGFR1 amplification status. The conflicting results may be related to differences in method and cutoff values used to assess and define FGFR1 amplification.[99]

In one study, FGFR1 amplification was noted in 5.6% of SCLC, mostly at high levels and as homogeneous staining regions.[101] Furthermore, inhibition of FGFR has resulted in a blockade of tumor growth, suggesting an important role of the FGF–FGFR signaling pathway for SCLC growth, which indicates that FGFR1 amplification may also be a therapeutic target in SCLC.[102]

Standardized screening criteria have been proposed to reliably identify patients who have lung cancers with FGFR1 amplifications for clinical trials with FGFR inhibitors. According to these criteria, high-level FGFR1 amplification is defined as an FGFR1/centromere 8 ratio of 2.0 or higher, an average number of FGFR1 signals per tumor cell nucleus of six or more, or 10% or more tumor cells containing at least 15 FGFR1 signals or large clusters; low-level amplification is defined as five or more FGFR1 signals in at least 50% of tumor cells.[99] The utility of the proposed criteria should be validated by the clinical response data from clinical trials with FGFR inhibitors.

The identification of FGFR1 amplification holds promise for the development of novel molecularly targeted therapeutic agents in the treatment of squamous cell lung carcinoma and SCLC, and recently developed FGF/FGFR-targeting anticancer agents are being studied in clinical trials.[80]

STRUCTURAL CHANGES LEADING TO ONCOGENESIS BY GENE FUSIONS

ALK Fusion

In 2007, Soda et al.[103] discovered that oncogenic fusion genes consisting of echinoderm microtubule-associated protein like 4 (*EML4*) and *ALK* are present in a small subset of NSCLCs. The endogenous *ALK* gene is normally not expressed in most adult tissues, including the lung epithelium, but *EML4–ALK* fusion leads to both ectopic expression and constitutive activation of ALK and its downstream signaling pathways, resulting in uncontrolled cellular proliferation and survival (Fig. 10.3).[104] The prevalence of ALK
Fig. 10.3. *ALK* and *ROS1* signaling pathway. *ALK,* anaplastic lymphoma kinase; *DAG,* diacylglycerol; *IP3,* inositol triphosphate; *JAK3,* Janus kinase 3; *LB,* ligand banding; *MAM,* meprin/A5-protein/PTPmu; *MAPK,* mitogen-activated protein kinase; *mTOR,* mechanistic target of rapamycin; *NF-κB,* nuclear factor-κB; *PIP2,* phosphatidylinositol 4,5-bisphosphates; *PKC,* protein kinase C; *PLC,* phospholipase C; *ROS1,* c-ros oncogene 1, receptor tyrosine kinase; *STAT3,* signal transducer and activator of transcription 3; *TKD,* tyrosine kinase domain.

fusions has been reported to be approximately 4% (range, 1.5% to 7.5%) in unselected NSCLC populations, representing potentially 40,000 new cases worldwide each year.[104,105] The frequency of ALK-positive tumors in NSCLC and methods to detect ALK have been evaluated in population studies (Table 10.1).[103,106–113] ALK-positive lung cancers are highly sensitive to ALK inhibitors, and an understanding of the resistance mechanisms to ALK inhibitors is crucial for the optimal therapy of ALK-positive NSCLC.[114]

ALK fusions result from various types of chromosomal rearrangements, all of which lead to aberrant activation of ALK.[115] *EML4–ALK* fusion, the most frequent ALK fusion in NSCLC, is the result of paracentric inversions (intrachromosomal rearrangement) involving the short arm of chromosome 2. Multiple studies have shown other, rare, fusion partners of *ALK*, such as kinesin family member 5B (*KIF5B*; 10p11.22), TRK-fused gene (*TFG*; 3q12.2), kinesin light chain 1 (*KLC1*; 14q32.3), and striatin, calmodulin binding protein (*STRN*; 2p22.2).[115–120] *ALK* fusion with *KIF5B*, *TFG*, or *KLC1* is the result of interchromosomal rearrangement, whereas *ALK* fusion with *STRN* is the result of intrachromosomal deletion.[120] Despite the diversity of fusion partners, most of them contain coiled-coil or leucine zipper domains that drive the dimerization or oligomerization of fusion kinase, which leads to ligand-independent activation of the tyrosine kinase.[115] To date, more than 20 *EML4–ALK* variants have been identified in NSCLC (Fig. 10.4).[103,106,109,116,117,119–127] Despite variable breakpoints of *EML4* (exons 2, 6, 13, 14, 15, 17, 18, 20, and 21), the genomic breakpoint within the *ALK* gene is conserved at exon 20 with few exceptions at exon 19.[127,128] Therefore all *EML4–ALK* fusion proteins involve the intracellular tyrosine kinase domain of ALK. All those rearrangements

are potentially detected by the break-apart FISH probe (Vysis ALK Break-Apart FISH Probe Kit, Abbott Molecular, Abbott Park, IL, USA; Fig. 10.5A). It is still unknown whether any particular *EML4–ALK* fusion variant may confer differential sensitivity to ALK inhibitors, which may underlie the heterogeneity in responses among patients with ALK-positive NSCLC. Heuckmann et al.[129] reported that *EML4–ALK* v2 had the shortest half-life and greatest sensitivity to crizotinib, whereas v1 and v3b had intermediate sensitivity and v3a had the least sensitivity.

ALK fusion has been associated with several distinct clinicopathologic features and treatment outcomes.[107,111–113,130] A strong association between *ALK* fusions and a never-smoking or light-smoking (fewer than 10 pack-years) history has been reported, with the frequency of *ALK* fusions in the never-smoking or light-smoking subgroup higher than in the unselected population and ranging from 8.3% to 39%.[107,111,112,130] A younger age at diagnosis and adenocarcinoma histology are other important features associated with *ALK*-positive lung cancers, and *ALK* fusions rarely overlap with other oncogenic drivers. Furthermore, *ALK*-positive tumors are substantially more likely to have abundant signet ring cells. Contrary to *EGFR*-mutant NSCLC, *ALK*-positive NSCLC has shown resistance to *EGFR* TKIs, and sensitivity of *ALK*-positive NSCLC to platinum-based chemotherapy has not differed from that of *ALK*-negative NSCLC.[112,113] The activity of pemetrexed-based chemotherapy in *ALK*-positive NSCLC is controversial and needs further validation.[112,131–133] According to guidelines from the National Comprehensive Cancer Network and from the College of American Pathologists/International Association for the Study of Lung Cancer/Association for Molecular Pathology, testing of *ALK* fusion and *EGFR* mutation

Fig. 10.4. ALK gene has been activated in lung cancer by numerous partners and multiple breakpoints and splicing forms have been identified. *ALK*, anaplastic lymphoma kinase; *EML4*, echinoderm microtubule-associated protein like 4; *KIF5B*, kinesin family member 5B; *KLC1*, kinesin light chain 1; *STRN*, striatin; *TGF*, transforming growth factor.
Fig. 10.5. Gene fusions in lung adenocarcinomas detected by break-apart FISH. (A) Two-target ALK FISH assay showing specimen positive for ALK rearrangement, represented by the split 3′ ALK and 5′ALK signals (red and green arrows, respectively); native copies of the *ALK* gene are represented by the fused *red/green* signals indicated by the *yellow arrows*. (B) Four-target FISH showing specimen positive for *ROS1* fusion. This assay combined two break-apart FISH probe sets, 3′-ALK *(red)*, 5′-ALK *(green)*, 3′-ROS1 *(aqua)*, and 5′-ROS1 *(yellow)*. Specimen was negative for ALK rearrangement with the fused 3′-ALK/5′-ALK signals indicated by the *yellow arrows*, and positive for *ROS1* rearrangement with single copies of 3′-ROS1 *(aqua)* indicated by the *turquoise arrows* and the native copies of native ROS1 *(fused aqua/yellow)* indicated by the *white arrows*. (C) Tritarget *RET–KIF5B* FISH assay (*red*: 3′-*RET*; *green*: 5′-*RET*; *yellow*: 5′-*KIF5B*) showing specimen positive for *KIF5B:RET* fusion. The native triplets (fused 3′-/3′-*RET [red/green signals]* and single 3′-KIF5B *[yellow signal]*) are indicated by the *pink arrows*; the abnormal triplet (fused 3′-RET:5′-KIF5B *[red/yellow signals]*) and single 5′-RET *(green signal)* are indicated by the *white arrows*. Specimen also has extra copies of single 5′-RET *(green arrows)* and 5′-KIF5B *(yellow arrows)*. ALK, anaplastic lymphoma kinase; FISH, fluorescence in situ hybridization; KIF5B, kinesin family member 5B; RET, ret proto-oncogene; ROS, C-ros oncogene 1, receptor tyrosine kinase.

is now recommended for all patients with advanced nonsquamous NSCLC.[54,134] Therefore given the low frequency of this genetic alteration, efficient screening for *ALK* fusion is a crucial issue in clinical practice. Currently, reverse transcription (RT)-PCR, FISH, and IHC have been used to detect ALK fusion.[103,106,135–137] RT-PCR is a potentially rapid diagnostic method with high sensitivity. It provides direct evidence of the genomic fusion, but the difficulty in obtaining high-quality RNA limits the clinical utility of this method.[103,106] FISH is currently the standard criterion used in clinical trials for detection of *ALK* fusion, and it was the first Food and Drug Administration (FDA)-approved method (Vysis ALK Break-Apart FISH Probe Kit) for use of crizotinib in *ALK*-positive NSCLC.[138] Any type of *ALK* fusions could theoretically be detected using this method, but the main disadvantages are a relatively high cost and the specialized technical training required. Because normal adult tissue, except for neural tissue, does not express *ALK*, IHC has been reported to be quite effective at detecting *ALK* fusion in several studies.[118,123,135–137,139] The sensitivity of *ALK* IHC is highly dependent on the affinity of the primary antibody and the signal amplification system. Using high-affinity antibody clones and a sensitive detection system, the overall sensitivity and specificity of *ALK* IHC were 90% to 100% and 95.2% to 98.0%, respectively.[123,136,139] However, methodologic standardization and proof of clinical utility of the *ALK* IHC assay are still in progress.

Crizotinib has shown significant clinical benefit in *ALK*-positive NSCLC. During phase I (PROFILE 1001) and phase II (PROFILE 1005) studies of crizotinib, the objective response rate was approximately 60%.[115,138] The responses were often rapid and durable, and the median duration of response was 49.1 weeks; the median progression-free survival was 9.7 months in the most recent update of the phase I study.[140] Crizotinib has been well tolerated, with mild adverse events, including visual disturbance, nausea/vomiting, diarrhea, constipation, and peripheral edema. On the basis of clinical activity and tolerability demonstrated in phase I and phase II studies, crizotinib received accelerated FDA

approval in August 2011 for the treatment of advanced *ALK*-positive NSCLC. This approval was conditioned on the results of randomized studies comparing crizotinib with standard chemotherapy (PROFILE 1007 and 1014). The results from the PROFILE 1007 phase III study were reported in 2013.[141] In this study, patients with advanced *ALK*-positive NSCLC were randomly assigned to receive either crizotinib or standard second-line chemotherapy (pemetrexed or docetaxel). Crizotinib was significantly superior to standard chemotherapy in terms of overall response (65% vs. 19%; $p < 0.001$) and progression-free survival (7.7 months vs. 3 months; $p < 0.001$). These results led to the regular approval by the US FDA in November 2013 for the treatment of advanced *ALK*-positive NSCLC.

Given the early success of crizotinib for the treatment of *ALK*-positive NSCLC, many next-generation *ALK* inhibitors are in development (Table 10.2). Some of these newer *ALK* inhibitors have shown activity against mutant forms of *ALK* that are resistant to crizotinib.

ROS1 Fusion

C-ros oncogene 1, receptor tyrosine kinase (*ROS1*) rearrangement has emerged as a new molecular subtype in NSCLC and now comprises a distinct molecular classification of NSCLC. *ROS1* rearrangements result in the formation of fusion proteins having constitutive tyrosine kinase activity, which subsequently stimulates downstream signaling (PI3K/AKT/mechanistic target of rapamycin [mTOR], RAS/MAPK, and signal transducer and activator of transcription 3 [acute-phase response factor], signal transducer and activator of transcription 3 [STAT3]), leading to enhanced cell growth, proliferation, and decreased apoptosis (Fig. 10.3).[142,143] The clinicopathologic characteristics of *ROS1* and *ALK* rearrangement overlap in patients with NSCLC, namely, younger age (median, approximately 50 years), history of never-smoking, and adenocarcinoma histology, suggesting that *ROS1* and *ALK* are evolutionarily related.[111,144,145]

[a]All patients were never-smokers.

CD74, CD74 molecule, major histocompatibility complex, class II invariant chain; *EZR*, ezrin; *FISH*, fluorescence in situ hybridization; *IHC,* immunohistochemistry; *LRIG3*, leucine-rich repeats and immunoglobulin-like domains protein 3; *ROS1*, c-ros oncogene 1, receptor tyrosine kinase; *RT-PCR*, reverse transcription-polymerase chain reaction; *SDC4*, syndecan 4; *SLC34A2*, solute carrier family 34 (type II sodium/phosphate contransporter), member 2; *TPM3*, tropomyosin 3.

Interestingly, the treatment outcome for *ROS1*-rearranged NSCLC has been similar to that for *ALK*-rearranged NSCLC, which also supports the biologic similarity of *ROS1* and *ALK*-rearranged NSCLC. Patients with *ROS1*-rearranged tumors have had poorer outcomes with *EGFR* TKIs and seemed to have had worse survival than patients with *ROS1*-negative tumors.[146,147] Of interest, *ROS1* rearrangement has been associated with significantly better overall response rate and median progression-free survival with pemetrexed than lack of *ROS1* rearrangement.[147] Similar to patients with *ALK*-rearranged tumors, patients with *ROS1*-rearranged lung adenocarcinomas and an HCC78 cell line seemed to have a low level of thymidylate synthase, supporting the clinical observation.[147]

ROS1 rearrangement may be detected by FISH (Fig. 10.5B) and other methods, and these screening methods, as well as the frequency of the rearrangement and its fusion variants, have been evaluated in population studies (Table 10.3). To date, nine *ROS1* fusion partners have been identified in lung adenocarcinomas (Fig. 10.6)—coiled-coil domain containing 6 (CCDC6)–ROS1; CD74 molecule, major histocompatibility complex, class II invariant chain (CD74)–ROS1; ezrin (EZR)–ROS1; Golgi-associated PDZ and coiled-coil motif containing protein (GOPC)–ROS1; KDEL (Lys–Asp–Glu–Leu) endoplasmic reticulum protein retention receptor 2 (KDELR2)–ROS1; leucine-rich repeats and immunoglobulin-like domains protein 3 (LRIG3)–ROS1; solute carrier family 34 (type II sodium/phosphate contransporter), member 2 (SLC34A2)–ROS1; syndecan 4 (SDC4)–ROS1; and tropomyosin 3
Fig. 10.6. *ROS1* gene fusion partners in lung cancer and schematic demonstration of breakpoints. *CCCD6,* Coiled-coil domain containing 6; *EZR,* ezrin; *GOPC,* Golgi-associated PDZ and coiled-coil motif containing protein; *KDELR2,* KDEL(Lys-Asp-Glu-Leu) endoplasmic reticulum retention receptor 2; *LRIG3,* leucine rich repeats and immunoglobulin-like domains protein 3; *ROS1,* c-ros oncogene 1, receptor tyrosine kinase; *SLC3A2,* solute carrier family 3 member 2; *SDC4,* syndecan 4; *TPM3,* tropomyosin 3.

(TPM3)–ROS1—all of which encode the same cytoplasmic portion of the ROS1 tyrosine kinase domain.[116,121,143,146,148–153] Of these fusion partners, CD74 is the most common ROS1 partner in NSCLC. The breakpoint of ROS1 in EZR and CCDC6 fusions is exon 34; in TPM3 fusion, the breakpoint is GOPC; in LRIG3 fusions, the breakpoint is exon 35; and in CD74, SDC4, and SLC34A2 fusions, the breakpoints are in exons 32 and 34.[154,155] The frequency of ROS1 rearrangement has ranged from 0.7% to 2.0% in unselected NSCLC populations.[116,121,144,146,148,149,156] However, enrichment of populations with never-smokers has resulted in a higher frequency (3.4%) of *ROS1* fusions, supporting that these fusions, together with EGFR mutations and ALK rearrangements, are the prevalent genetic alterations in never-smokers.[112,144,147] *ROS1* rearrangements rarely overlap with *EGFR* or *KRAS* mutations or *ALK* fusions, the three major recurrent oncogenic mutations in NSCLC.[144,147] The current knowledge defines *ROS1* rearrangement as a unique subset of lung cancer with a potentially targetable driver oncogene in populations enriched with never-smokers with EGFR/MET/ALK-negative (pan-negative) lung adenocarcinomas.[144,147,157]

Given that ALK and ROS1 share an approximately 49% amino acid sequence in the kinase domain, several ALK inhibitors have been shown to inhibit ROS1.[154] Using an automatic platform to examine the molecular basis of drug sensitivity, McDermott et al.[158] demonstrated that cell line HCC78 harboring *SLC34A2–ROS1* showed marked sensitivity to TAE684, a potent and selective ALK inhibitor. Subsequently, the transforming activity of the GOPC–ROS1 (FIG–ROS1) fusion transcripts found in cholangiocarcinoma was again successfully inhibited by TAE684 in vitro.[152] Crizotinib was reported to inhibit the growth of the HCC78 cell line and the phosphorylation of ROS1 in HEK293 cells transfected with CD74–ROS1 complementary DNA.[144] In addition, preliminary data from a phase I trial of crizotinib in the ROS1-positive NSCLC expansion cohort demonstrated an overall response rate of 61%.[159] Other clinical trials of second-generation ALK inhibitors targeting ROS1 rearrangement were ongoing at the time of publication (Table 10.4). A four-target, four-color ALK/ROS1 break-apart FISH probe has been developed for simultaneous testing of rearrangements in both genes (Fig. 10.5B) and will improve the efficiency of molecular testing in small specimens.

RET Fusion

The ret proto-oncogene (*RET*) encodes the tyrosine kinase receptor of growth factors belonging to the glial-derived neurotrophic factor family. *RET* rearrangement has been described

CCDC6, coiled-coil domain containing 6; *FISH*, fluorescence in situ hybridization; *IHC*, immunohistochemistry; *KIF5B*, kinesin family member 5B; *NA*, not available; *NCOA4*, nuclear receptor coactivator 4; *qPCR*, real-time polymerase chain reaction; *RET,* ret proto-oncogene; *RT-PCR*, reverse transcription-polymerase chain reaction; *TRIM33*, tripartite motif containing 33.

as a distinct molecular subset of NSCLC.[121,151,160–163] To date, four fusion partners for *RET*—KIF5B, CCDC6, tripartite motif containing 33 (TRIM33), and nuclear receptor coactivator 4 (*NCOA4*)—have been identified in lung adenocarcinoma. Expression of exogenous *KIF5B–RET* induced morphologic transformation and anchorage-independent growth of NIH3T3 fibroblasts.[161] *KIF5B–RET* is the most common type of fusion and is present in approximately 90% of fusions reported thus far.[164] The breakpoints are in exons 15 and 16 or 22–24 for *KIF5B* and in exons 8, 11, or 12 for *RET*.[121,151,160–165] All *KIF5B–RET* fusion variants contain the entire kinase domain of *RET*, but only the variant with fusion between exon 24 of *KIF5B* and exon 8 of *RET* (K24;R8) allows the resulting chimeric protein to harbor the transmembrane domain. All variants retain the coiled-coil domain necessary for homodimerization of the fusion proteins, contributing to aberrant activation of *RET* tyrosine kinase. Among all fusion variants, *KIF5B* exon 15 fused with *RET* exon 12 (K15;R12) was the most frequently found variant.[121,151,160,161,163,166–168]

The frequency of *RET*-positive NSCLCs and the screening methods used to detect the fusions have been reported in population studies (Table 10.5). The prevalence of *RET* fusions has been estimated to be approximately 0.9% to 1.9% in NSCLC and 1.2% to 2.0% in lung adenocarcinomas.[121,151,160–162,165] Kohno et al.[161] reported the identification of seven *KIF5B–RET* fusions in 429 lung adenocarcinomas. In a larger cohort of Japanese patients, *KIF5B–RET* or *CCDC6–RET* fusions were identified in 13 (0.9%) of 1482 NSCLCs and in 13 (1.2%) of 1119 adenocarcinomas.[121] Of note, similar to the situation with *EML4–ALK* fusion, the frequency of *RET* fusion increases substantially (up to 10 [8.9%] of 112) among never-smokers with tumors lacking *EGFR* mutation.[160] In most studies, *RET* fusions have been found exclusively in lung adenocarcinomas. However, in more recent studies, *RET* fusions were found in SCCs and low-grade neuroendocrine tumors.[165,169]

Given the low incidence of *RET* fusion, identifying the enriched population of the fusion gene in NSCLC could contribute to improving the efficiency of future clinical screening. Among 936 Chinese patients with surgically resected NSCLC, patients with *RET*-positive lung adenocarcinomas tended to be younger and never-smokers, with more poorly differentiated tumors, tumors that displayed solid subtype, or smaller tumors with N2 disease.[160] *RET*-positive lung adenocarcinoma frequently shows signet ring cell pattern and mucinous cribriform pattern, which are distinctive histopathologic features of *EML4–ALK* fusion.[121,170] *RET* fusion has been mutually exclusive with other driver oncogenic mutations, such as *EGFR*, *ERBB2*, v-raf murine sarcoma viral oncogene homolog B (*BRAF*), or *KRAS* mutations or *EML4–ALK* fusion, indicating their role as driver mutations.[162,168] Of 70 *RET* fusions identified to date, 57 (81%) occurred in never-smokers or light smokers, suggesting a strong relationship of this genetic

TABLE 10.6 Clinical Trials of Drugs Targeting *RET* Fusions

Drug	Sponsor[a]	Phase of Trial	Primary End Point	ClinicalTrials.gov NCT Identifier
Lenvatinib	Eisai	II	Overall response rate	01877083
Cabozantinib	Memorial Sloan-Kettering Cancer Center	II	Overall response rate	01639508
Vandetanib	Seoul National University Hospital	II	Overall response rate	01823068
Ponatinib	Massachusetts General Hospital	II	Overall response rate	01813734
Ponatinib	University of Colorado	II	Overall response rate	01935336
Sunitinib	Dana-Farber Cancer Institute	II	Overall response rate	01829217
AUY922	National Taiwan University Hospital	II	Overall response rate	01922583

[a]Eisai, Woodcliff Lake, NJ, USA.
RET, ret proto-oncogene.

alteration with never-smoking history.[121,151,160–168] In a Chinese study, *KIF5B–RET* fusion-negative tumors were associated with a strong trend toward better overall survival than *KIF5B–RET* fusion-positive tumors.[165]

Various screening methods for *RET* fusion have been used, including RT-PCR, IHC, and FISH. The RT-PCR assay is highly sensitive, inexpensive, and easily available, but it can detect only known fusion gene variants.[165] The FISH assay allows the pathologist to perform a more reliable quantification of the genomic alteration, but presents challenges because several of the partner genes are mapped closely to *RET*. A customized three-target, three-color probe has been developed to assist with the interpretation (Fig. 10.5C). IHC staining has limited value in screening for *RET* fusion in NSCLC because there has been no substantial difference in *RET* staining between *RET*-positive and *RET*-negative tumors.[160]

RET fusions are potential targets for existing small molecule TKIs, including sorafenib, sunitinib, and vandetanib. These agents with *RET* inhibitory activity effectively inhibited *RET*-positive lung cancer cells in vitro.[121,161,162] Therefore *RET* kinase inhibitors should be tested in prospective clinical trials for therapeutic benefit in individuals with NSCLC with the *RET* fusion. Cabozantinib, an inhibitor of *MET*, *VEGFR*, and *RET*, has shown promising preliminary results (two confirmed partial responses and one prolonged stable disease) in patients with *RET*-positive advanced NSCLC.[164] Several clinical trials of *RET* inhibitors in NSCLC were ongoing at the time of publication (Table 10.6).

Other Fusions

Through targeted next-generation DNA sequencing and FISH assays, the new gene fusions involving the kinase domain of the neurotrophic tyrosine kinase, receptor, type 1 (*NTRK1*) gene that encodes the high-affinity nerve growth factor receptor (tropomyosin receptor kinase A [TRKA] protein) have been reported in 3 (3.3%) of 91 lung adenocarcinomas with no known oncogenic alterations.[171] The myosin phosphatase Rho interacting protein (*MPRIP*)–*NTRK1* and CD74–*NTRK1* fusions lead to constitutive *NTRK1* activity and are oncogenic. Treatment of cells expressing *NTRK1* fusions with TRKA inhibitors inhibited autophosphorylation of TRKA and cell growth.[171]

Although most oncogenic fusions have been found in lung adenocarcinomas, BCL2-associated athanogene 4 (BAG4)–FGFR1, FGFR2–KIAA1967, and transforming, acidic coiled-coil containing protein 3 (TACC3)–FGFR3 fusions have been newly identified in advanced SCCs of the lung through transcriptome sequencing.[120,172] All of these *FGFR* gene fusions expressed FGFR1–3 as a 5′ or 3′ fusion partner with intact kinase domains.

Like fusion partners for *RET*, all *FGFR* fusion partners have dimerization motifs, which suggests that oligomerization may serve as the common mechanism of activation of FGFR fusion proteins. Overexpression of FGFR fusion proteins induce cell proliferation, and cells harboring FGFR fusions have shown enhanced sensitivity to FGFR inhibitors.[172]

CONCLUSION

The first decade-and-a-half of the 21st century has brought new windows of opportunity for a better understanding of genomic and chromosomal factors and mechanisms causally related to lung cancer, mainly NSCLC. Importantly, the identification of driver genes and essential signaling pathways for lung oncogenesis has been supporting the discovery and development of novel targeted therapy agents, which are causing rapid, dramatic, and stable tumor shrinkage in many patients. This new scenario conveys a great deal of enthusiasm, not only for patients and their families, but also among a diversity of health-care professionals. Given this perspective, the role of molecular testing using cytogenetic strategies has reached an unprecedented clinical utility.

11 Mutational Events in Lung Cancer: Present and Developing Technologies

Daniel Morgensztern, Siddhartha Devarakonda, Tetsuya Mitsudomi, Christopher Maher, and Ramaswamy Govindan

SUMMARY OF KEY POINTS

- Cancer genomes are characterized by the presence of a variety of alterations including base substitutions, copy-number alterations (amplifications or deletions), and structural rearrangements (translocations or chromosomal rearrangements).
- Among the early methods of DNA sequencing (now known as first-generation methods), the most successful has been the Sanger sequencing or chain termination reaction method. Despite its effectiveness, accuracy, and the substantial improvements since its original description, first-generation sequencing has been limited by high cost, labor intensity, and low throughput (amount of data generated per unit of time).
- Next-generation sequencing (NGS) is a broad term describing different technologies characterized by high-throughput, lower cost, and faster sequencing time compared with first-generation methods. NGS enhances the ability to comprehensively identify all alterations in the cancer genome, including mutations, copy-number alterations, and changes in gene expression, in a reasonable time frame.
- NGS studies in patients with lung cancer have allowed comprehensive characterization of the molecular alterations in lung adenocarcinomas, squamous cell carcinomas, and small cell carcinomas. These studies have also facilitated the study of the clonal architecture of lung cancer samples and its clinical implications.
- It is possible today, with newer technologies, to utilize circulating tumor DNA isolated from peripheral blood or other body fluids of patients for genetic testing. Such testing is less invasive and is becoming increasingly popular in the clinical setting.

The advent of targeted therapies has brought about a paradigm shift in the management of lung cancer. The majority of these drugs, however, only benefit a small subset of patients whose tumors are driven by specific aberrations in cell signaling pathways. Cancer cells demonstrate several types of genomic alterations including base substitutions, copy-number alterations (amplifications or deletions), and structural rearrangements (translocations or chromosomal rearrangements). Point mutations or single base substitutions (also known as single nucleotide variants [SNVs]) represent one of the most common types of DNA alteration. SNVs in protein-coding genes may result in a variety of effects in the resulting proteins. Synonymous mutations alter the DNA sequence of protein-coding genes in a way that the modified sequence at the mutated location still codes for the same amino acid. These mutations are therefore viewed as being "silent," although recent data suggest that some of these mutations could have important functional consequences.[3] By contrast, missense and nonsense mutations are associated with the substitution of one amino acid for another or premature termination of protein synthesis, respectively. Mutations that arise from the insertion or deletion of one or more nucleotides are referred to as "Indels" (short for insertions and deletions). These mutations can result in frameshift mutations that alter the reading frame of a protein-coding gene. The reading frame of a coding sequence refers to groups of three bases (or codons) in the sequence of a gene, each of which codes for a specific amino acid. When the number of nucleotides inserted or deleted from a coding sequence is not a multiple of three, the reading frame of the coding sequence downstream of the mutation is shifted, resulting in missense or nonsense alterations and the production of an abnormal or nonfunctional protein.

The processing of precursor messenger RNA (mRNA) into mature form occurs through removal of introns and joining of exons in a process termed "splicing."[4] This process is regulated in cells through proteins that constitute a cell's splicing machinery. These proteins distinguish introns from exons based on characteristic base sequences within the intron, within the exon, and at intron–exon junctions. Splicing mutations alter these specific sites and deregulate splicing, leading to the abnormal inclusion or exclusion of introns or exons from the final mRNA. This can result in the production of aberrant and nonfunctional proteins. Copy-number alterations are changes in gene number from the two copies present in the normal diploid genome. Rearrangements occur when DNA from one segment is broken and rejoined to a DNA segment from elsewhere in the genome. Rearrangements occurring within the same chromosome or involving regions on different chromosomes are referred to as intrachromosomal or interchromosomal translocations, respectively.

Somatic mutations in cancer cells are identified by comparing the DNA sequence of cancer cells with that of noncancerous "normal" cells acquired from the same individual. Although these somatic mutations occur randomly throughout the genome of a cancer cell, a subset of somatic mutations occurs in a key set of genes that confer growth advantage to the cells harboring them. These "driver" mutations are positively selected during cancer evolution and implicated in oncogenesis.[5] One of the important objectives of cancer genomic studies is to distinguish these driver mutations from bystander "passenger" mutations that do not confer a survival advantage, in an unbiased fashion. This process entails the use of complex statistical algorithms.[2] Apart from offering an insight into the biology underlying malignant transformation, such analyses also facilitate the identification of novel therapeutic targets.

OVERVIEW OF GENOMIC TECHNOLOGIES

First-Generation Sequencing

Among the early methods of DNA sequencing (now known as first-generation methods), the most successful has been the Sanger sequencing or chain termination reaction method.[6] When a dideoxynucleotide triphosphate (ddNTP) is incorporated into a growing oligonucleotide DNA molecule instead of a

deoxynucleotide (deoxynucleotide triphosphate [dNTP]), its lack of a 3′-hydroxyl group, which is required for the formation of a phosphodiester bond between two nucleotides, leads to the inhibition of DNA polymerase I and further strand elongation.[7] This chain termination forms the basis of Sanger sequencing. The first step in Sanger sequencing is the preparation of identical single-stranded DNA molecules with a short oligonucleotide annealed to each molecule. This short oligonucleotide helps prime DNA synthesis that is complementary to the single-stranded DNA (template) molecules. Both the DNA template and the primer are incubated with DNA polymerase in the presence of a mixture of the four dNTPs and a small amount of each of the four ddNTPs labeled with radioactive 32-P. Although DNA polymerase does not discriminate between dNTPs and ddNTPs, the considerably larger amount of dNTPs compared with ddNTPs allows the incorporation of several hundred nucleotides before a ddNTP is randomly incorporated into the nascent DNA. Because each reaction is performed with one subtype of ddNTP, the result is a group of nascent DNA molecules of different lengths, but with each ending in a ddNTP. The mixture with each of the ddNTPs is loaded into one of four parallel wells of polyacrylamide slab gel and the molecules are separated according to their molecular mass to allow a deduction of the DNA sequence by visualization of the bands by autoradiography. Because of the relatively easier process and reliability compared with the other technologies, autoradiography has become the method of choice for DNA sequencing. Advances in fluorescent technology allowed the tagging of either the primer or the terminating ddNTP with a specific fluorescent dye and the development of automated sequencing.[8–10] Four-color fluorescent dyes eventually replaced the radioactive labels and allowed the separation of molecules by capillary electrophoresis, which in turn replaced the slab gel method. One of the advantages of the capillary electrophoresis is that it allows all four reactions to be performed in a single tube.

Despite the effectiveness, high accuracy, and substantial improvements since its original description, first-generation sequencing has been limited by high cost, labor intensity, and time consumed due to the low throughput (defined as amount of data generated per unit of time). Using modern techniques, the automated chain-termination method can involve up to 96 sequencing reactions simultaneously. With each run capable of generating approximately 500 bases of sequence, the 96 sequencing reactions may produce, at most, approximately 48 kilobases (kb) every 2 hours. Although this technology was very useful for sequencing lower organisms,[11–13] it is not particularly suitable for sequencing the human genome, which is approximately 3 billion base pairs (bp) long.[14]

Next-Generation Sequencing

Next-generation sequencing (NGS) is a broad term describing different technologies characterized by high-throughput, lower cost, and faster sequencing time compared with first-generation methods. Although the Sanger sequencing method allowed the study of one modality of cancer genomic alterations at a time, NGS enhances the ability to comprehensively identify all alterations, including mutations, copy-number alterations, and changes in gene expression, in a reasonable time frame.[15] NGS is also referred to as massively parallel sequencing, because it allows for a substantial increase in the number of sequence reads simultaneously generated, facilitating higher throughput and leading to considerable cost reduction. Initially, the increased output was achieved with substantial sacrifices in length and accuracy of the individual reads compared with the Sanger sequencing method.[16] Nevertheless, to overcome the higher error rates, NGS platforms use a high level of redundancy or sequence coverage to increase the confidence in base calling. Sequence coverage or depth is the number of times a nucleotide mapped to a genome position is read during the sequencing process, due to overlap of the reads generated during sequencing.[17] Physical coverage is the number of fragments that span a specific location in the genome. A common method to characterize the quality of sequencing reads is the combination of PHRED and PHRAP quality scores, which are algorithms used to evaluate the accuracy of base calling in the raw and assembled sequence, respectively.[18–20] Both scores correspond to an error probability of $10^{-x/10}$. Therefore, PHRED or PHRAP quality scores of 20 and 30 correspond to an accuracy of 99% and 99.9%, respectively.

The most common platforms used for NGS are the Roche 454 (Basel, Switzerland), Illumina (San Diego, CA, USA), and SOLiD (Sunnyvale, CA, USA). The Roche 454 was the first NGS platform available as a commercial product and uses pyrosequencing, an alternative method of DNA sequencing based on measuring inorganic pyrophosphate (PPi) generated during DNA synthesis.[21] In this method, the DNA fragment of interest is hybridized to a sequencing primer and incubated with DNA polymerase, adenosine triphosphate (ATP) sulfurylase, firefly luciferase, and a nucleotide-degrading enzyme.[22–24] Deoxynucleotides are added in repeated cycles and incorporated into the growing DNA strand at complementary sites of the template strand. During this process, PPi is released in equal molarity to the incorporated deoxynucleotide. ATP sulfurylase catalyzes the conversion of PPi and adenosine phosphosulfate into ATP and sulfate.[25] ATP provides the energy for the oxidation of luciferin into oxyluciferin by luciferase, generating light that can be estimated by a photodiode or charge-coupled device camera. The unincorporated deoxynucleotides are degraded between the cycles by a nucleotide-degrading enzyme, most commonly apyrase. The overall reaction from polymerization to light detection takes approximately 3 seconds to 4 seconds at room temperature. The Illumina platform uses a sequence-by-synthesis (SBS) approach where all four nucleotides, each carrying a base-unique fluorescent label, are added simultaneously to the flow channels together with DNA polymerase and reversible terminators. Each base incorporation step is followed by fluorescent imaging and chemical removal of the terminator. The unique feature of the SOLiD platform is the use of sequencing by ligation, which uses DNA ligase instead of DNA polymerase.[26,27] The Illumina platform is currently the most widely used platform for NGS.

APPLICATIONS OF NEXT-GENERATION SEQUENCING

Whole-Genome Sequencing

Whole-genome sequencing (WGS) is the analysis of the entire genomic DNA sequence of a cell at a single time, providing the most comprehensive characterization of the genome. WGS became available after the publication of the Human Genome Project, which generated the reference for human genome sequences.[14,28] With the use of matched noncancerous genomes, which are usually obtained from skin biopsies in patients with hematologic malignancies[26,29] and peripheral blood mononuclear cells or adjacent normal tissue in solid tumors for comparison,[30,31] WGS allows the detection of the full range of genomic alterations as well as noncoding somatic mutations in cancer cells.

The first whole cancer genome sequence was reported in 2008 in a patient with cytogenetically normal acute myeloid leukemia.[32] Using the patient's skin as the matched normal counterpart, the authors described 10 genes with acquired mutations, including two previously known and eight new mutations. Shortly after that, the initial studies on WGS in lung cancer and other solid tumors were reported.[33–35] Several tumor samples obtained from patients with various malignancies have been sequenced to date by independent groups and large-scale consortia such as The Cancer Genome Atlas (TCGA).[36,37]

Whole-Exome and Targeted Gene Sequencing

Whole-exome sequencing (WES) and targeted sequencing are alternatives to WGS that allow increased coverage of regions of interest at a lower cost. WES is a process used to evaluate the small percentage of the genome that encodes for proteins. Another approach is the use of cancer-specific gene panels through which only preselected genes are sequenced (Fig. 11.1). Targeted sequencing may be performed using multiplex polymerase chain reaction (PCR) or NGS. Multiplex PCR entails the simultaneous amplification of two or more DNA targets with unique label probes in a single reaction vessel.[38] Some of the benefits of multiplex PCR include the reduced sample requirements, decreased time, and lower cost compared with singleplex reactions. SNaPshot is one such multiplex PCR platform, in which multiplex PCR is followed by single-base extension reactions that generate allele-specific fluorescently labeled probes designed to test more than 50 hot-spot mutation sites in 14 key cancer genes.[39] With the advances in biotechnology and decreased cost of sequencing, NGS methods are quickly gaining popularity and being routinely employed for targeted sequencing, both in the research setting and in the clinical setting.[40]

Transcriptome

Transcriptome refers to the complete set of mRNA and noncoding RNA (ncRNA) transcripts produced by a cell. One method to characterize the transcriptome is the conversion of mRNA into complementary DNA (cDNA) followed by sequencing of the resulting cDNA library. The subsequent comparison between cDNA and genomic sequences enables the evaluation of actively transcribed regions. Although feasible, this approach with routine full-length cDNA was costly and had low coverage, limiting its use for the characterization of whole transcriptomes in multicellular species. The development of both expressed sequence tag and serial analysis of gene expression (SAGE) techniques allowed for substantial advances in transcriptome sequencing methodology.[41] Expressed sequence tags refer to single-pass sequencing reads from either the 3′ or 5′ end of a cDNA clone, which are then used to identify expressed genes.

These tags are short and, unlike full-length cDNA sequencing, do not cover the whole length of cDNA. SAGE represented the first sequencing-based method for high-throughput gene expression profiling. SAGE involves the generation of short sequence tags from 3′ ends of mRNA transcripts that are subsequently sequenced and measured to provide estimates of the transcript expression. With the development of NGS platforms, there has been a substantial increase in the throughput and the ability to identify sequence aberrations, alternative splice variants, and ncRNAs through RNA sequencing. ncRNAs are molecules transcribed from genomic DNA but not translated into proteins and include microRNAs, small interfering RNAs, and long ncRNAs. Transcriptome sequencing has also been shown to be a sensitive and efficient approach to detect intragenic fusions in solid tumors.[42,43]

Epigenome

Epigenome is the complete description of all the chemical modifications to DNA and histone proteins that regulate the expression of genes within the genome. These modifications occur without intrinsic changes in the primary DNA sequence and are necessary for key biologic processes, including differentiation, genomic imprinting of one of the two parental alleles of a gene to ensure monoallelic expression, and silencing of large chromosomal domains such as the X chromosome.[44] The most common mechanisms of epigenetic modification include DNA methylation, histone modifications, and transcription of small ncRNA. In humans, DNA methylation occurs in cytosines that precede guanines (dinucleotide CpGs). CpG-rich regions, also known as CpG islands, are present in approximately 50% to 70% of the 5′-gene promoter regions.[45] DNA methylation of the gene promoter at CpG islands is mediated by DNA methyltransferases, which leads to silencing by direct inhibition of transcription factor binding to their relative sites and recruitment of methyl-binding domain proteins.[46] Cancer cells frequently display global hypomethylation, which is found within the body of genes and regions flanking the genes, and CpG island promoter-specific hypermethylation. Whereas global hypomethylation accounts for the
Fig. 11.1. Applications of next-generation sequencing (NGS). Whole-genome sequencing and whole-exome sequencing evaluate the entire DNA sequence and the small percentage of the genome that encodes proteins, respectively. Targeted sequencing with multiplex evaluates two or more DNA targets in a single reaction vessel. Implementing personalized cancer genomics in clinical trials.* Nat Rev Drug Discov. *2013;12(5):358–369.)*

activation of proto-oncogenes and loss of imprinting, promoter hypermethylation is associated with decreased gene expression, leading to an alternative way of silencing key tumor suppressor genes.[47] Epigenetic modifications have been implicated in conferring the second hit for cancer initiation by silencing the remaining active alleles of a previously mutated tumor suppressor gene. Posttranslational histone modifications occur mainly at the *N*-terminal tails of histones and are mediated by several enzymes, including histone methyltransferases and demethylases, which introduce and remove methyl groups, respectively, and acetyltransferases and deacetylases, which introduce and remove acetyl groups, respectively. The various combinations of modifications in specific genomic regions lead to changes in the chromatin structure with activation or repression of gene expression.[48]

The three most common techniques for the evaluation of DNA methylation are the digestion of genomic DNA with methyl-sensitive restriction enzymes, affinity-based enrichment of methylated DNA fragments, and chemical conversion methods.[49] The standard method for mapping DNA methylation is bisulfite sequencing, a chemical conversion method. Treatment of genomic DNA with sodium bisulfite chemically converts unmethylated cytosines to uracil. Assuming a near-complete bisulfite conversion, all unmethylated cytosines become thymidines after PCR and the remaining cytosines are the ones methylated at the fifth carbon or 5-methylcytosine.

COMPREHENSIVE GENOMIC STUDIES USING NGS IN LUNG CANCER

Nonsmall Cell Lung Cancer

Multiple independent groups and TCGA research network have together sequenced over a thousand lung cancer samples to date.[50–58] Data from these studies indicate that recurrent alterations in known receptor tyrosine kinase (RTK)-RAS (RAt sarcoma)-rapidly accelerated fibrosarcoma (RAF) pathway genes such as *EGFR*, *KRAS*, *BRAF*, *MET*, and *ALK* are observed in the majority of lung adenocarcinoma genomes. Nearly 76% of lung adenocarcinomas showed alterations in this pathway in a recent analysis including 660 tumor samples.[50] Although tumors obtained from both smokers and never-smokers show alterations in the RTK pathway genes, cancers arising in these populations differ in other aspects such as mutational burden and pattern of SNVs, and also show enrichment for alterations in specific genes.[51,53] The exonic mutation rates are significantly higher in smokers than in never-smokers (median, 9.8 vs. 1.7 per megabase [Mb], $p = 3 \times 10^{-9}$), with the predominant mutation patterns being C-to-T transitions and C-to-A transversions in never-smoker and smoker lung cancer genomes, respectively (Fig. 11.2).[51,54] In addition to mutations in RTK-RAS-RAF signaling, lung adenocarcinomas also show alterations in tumor suppressors such as *TP53*, *CDKN2A*, *STK11*, and *NF1*. Furthermore, adenocarcinomas also show recurrent alterations in genes involved in epigenetic or RNA deregulation such as *BRD3*, *SETD2*, and *ARID1A*, and genes that regulate splicing such as *U2AF1*, *RBM10*, and *SF3B1*. Alterations in these genes possibly drive malignant transformation by altering the splicing of oncogenes such as *CTNNB1*.[51] Because genes involved in epigenetic or RNA deregulation cannot be readily assigned to one of the 10 hallmarks of cancer that were originally described, these data suggest that such alterations could constitute the 11th hallmark (Fig. 11.3).[59,60]

In addition to the identification of recurrent pathway alterations, NGS also has the ability to identify potential targets for therapy.[53] For instance, TCGA investigators reported alterations in cellular pathways known to be potentially targetable, such as phosphatidylinositol-3-OH kinase (PI3K)/AKT and RTK-RAS-RAF, in nearly 75% of lung adenocarcinomas and 69% of

squamous cell carcinomas.[51,61] Targeted sequencing with a high-read coverage can also help in the estimation of variant allele frequencies, based on the distribution of which, it is possible to infer the number and size of clonal populations within each tumor sample. Using these techniques, several groups have described the clonal architecture of lung adenocarcinomas.[53,62–64] These analyses indicate that lung cancers show a considerable extent of intratumor heterogeneity (Fig. 11.4).[65]

Founder clone mutations refer to those mutations that are present ubiquitously within all tumors cells, implying that they are acquired early on in the course of disease evolution. In one analysis, Zhang et al.[64] observed that on average 76% of all mutations observed through multiregion sequencing of adenocarcinoma samples were present in all regions of the tumor. Alterations (mutations) in known cancer genes such as *TP53*, *EGFR*, and *KRAS* were ubiquitous, suggesting early acquisition. Understanding the clonal architecture of tumors has, in theory, the ability to guide therapy because treatments that target clonal alterations are more likely to succeed than those that target subclonal alterations.

TCGA investigators initially profiled tumor specimens from 178 patients with squamous cell lung cancer, along with peripheral blood (41 patients) or adjacent histologic normal tissues resected at the time of surgery (137 patients) as the matched noncancerous germline DNA.[61] Samples from all 178 patients were evaluated with WES, RNA sequencing, DNA methylation, and copy-number evaluation, whereas 18 paired samples were evaluated with WGS and 158 paired samples were evaluated with microRNA sequencing. WES and WGS were performed with the Illumina HiSeq platform. As observed in lung adenocarcinoma from smokers, the investigators identified a mean of 228 nonsilent exonic mutations per tumor (mean somatic mutation rate of 8.1 per Mb) in these tumors. Somatic alterations of potentially targetable genes were found in 114 (64%) samples. The most commonly altered pathways were the PI3K-RTK-RAS signaling (69%); squamous differentiation, including *SOX2*, *TP53*, *NOTCH1*, *NOTCH2*, *ASCL4*, and *FOXP1* (44%); and the oxidative stress response pathway consisting of *KEAP1*, *CUL3*, and *NFE2L2* (34%; Fig. 11.5). The *CDKN2A* tumor suppressor gene was inactivated in 72% of the cases by a variety of mechanisms, including homozygous deletion (29%), epigenetic silencing by methylation (21%), inactivating mutation (18%), and exon 1-beta skipping (4%).

However, unlike adenocarcinomas, mutations in RTK-RAS-RAF pathway genes such as *KRAS*, *EGFR*, and *BRAF* were infrequent in these tumors. In an updated analysis, TCGA investigators sequenced and compared mutational profiles of 660 adenocarcinomas and 484 squamous cell carcinomas.[50] Only a 12% overlap was observed between genes mutated at a statistically significant level between the two histologies. Interestingly, more similarity was observed among significantly mutated genes in squamous cell lung and other smoking-associated cancers such as head and neck squamous cell and bladder cancers, highlighting the molecularly distinct natures of the different subtypes of lung cancer, despite their identical anatomic site of origin.

Small Cell Lung Cancer

Unlike nonsmall cell lung cancers, small cell lung cancer (SCLC) samples rarely show mutations in RTK signaling pathways. However, almost all SCLCs show alterations in the tumor suppressors *TP53* and *RB1*.[55] Peifer et al.[56] sequenced 29 exomes, two genomes, and 15 transcriptomes from patients with SCLC using the Illumina HiSeq platform. Similar to other smoking-related tumors, the rate of the protein-changing mutations was 7.4 per Mb. Mutation and loss of *TP53* and *RB1* were noted in all patients, and preclinical studies have shown that conditional deletion of both genes in mice is associated with
Fig. 11.2. Mutational differences between smokers and never-smokers. Comparison between the mutation rates and characteristics between smokers and never-smokers showed a significantly higher median number of point mutations among smokers. Among the point mutations, C-to-A transversions were the predominant type in smokers, whereas C-to-T transitions were the most common type in never-smokers. *(Reprinted, with permission, from Govindan R, Ding L, Griffith M, et al. Genomic landscape of non-small cell lung cancer in smokers and never-smokers. Cell. 2012;150:1121–1134.)*

the development of SCLC.[66,67] Inactivation of cyclic adenosine monophosphate response element binding (CREB)-binding protein (*CREBBP*) and *EP300* are likely to play a substantial role in the development of SCLC as well, with mutations clustered around the sequence encoding the histone acetyltransferase domain of these genes occurring in 18% of patient samples and cell lines. The *MLL* gene, which codes for a histone-modifying enzyme, was mutated in 10% of the patient samples suggesting a substantial role for histone modifications in SCLC. Rudin et al.[57] evaluated the exome, transcriptome, and copy-number alterations in 80 SCLC samples using the Illumina HiSeq 2000 platform. The samples included 36 primary SCLC human tumors with adjacent normal sample pairs, 17 paired SCLC cell lines with matched lymphoblastoid cell lines, and four primary SCLC and 23 SCLC cell lines without matched controls. The investigators performed WGS in one SCLC tumor with a normal tissue pair and found an average of 175 nonsynonymous mutations per sample, with a mean of 5.5 mutations per Mb and a predominance of G-to-T transversions, which is the

smoking-related signature. Twenty-two genes were frequently mutated. The most commonly mutated genes from the combined initial and validation cohorts were *TP53* (77.4%), *RB1* (30.6%), *COL22A1* (25.8%), and *BCLAF1* (16.1%). Four of the 41 gene fusions identified in this analysis were recurrent, including the fusion between *RLF* and *MYCL1*, which was found in one primary SCLC tumor and four SCLC cell lines. The decreased proliferation of *H1097* and *CORL47* fusion-positive cell lines with the use of small interfering RNA targeting *MYCL1* supported *MYCL1's* role as an oncogene in SCLC. Several of these findings were confirmed in a subsequent analysis of 110 SCLC samples by George et al.[55] In addition to recurrent *TP53* and *RB1* mutations, mutations in the tumor suppressors *TP73*, *PTEN*, *RBL1*, and *RBL2* were also observed in these samples. Mutations in the NOTCH family of genes were observed in 25% of the samples sequenced in this study. The NOTCH pathway plays an important role in regulating neuroendocrine differentiation, implying a crucial role for these alterations in the development and progression of SCLC.

EMERGING TECHNOLOGIES: THIRD-GENERATION SEQUENCING

Third-generation sequencing or single-molecule sequencing is the sequence analysis of individual molecules without prior cloning. This approach is associated with several potential benefits over NGS including overcoming the biases caused by PCR amplification and dephasing, leading to increased read lengths and a decrease in time to results. The increased read lengths may decrease the number of reads performed on each analysis as a necessary step to increase the coverage, possibly facilitating the bioinformatics analysis and improving the accuracy.[68,69] Another advantage of third-generation sequencing is the use of lower DNA input material, which could be particularly important in patients with unresected tumors, where the samples are often too small for NGS.

The two most advanced single-molecule sequencing platforms are the HeliScope and Pacific Biosciences platforms. Both platforms use SBS, in which laser excitation generates a fluorescent signal from the labeled nucleotides. Helicos Biosciences (Cambridge, MA, USA) introduced the first single-molecule DNA sequencer, HeliScope, which was based on labeled reversible chain-terminating nucleotides using an SBS method. This platform produces short reads of a maximal length of 55 bp and has not been widely adopted. PacBio RS from Pacific Biosciences (Menlo Park, CA, USA) is a platform based on the single-molecule real-time technology with nanostructures called zero-mode waveguides, each with a single DNA polymerase attached to it. The fluorescence of each nucleotide is detected in real time during its incorporation into the growing DNA strand. PacBio RS allows the simultaneous sequencing of 75,000 DNA molecules in parallel, and the read lengths are considerably longer than those with the HeliScope, averaging 1000 bp.[70]

An alternative approach is the use of sequencing with nanopores, which relies on the transit of single DNA molecules through nanoscale pores, with the bases detected by electric current or optic signal. Unlike all other sequencing methods, nanopore technologies usually do not require an exogenous label because they rely on the electronic or chemical structure of the different nucleotides for base calling.[68,71,72]

SEQUENCING IN SUBOPTIMAL SAMPLES

Formalin-Fixed Samples

Although fresh tissue from biopsy or surgery is the preferred specimen for most molecular tests, it is seldom available because of logistic issues related to the collection and storage of samples. Most specimens are formalin-fixed and paraffin-embedded (FFPE) tissue blocks, stored in the pathology laboratory. Formaldehyde from FFPE reacts with DNA and proteins with the formation of methylene, which crosslinks DNA to DNA, RNA, or proteins, resulting in sequence aberrations. Despite these challenges, studies comparing paired fresh-frozen and FFPE samples have shown the feasibility of NGS in FFPE samples.[73,74] In one such study, Spencer et al.[75] evaluated 27 cancer-related genes from 16 paired fresh-frozen and FFPE lung adenocarcinoma samples and observed no significant differences in the total number of reads, raw sequence error rate, or coverage of the target regions for the preselected genes. The agreement in base calling was greater than 99.99%. Nevertheless, because formalin promotes deamination of cytosine residues, there was an increase in C-to-T transitions in FFPE compared with fresh tissue.

Cytology Samples

Minimally invasive fine-needle aspiration (FNA) is a convenient method for establishing the diagnosis of solid tumors, with lower risks for complications compared with large-bore needle biopsies. However, although FNA is a standard modality

for establishing morphologic diagnosis, the small tumor sample is often inadequate for NGS. Two studies have demonstrated the feasibility of FNA samples for NGS. Young et al.[76] evaluated FNA samples from 16 consecutive patients with pulmonary tumors and 26 with pancreatic tumors. NGS was performed with the Illumina HiSeq 2000 platform, and the tumor samples were evaluated for base substitutions, Indels, amplifications, homozygous deletions, and gene rearrangements. In this study, genomic profiles were successfully generated in 100% of patients with either pulmonary or pancreatic tumors. Kanagal-Shamanna et al.[77] evaluated 31 cytologic tumor specimens obtained through FNA, including 16 samples from patients with lung cancer. NGS was performed with the Torrent platform (V2.01; Life Technologies, Carlsbad, CA, USA) and the results were confirmed by at least one of three conventional platforms, including the Sanger sequencing, pyrosequencing, or MassARRAY system (Sequenom, San Diego, CA, USA). All tested samples underwent successful targeted sequencing of the selected panel of 46 genes, with a concordance of 100% between NGS and the conventional confirmatory platforms. Furthermore, NGS detected variants in 19 (61%) of 31 samples that were not detected by the traditional platforms. Therefore, the results of these two studies indicate that FNA may be an acceptable method to obtain samples for NGS.

Liquid Biopsies

Serial biopsies of patient tumors for treatment planning are becoming increasingly important with the development of therapies targeting resistance mechanisms in lung cancer patients progressing on tyrosine kinase inhibitors.[78–80] Because serial biopsies are invasive and associated with significant procedural risk, alternate methods of obtaining genomic DNA from circulating tumor cells, exosomes, or cell-free DNA (cfDNA) isolated from body fluids such as blood and urine (often referred to as "liquid biopsies") are gaining increasing popularity (Fig. 11.6).[81,82] Recent studies have shown the feasibility of these techniques in detecting targetable alterations without the need for invasive biopsy procedures.[83,84] In a recent analysis conducted by Wakelee et al.,[84] the ability to detect *EGFR* T790M mutations in patients enrolled into the phase 1/2 study TIGER-X was compared between assays based on cfDNA isolated from blood and urine, with DNA extracted from a matched tumor biopsy specimen. The agreements of T790M status between cfDNA obtained from blood and urine with matched tumor biopsy were 81.5% and 83.8%, respectively. Responses in T790M mutation-positive patients to rociletinib were comparable irrespective of the source of DNA.

Circulating tumor DNA assays are likely to contain DNA released from multiple tumor regions and can facilitate the
Fig. 11.6. Liquid biopsies for genotyping a tumor involve isolation of circulating free DNA that is released from dying cancer cells (through necrosis or apoptotic cell death), or DNA isolation from circulating tumor cells. *ctDNA,* circulating tumor DNA. *(Image adapted from Crowley E, Di Nicolantonio F, Loupakis F, Bardelli A. Liquid biopsy: monitoring cancer-genetics in the blood.* Nat Rev Clin Oncol. *2013;10:472–484.)*

identification of mutations missed on testing single-region tumor biopsies due to spatial heterogeneity in the clonal architecture of tumors. Seven patients in the study conducted by Wakelee et al.[84] who were negative for T790M mutations in the biopsy specimen, had detectable mutations through cfDNA testing and showed responses to rociletinib. These results demonstrate that circulating DNA testing could be complementary to traditional biopsy-based diagnostic testing for identifying targetable alterations in tumors and also facilitate the study of novel mechanisms underlying treatment resistance. Despite these advantages, these assays are limited by factors that affect the amount of DNA released by the tumor such as tumor size, disease burden, site of disease, and grade of the tumor.[85-87]

FUTURE DIRECTIONS

The use of NGS with integrated analyses of the genome, transcriptome, and epigenome of a large number (a few thousand) of tumor samples may allow a more comprehensive study of tumorigenesis, with the detection of low-frequency abnormalities that are unlikely to be found by first-generation unidimensional studies.[101] For example, the combined analysis of over 600 non-small cell lung cancer samples by TCGA highlighted the presence of low-frequency mutations in RTK-RAS-RAF pathway genes such as *VAV1*, *SOS1*, and *RASA1*, which were not mutated at a statistically significant level in previous studies owing to a sample size that was inadequate for their detection.

High tumor mutation burden has been shown to correlate with responses to immune checkpoint inhibitors.[102,103] In a recent analysis, McGranahan et al.[103] have also shown the clonality of neo-epitopes to play a predictive role in determining responses to immunotherapy, apart from the total mutation burden itself, with patients having a large fraction of clonal mutations showing durable responses compared with poor-responders whose tumors showed a large fraction of subclonal mutations. Determining the total mutation burden of a tumor sample and its clonal architecture therefore has important implications for therapy. The clonal architecture of a tumor can also serve as a prognostic biomarker and potentially guide adjuvant therapy in patients with early stage lung cancer, because patients with resected tumors with complex clonal architectures are more likely to relapse compared with those with less complex tumors.[64]

12 Epigenetic Events in Lung Cancer: Chromatin Remodeling and DNA Methylation

Ite A. Laird-Offringa and Montse Sanchez-Cespedes

SUMMARY OF KEY POINTS

- Distinct cellular phenotypes are based on differential gene expression, which is achieved through heritable epigenetic modifications that maintain active and inactive chromosomal regions.
- Epigenetic mechanisms include DNA methylation, histone modifications, regulatory DNA-binding proteins, regulatory RNAs, genome-organizing proteins, and chromatin remodeling complexes, all of which can be altered in lung cancer.
- Both *genetic* and *epigenetic* alterations can contribute to lung cancer and they can interact; genetic changes in epigenetic modifiers can affect the epigenome, and epigenetic silencing of genes involved in genome integrity can lead to genomic alterations.
- Numerous DNA methylation changes are seen in lung cancer, most commonly hypermethylation of promoter CpG-dense regions and loss of methylation in gene bodies, but only a fraction of DNA methylation alterations has functional consequences.
- DNA methylation alterations in a variety of bodily fluids can be used as biomarkers for the presence of lung cancer.
- Proteins involved in chromatin remodeling are commonly altered in lung cancer, with the ATPase BRG1 frequently mutated in non-small cell lung cancer tumors and cell lines.
- Epigenetic alterations are in principle reversible; epigenetic therapies thus offer opportunities for treatment by undoing cancer-driving epigenetic changes or by activating targets for therapy such as cancer/testis antigens and others.

The cells that make up the human body exhibit an incredible variety of phenotypes, despite the fact that they all carry the same genome, inherited from a single fertilized egg. This phenotypic diversity arises from the different gene expression profiles in each distinct cell type and is achieved by creating and maintaining specific activated and inactivated genomic regions as cells differentiate into their destined types. These distinct genomic regions are established through the layering of information, or so-called biomarks, on top of the genome. The study of these regions and marks is called epigenetics.

Epigenetic information can come in many forms (Fig. 12.1). One form is the direct chemical modification of DNA. The best studied chemical modification is DNA methylation,[1] but more recently, hydroxymethylation, formylation, and carboxylation have also been noted.[2] Chemical marks can also be deposited on the proteins that interact with DNA, the most prominent of which are the histones. Histones can be decorated with a wide variety of modifications, which can affect the accessibility of DNA to regulatory factors and thereby modulate the ability of genes to be expressed.[3,4] In addition to covalent modifications of the histone tails, chromatin structure is also regulated by movement of nucleosomes in an adenosine triphosphate (ATP)–dependent manner through the activity of chromatin remodeling complexes.[5–7] These complexes utilize ATP to disrupt nucleosome-DNA contacts and render DNA available to proteins requiring access to histones or DNA during distinct cellular processes. Besides histones and nucleosomes, other proteins can affect the epigenetic readout of the genome: numerous proteins or protein complexes bind directly or indirectly to the DNA and can either affect transcription through modulating the activity of enhancers or promoters, or can influence genomic organization and thereby gene activity. Lastly, regulatory RNAs, such as microRNAs (miRNAs) and long noncoding RNAs, exist that can epigenetically regulate gene expression.[6,8,9] Collectively, these biomarks on the DNA are referred to as the epigenome; they are inherited following cell division, allowing cell phenotypes to be passed on to daughter cells.

The importance of epigenetic marks in retaining proper cell phenotypes implies that their disruption would lead to disease. Indeed, it has become abundantly clear that epigenetic deregulation contributes very importantly to numerous diseases, including cancer.[8,10–13] Epigenetic alterations have been widely implicated in the development and progression of lung cancer.[14–19] Understanding the consequences of epigenetic changes can help dissect the molecular basis of lung cancer, providing insights into cancer development and progression, and thus new focal points for targeted therapies.[20] In addition, epigenetic alterations in lung cancer show potential as molecular markers that could be applied to early detection, tumor classification, risk assessment, prognostication, and monitoring of cancer recurrence.[14,21] Lastly, given that epigenetic information is layered on the genome without alteration of the DNA sequence, it is in principle reversible and is a prime target for the development and application of new therapies. Epigenetic drugs, such as histone deacetylase inhibitors and DNA methylation inhibitors, are in clinical trials for numerous cancers including those of the lung.[22,23] With the advent of ever more powerful tools for genome-wide assessment of epigenetic marks, our understanding of the lung cancer epigenome and its application to diagnosis and treatment promises to increase dramatically in the years to come.

In this chapter, we review the basic concepts of epigenetics and discuss the current knowledge concerning epigenetic alterations in lung cancer, including the types of changes identified and their pathologic and clinical implications. Given the large number of epigenetic alterations analyzed to date and the dramatic acceleration in acquired data, it is impossible to be comprehensive in one chapter. Therefore, we discuss the basic principles and focus in more detail on two specific areas: chromatin remodeling and DNA methylation. These two examples beautifully illustrate the importance of considering the interplay between genetic and epigenetic alterations in cancer. Due to space limitations, reviews are cited throughout as a source of more detailed information.
Fig. 12.1. Overview of epigenetic mechanisms. Gene expression can be affected by numerous epigenetic mechanisms, as indicated in the diagram. From left to right: Repressors can negatively regulate transcription; transcription factors can modulate transcription and aid in the response to environmental cues; DNA methylation, when present in promoter CpG islands (as seen in cancer) is commonly associated with gene silencing; regulatory RNAs include microRNAs and long noncoding RNAs that can upregulate or downregulate genes through a variety of mechanisms; enhancers can lie upstream or downstream of genes and can stimulate gene expression from a distance; genome organizers are proteins such as CCCTC-binding factor that create boundaries between genomic regions and aid in the higher order structuring of the genome; histone modifying enzymes affect the modifications of histone tails, which in turn can loosen or tighten chromatin, facilitating or decreasing gene expression; chromatin remodeling complexes organize the chromatin and can move the nucleosomes (consisting of an octamer of histones with approximately 150 nucleotides of DNA wound around them), modulating the access of other factors to the DNA.

GENETIC AND EPIGENETIC INTERACTIONS

Initial research into the molecular basis of lung cancer focused on genetic alterations, such as mutations, loss of heterozygosity, deletions, and gene amplification.[24,25] Well-known examples of genetic alterations in lung cancer include mutations in V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog *(KRAS)*, the epidermal growth factor receptor *(EFGR)*, and tumor protein 53 *(TP53)*.[26] However, it has become abundantly clear that epigenetic alterations contribute equally importantly to the development and progression of lung cancer.[14–19,27,28] Epigenetic alterations seen in lung cancer consist of changes in histone modifications, alterations in chromatin structure and chromatin-associated proteins, changes in regulatory RNAs such as microRNAs, and DNA methylation changes (both loss and gain of methylation).

The interaction between genetic and epigenetic hits in cancer cells further amplifies the consequences of these molecular alterations (Fig. 12.2).[10,29,30] For example, as discussed later, genetic alterations in the genes encoding components of the epigenetic machinery (such as histone (de)acetylases, chromatin remodeling complexes, and DNA methyltransferases) can affect the activity of these enzymes and thereby the transcriptional activity of many additional genes. Somatic changes in parts of the epigenetic machinery are found in numerous cancers, including lung cancer.[10,31] This potential for genetic alterations to affect epigenetics is further underscored by the reported link between genetic polymorphisms in several genes encoding epigenetic enzymes, and lung cancer risk.[31] Conversely, epigenetic alterations can lead to further genetic damage. For example, hypermethylation of DNA repair genes or genes encoding detoxification enzymes can affect the cell's susceptibility to mutagenesis and could result in the genetic (in)activation of additional genes.[32] DNA methylation of 6-*O*-methylguanine DNA methyltransferase *(MGMT)*, an enzyme involved in the repair of alkylated guanine, is commonly seen in lung cancer.[33] Inactivation of *MGMT* has been linked to

an increase in the frequency of *RAS* gene mutation.[34] In support of their potential to affect cancer development, polymorphisms in *MGMT* and other DNA repair genes have been linked to lung cancer risk in various populations.[35–37] These examples illustrate that genetic and epigenetic changes should not be seen as independent, but rather as components of a complex interactive network that is responsible for the development and progression of numerous cancers, including lung cancer. Combined analysis of both types of molecular changes will accelerate the elucidation of the molecular pathways affected in lung cancer and may be especially helpful in characterizing particular types of lung cancer (e.g., histologic subtypes or lung cancer from smokers compared with nonsmokers). This holistic view of epigenetic alterations is also highly relevant to the clinic, as the use of certain cytotoxic drugs may potentiate or inhibit the efficacy of epigenetic drugs and vice versa.[38–41]

HISTONE MODIFICATIONS AND THEIR ROLE IN LUNG CANCER

The nucleosomal core around which DNA is coiled is composed of two molecules each of histones 2A, 2B, 3, and 4. The lysine and arginine-rich *N*-terminal regions extend from the core and can be heavily decorated with mono-, di-, and trimethylation, acetylation, ubiquitination, phosphorylation, and other modifications.[3] These modifications do not exist in isolation; functional and physical crosstalk ensures a complex web of epigenetic signals, in which DNA methyltransferases, methyl-binding proteins, histone variants, histone modifying enzymes, and other chromatin and transcriptional components play a role (Fig. 12.3).[42] Many of the enzymes that modify histones recognize other modifications on the same or different histone tails or on DNA. For example, proteins that bind to methylated DNA frequently carry additional domains that interact directly or indirectly with histone-modifying proteins such as deacetylases.[43] Acetylation of histones on lysine promote active transcription. On one hand, this modification

Potential Interactions of Genetic and Epigenetic Alterations in Cancer

GENETIC
generally irreversible
- Mutation
- Loss of heterozygosity
- Amplification
- Deletion
- Chromosome translocation
- Retroviral insertion

Consequences:
Gene activation
(mutation, amplification, translocation, viral insertion)
Gene inactivation
(mutation, LOH, deletion, translocation, viral insertion)

Can affect epigenome
E.g., if altered genes are
DNA methyltransferases
Methyl-binding proteins
Histone-modifying enzymes
Histone variants
Chromatin-remodeling proteins
Chromatin organizers
miRNAs, lncRNAs

EPIGENETIC
potentially reversible
- DNA methylation
- Histone modification
- Nucleosome presence
- Chromatin structure (e.g., looping)
- miRNA, lncRNA

Consequences:
Gene inactivation
(promoter CpG island methylation, histone deacetylation, histone methylation, chromatin condensation)
Gene activation
(demethylation of testes antigens, loss of imprinting, retroviral/repeat sequence activation, histone modification)
Genomic instability
(global hypomethylation, mobile element activation)

Can affect genome
E.g., if altered genes function in
DNA repair
DNA replication
Detoxification

Fig. 12.2. Interaction between genetic and epigenetic alterations in cancer. Left panel: Genetic hits, which are generally irreversible and can result in activation or inactivation of the altered gene. If such a gene encodes a product involved in epigenetic regulation, like a histone methyltransferase, a DNA methyl-binding protein, a histone isoform, an enzyme that adds or removes histone modifications, or a protein that interacts with such modifications (transcriptional regulators, coactivators, or corepressors), this finding could result in epigenetic alterations. Right panel: Epigenetic hits are potentially reversible, and when they occur in genes that affect the integrity of the genome, such as DNA repair genes or genes encoding proteins involved in DNA replication or detoxification, they can increase the likelihood of acquisition of additional genetic alterations.

reduces a positive charge and minimizes the electrostatic attraction of the histone tails for the DNA phosphate backbone, thereby relaxing chromatin structure. On the other hand, acetylated histone *N*-terminal tails are landing pads for bromodomain-containing proteins, such as transcriptional coactivator p300/CBP associated factor and TAF1, a component of the transcription initiation complex.[4,44] Key acetylation marks are histone 3 lysine 27 acetylation (H3K27Ac), a mark found predominantly on active enhancers, and H3K9Ac, a mark found mainly on active promoters. Multiple enzymes that add or remove acetyl groups exist in the cell, and the deacetylases are particularly promising therapeutic targets in cancer.[45] In addition to acetylation, common histone tail modifications are methylation, ubiquitination, and phosphorylation.[46] Methylation does not affect histone tail charge, functioning instead by altering protein/protein interactions. One or two methyl groups can be added to arginine and up to three to lysine; the effects depend on the modified position and the number of added methyl groups. For example, histone 3 lysine 9 and lysine 27 trimethylation (H3K9me3, H3K27me3) are repressive marks, whereas H3K4me3 is found in transcribed regions.

As yet, relatively little is known about how histone modification is affected in lung cancer; molecular changes on the histone *N*-terminal regions are much more difficult to interrogate than DNA methylation changes. The most commonly used technique is chromatin immunoprecipitation (ChIP), in which formaldehyde crosslinking of cells is followed by specific immunoprecipitation of the proteins of interest (such as particular histone modifications) and local polymerase chain reaction (PCR)–based interrogation of specific regions. Due to advances in high-throughput sequencing technologies, ChIP can now be carried out genome-wide to gain global insights into the marks on or protein occupancy of the entire genome. In one study, researchers classified patients with

non-small cell lung cancer (NSCLC) into seven distinct groups based on differential histone modifications and noted differences in survival depending on histology and histone 3 modifications.[42] This early report hints at the potential use of this kind of epigenetic characterization to guide treatment. A key challenge in furthering these studies is the large amount of material needed for genome-wide interrogations, which limits current analyses largely to lung cancer cell lines. However, as the ability to extract epigenomic information from ever smaller quantities of material improves, the analysis of archival tumor specimens will become possible.

As alluded to previously, alterations in the enzymes that deposit or remove histone marks can lead to further epigenetic changes. A mutation of the histone acetyltransferase EP300 was found several years ago in a small cell lung cancer (SCLC) cell line.[47] More recently, genome-wide sequencing approaches have provided further evidence for alterations in numerous genes encoding enzymes involved in histone modification (Table 12.1). Mutations of the histone acetyltransferases CREBBP and EP300 and the histone methyltransferases MLL and MLL2 have now been detected in SCLC.[48] In NSCLC, mutations in multiple histone methyltransferases including ASH1L, MLL3, MLL4, WHSC1L1, and SETD2 have been noted.[49–51] Among these, one of the mutations in SETD2 was identified in a lung tumor from a never-smoker. More recently, amplification of the histone methyltransferase *SETDB1* gene was found in a subset of NSCLC and SCLC cell lines and primary tumors.[52] Depletion of SETDB1 expression in amplified cells was shown to reduce cancer growth in cell culture and in nude mice, whereas its overexpression increased tumor invasiveness. Mutations in histone demethylases and deacetylates have also been noted in NSCLC, further underlining the contributions of epigenetic deregulatory events in lung cancer.
Fig. 12.3. Epigenetic abnormalities in cancer. In nontumor cells (left), CpG islands are generally unmethylated (green lollipops), whereas sporadic CpGs are usually methylated (red lollipops). In actively transcribed genes, the structure of chromatin is loose, allowing access of the transcriptional machinery to the promoter region. Acetylation of lysines (triangles) in the *N*-terminal tails of histones 3 and 4 reduces positive charge and relaxes the attraction to negatively charged DNA. Acetylation, mono-, di-, and trimethylation (balls), and other modifications such as phosphorylation and sumoylation (stars) of the histone tails can mediate interactions directly or indirectly with the transcriptional machinery and with enzymes that can add further posttranslational modifications. In cancer cells (right), a genome-wide loss of DNA methylation at sporadic CpGs and previously methylated sequences such as repeats is seen. (In certain cases this can lead to gene activation, not shown.) Simultaneously, many promoter CpG islands become hypermethylated, which can result in silencing of tumor suppressor genes. Methyl-binding proteins interacting with methylated cytosines can recruit histone deacetylases, which can in turn lead to reduced chromatin access and transcriptional silencing. This model is a simplification; methylation, histone modification, and transcription are not always concordant, not all methylated genes are silenced, nor are all silent genes methylated.

TABLE 12.1 Histone-Modifying Enzymes Altered in Lung Cancer[a]

Enzyme	Lung Cancer Type	Reference(s)
HISTONE DEMETHYLASES		
KDM6A	NSCLC	49
HISTONE METHYLTRANSFERASES		
ASH1L	NSCLC	49,51
MLL	NSCLC	49
MLL2	NSCLC	49
MLL3	NSCLC	51
MLL4	NSCLC	51
SETD2	NSCLC	50,51
SETDB1	NSCLC	52
WHSC1L1	NSCLC	51
MLL	SCLC	237
MLL2	SCLC	48

CREBBP	SCLC	237
EP300	SCLC	237
HISTONE DEACTYLASES		
HDAC9	NSCLC	49
HDAC9	NSCLC	49

[a]These data, obtained from high-throughput approaches, are preliminary, and validation in larger sets of well-characterized lung tumors is needed. *NSCLC*, Non-small cell lung cancer; *SCLC*, small cell lung cancer.

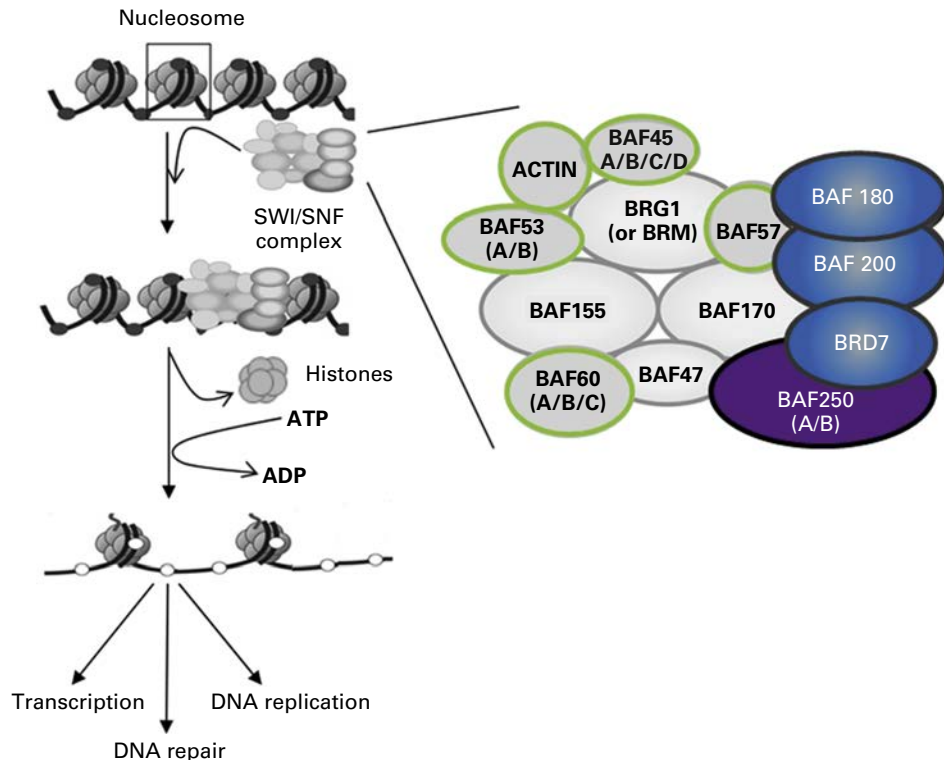
Abnormalities in genes encoding histone acetylases and deacetylases have also been found in noncancerous diseases of the lung, including chronic obstructive pulmonary disease (COPD), an irreversible and slowly progressive condition characterized by airflow limitation. Oxidative stress and inflammation are the major hallmarks of COPD, which, like lung cancer, has cigarette smoking as the major etiologic factor. In COPD, oxidative stress enhances inflammation by activating various kinase signaling pathways that lead to chromatin modifications (histone acetylation/deacetylation and histone methylation/demethylation). The activation of these pathways orchestrates several responses to stress, including proinflammatory and antioxidative responses. One of the main hurdles that precludes the clinical treatment of COPD is its resistance to antiinflammatory glucocorticoid (GC) treatment. GCs are not only involved in lung embryonic development and normal lung function but are also critical for lung cancer prevention.[53,54] In this regard, a failure to respond to GCs constitutes a risk factor for developing lung cancer, especially in smokers.[55] GC-mediated suppression of inflammation involves the recruitment by the GC receptor of histone deacetylase 2 (HDAC2) to the genes that mediate inflammation, resulting in histone deacetylation and reduced transcription.[56] The GC-resistance in patients with COPD appears to occur as the result of a marked reduction in the levels and activity of HDAC2 in the lung parenchyma, provoked by the chemicals in cigarette smoke and by oxidative stress.


Fig. 12.4. The chromatin remodeling complex SWI/SNF. On the left, a schematic representation that depicts how the SWI/SNF complex alters the structure of the nearby nucleosomes, thereby permitting increased access of transcription factors, DNA polymerases, and other DNA-binding proteins, to the DNA. On the right, the different components of the SWI/SNF chromatin complex in humans are indicated. Light gray circles highlight the components that constitute the core members of the complex; the black-lined gray ovals show the noncore members that are common for both the BAF and the pBAF complexes; the purple and the blue ovals show the components that are unique to the BAF and the pBAF, respectively.

Taking into account that patients with bronchial obstructive changes, including COPD, are at increased risk for lung cancer,[55] and that lung cancer cells are refractory to GC,[57] it is interesting to speculate that the acquisition of resistance to GC may be among the factors that contribute to this increased lung cancer risk. However, there is as yet little evidence for decreased HDAC2 levels in lung cancer. One of the few reports examining the levels of HDACs in lung cancer specimens demonstrated a reduced expression of class II HDACs (HDACs 4–7, 9, and 10), especially HDAC10, and an association with poor prognosis.[58] In contrast, a different study reported that increased expression of HDAC1 in tumor cells was an independent predictor of poor prognosis in patients with lung adenocarcinoma.[59] Although the involvement of alterations in HDACs in lung cancer remains unclear, they should be considered as one of the possible mechanisms responsible for resistance to GC and similar compounds. Regardless of the possible involvement of alterations in HDACs, as discussed previously, loss of activity of chromatin remodeling complexes is among the most common causes of unresponsiveness to GC in lung cancer.[57]

CHROMATIN REMODELING COMPLEXES

Chromatin is controlled by multiprotein complexes that use the energy of ATP to disrupt histone–DNA contacts, thereby providing access to proteins that must contact DNA or histones during different cellular processes.[5,7] These processes include the establishment of transcriptional control during embryonic development, cell differentiation, and the reprogramming of somatic cells, as well as the formation of heterochromatin, the execution of DNA repair, and DNA replication.[7,60,61]

Four different families of chromatin remodeling complexes have been described: SWI/SNF, INO80, ISWI, and CHDs, distinguishable by the identity of their ATPase subunit.[7] Several chromatin remodeling complexes have been implicated in cancer initiation and progression, most prominently the "switch/sucrose not fermenting" (SWI/SNF) complex. Therefore, we focus mainly on the SWI/SNF complex. However, it is anticipated that other chromatin remodeling complexes may also be ultimately found to be relevant in carcinogenesis. The name SWI/SNF describes genes first identified in yeast screens for mutants affecting mating type switching and sucrose fermenting.[62,63] The SWI/SNF complex is powered by either of two ATPases that are highly homologous and have similar domains: ATP-dependent helicase SMARCA2 (BRM) or ATP-dependent helicase SMARCA4 (BRG1). In mammals, two different SWI/SNF multiprotein complexes have been described: BRG1 associated factors (BAF), also called SWI/SNF-α, and polybromo-BRG1 associated factors (PBAF), also known as SWI/SNF-β. The complexes contain a number of common proteins, such as BAF170, BAF155, BAF60a/b/c, BAF57, BAF53a/b, BAF47, BAF45a/b/c/d, and β-actin, but differ with respect to other components (Fig. 12.4).[7] The β complex contains up to three additional members: BAF180, BAF200, and BRD7. However, the main difference between the SWI/SNF complexes is the participating ATPase. In SWI/SNF-α the ATPase can be either BRG1 or BRM, but in SWI/SNF-β the ATPase is only BRG1. Numerous findings implicate subunits of these complexes in the development of lung cancer, as will be discussed. The nomenclature for involved factors is sometimes redundant (Table 12.2).

TABLE 12.2 Subunits of the Chromatin Remodeling Complex, SWI/SNF, and Mutations in Cancer

Name			Mutated in Cancer	Mutated in Lung Cancer	Characteristics of the Mutations in Lung Cancer
Official HNGC	**Other Common**	**Other Less Common**			
SMARCA4	BRG1	SNF2-like4, SNF2B, SNF2, SWI2, SNF2LB	Yes	Yes	More than 70% of truncating and nonsense mutations[66] Mutations preferentially in NSCLC[66] Mutations preferentially in smokers[68] Mutations mutually exclusive with amplification of MYC and mutations of EGFR[66]
ARID1A	SMARCF1, BAF250A	ELD, B120, OSA1, P270, hELD, BM029, MRD14 hOSA1,	Yes	Yes	About 50% of truncating and nonsense mutations[50] Mutations preferentially in NSCLC[50]
ARID2	BAF200	P200	Yes	Yes	About 50% of truncating and nonsense mutations[238] Mutations preferentially in NSCLC[51] Mutations in smokers and nonsmokers[238]
SMARCA2	BRM	SNF2, SWI2, NCBRS, Sth1p, BAF190, SNF2L2	Yes	NI	
SMARCB1	INI1, SNF5, BAF47	Snr1, MRD15, RTPS1, Sfh1p, hSNFS, SNF5L1	Yes	No	
SMARCC1	BAF155	Rsc8, SRG3, SWI3, CRACC1	Yes	NI	
ACTIN	ACTB		NI	NI	
ACTL6A	BAF53A	ACTL6A	NI	NI	
ACTL6B	BAF53B	ACTL6B,	NI	NI	
ARID1B	BAF250B	OSA2, 6A3–5, DAN15, MRD12, P250R, BRIGHT	Yes	NI	
BRD7		BP75; NAG4; CELTIX1	Yes	NI	
BRD9		PRO9856; LAVS3040	NI	NI	
PBRM1	BAF180	PB1	Yes	NI	
SMARCC2	BAF170	CRACC2, Rsc8	NI	NI	
SMARCD1	BAF60A	Rsc6p, CRACD1	Yes	NI	
SMARCD2	BAF60B	Rsc6p, CRACD2, PRO2451	NI	NI	
SMARCD3	BAF60C	Rsc6p, CRACD3	NI	NI	
SMARCE1	BAF57		Yes	NI

Genetic Alterations at SWI/SNF Chromatin Remodeling Factors in Lung Cancer

The first observation that linked chromatin remodeling and cancer development was the presence of inactivating mutations at *SNF5* (also named *SMARCB1*) in rare cases of pediatric tumors, especially in malignant rhabdoid tumors.[64] Mutations at *SNF5* arise either somatically or in the germline, in the case of the germline conferring a cancer predisposition syndrome.[65] Although *SNF5* inactivation is infrequent in lung cancer, alterations at *BRG1* (also named *SMARCA4*) are a more common event. Inactivation of *BRG1* in lung cancer was first found by the detection of homozygous deletions of this gene in a small subset of cell lines of different tumor origins, including those from lung.[19] The restoration of *BRG1* in lung cancer cells induced growth arrest and a flattened phenotype.[19] A few years later, it was reported that alterations at *BRG1* occur in about one-third of NSCLC cell lines.[66] A role of *BRG1* loss in lung cancer has been verified in subsequent studies.[49,50] Taking into account our current genetic knowledge of lung cancer, *BRG1* can be considered among the five most commonly altered tumor suppressor genes in NSCLC, after *TP53*, *CDKN2A*, and *LKB1*.[50,67] In the vast majority of cases, the *BRG1* mutations detected in lung cancer cell lines are biallelic and the mechanisms for inactivation include loss of one allele in combination with deletion of the other allele or frameshifts, indels, and nonsense/missense mutations, most of them yielding a truncated protein.[17] The biallelic loss and inactivation mutations of *BRG1* leave little doubt that *BRG1* is a bona fide tumor suppressor gene, critical in the development of a large proportion of lung cancers. Mutations

at *BRG1* are more frequently detected in lung cancer cell lines as compared with lung primary tumors,[68,69] similar to the findings for other tumor suppressor genes, such as *TP53*, *CDKN2A*, and *LKB1*.[67] This finding could be attributed to technical difficulties related to the normal cell contamination often associated with the genetic analysis of primary tumors. In this regard, immunohistochemical evaluation of BRG1 levels in lung primary NSCLCs supports the absence of protein in 30% of the tumors.[70] In contrast to *BRG1*, genetic inactivation of BRM has not been reported in lung cancer.[57] Some lung cancer cell lines have no detectable BRM protein by Western blot, but the mechanisms underlying the apparent loss of *BRM* protein are still elusive.

To date there is little information about the clinical, pathologic, and molecular correlations with the loss of *BRG1* expression in lung cancer. Approximately one-third of NSCLC cell lines and 5% of SCLC cell lines have featured *BRG1* inactivation.[66] Moreover, these alterations seem to be associated with smoking and frequently coexist with mutations at other commonly altered genes in lung cancer, such as *TP53*, *KRAS*, and *LKB1*.[17] However, it was noted that mutations in *BRG1* were mutually exclusive with amplification of the V-Myc avian myelocytomatosis viral oncogene homolog *(MYC)* oncogenes.[57,71] Although these findings are still preliminary, they indicate that *MYC* and *BRG1* exert a similar biologic function during lung tumorigenesis, which is in agreement with functional observations demonstrating that the SWI/SNF complex is required for the *CMYC*-mediated gene transactivation and that recruitment of SWI/SNF to the promoters regulated by MYC depends on MYC-INI1 interaction.[72] In further support of the MYC-BRG1 functional relationship in

lung cancer cells, it was found that wild-type BRG1 is required to decrease the levels of the MYC protein in response to differentiation agents.[57]

Immunohistochemical analysis of BRG1 in 41 primary lung adenocarcinomas and 19 primary lung squamous cell carcinomas showed that loss of nuclear expression of BRG1 and/or BRM was associated with worse survival in patients with NSCLC.[70] In another study, the levels of several core proteins involved in the chromatin remodeling machinery were determined in 150 lung adenocarcinomas and 150 squamous cell carcinomas, using immunohistochemistry.[73] Positive nuclear BRM staining correlated with a favorable prognosis in both patients with lung adenocarcinomas and primary lung squamous cell carcinomas with a 5-year survival rate of 53.5% compared with 32.3% for those whose tumors were negative for BRM ($p = 0.015$). Furthermore, patients whose tumors stained positive for both BRM and BRG1 had a significantly better 5-year survival (72% compared with 33.6% for those whose tumors were positive for either or negative for both markers) ($p = 0.013$). In another study, the authors found that loss of expression of BRG1 and BRM was found to be frequent in solid predominant lung adenocarcinomas and in tumors with low expression of lung transcription factor NKX2-1 (previously called thyroid transcription factor-1 or TTF-1) and low cytokeratins and E-cadherin.[74] The same study demonstrated that the loss of BRG1 protein was mutually exclusive with EGFR mutations, which is in agreement with the higher frequency of BRG1 mutations in lung cancers in smokers (Table 12.2).

In addition to mutations in *BRG1* and *BRM*, novel deep sequencing technologies of lung cancer samples have allowed the identification of inactivating mutations in numerous genes encoding core members of the SWI/SNF complex, including *ARID1A* and *ARID2* (Table 12.2).[75] Most of the data come from deep sequencing technologies applied to the whole genome or to exomes, a type of approach that leads to a certain number of false-negative results. It is anticipated that the rates of inactivation at each individual component of the SWI/SNF complex in the distinct types of tumors will become known in the coming years. Intriguingly, germline mutations of components of the SWI/SNF chromatin remodeling complex (i.e., *SMARCB1, BRG1/SMARCA4, SMARCE1, ARID1A, ARID1B*, and *BRM/SMARCA2*) have also been noted and they have been linked to human syndromes. In particular, the very rare autosomal dominant syndromes Nicolaides–Baraitser and Coffin–Siris show several common clinical characteristics, including multiple congenital malformations, microcephaly, and intellectual disability.[75] To date, there is no information as to whether these syndromes confer a predisposition to lung cancer or any other type of cancer.

Although abnormal functioning of chromatin remodeling is now acknowledged to be involved in the development of lung cancer, our knowledge of the potential role of other epigenetic modifiers in lung cancer is still limited. As efforts to sequence the genomes of more tumors continue, more genes encoding chromatin modifiers are likely to emerge as mutated in lung cancer. However, functional analysis and validation in larger sets of well-characterized lung tumors will need to be undertaken to definitely determine the relevance of these different mutations in the development of lung cancer and to assess the precise frequency of alterations and the possible correlates with histopathology, etiology, and clinical parameters.

Functional Consequences of Abnormalities in Chromatin Remodelers and Other Epigenetic Modifiers in Lung Cancer Development

As previously mentioned, chromatin remodeling complexes function as transcriptional regulators of large sets of genes involved in multiple developmental pathways, including early embryonic development and tissue specification.[60,61,76] The control exerted by the SWI/SNF complex on some of these processes is related to its involvement in regulating hormone-responsive promoters. Specific components of the SWI/SNF complex bind to various nuclear receptors for estrogens, progesterone, corticoids, retinoic acid, and vitamin D3, leading to their recruitment to gene-specific promoters.[77–79] On the other hand, the ligands that bind specific nuclear receptors, such as retinoids and corticoids, are known to be critical for lung embryonic development as well as for normal lung differentiation and function.[53,54,80] Given the involvement of the SWI/SNF complex in tissue specification and in developmental programs, one of the processes that would be expected to be disrupted in cancer cells carrying inactivated SWI/SNF is the capability to sustain gene expression programs during cell differentiation. Indeed, restoration of BRG1 activity in lung cancer cells induces gene expression changes, increasing resemblance to normal lung gene expression signatures.[57] Furthermore, it was shown that lung cancer cells require wild-type BRG1 to respond to retinoic acid or GC treatment. Together, these findings support the notion that an inactive BRG1 confers resistance to retinoic acid and GCs, which prevent cancer cell differentiation. Given that BRG1 is part of the SWI/SNF complex, alterations in other members of the SWI/SNF complex may act through the same mechanism, although this hypothesis must be tested.

Several cancer-related proteins, such as P21, BRCA1, LKB1, SMADs, CFOS, CMYC, and FANCA, have been associated with BRG1 or other components of the SWI/SNF complex, supporting the participation of the SWI/SNF complex in other important cell processes, such as cell-cycle control, DNA repair, and the regulation of apoptosis in response to DNA damage.[17,81] However, how the SWI/SNF complex affects these processes in the development of lung cancer is still poorly understood. A mouse model that permits conditional biallelic knockout of *BRG1* in lung epithelial cells indicates that the loss of both *BRG1* alleles induces apoptosis, as determined by significant increase in Apo-BrdUrd and cleaved caspase-3 in nontransformed lung epithelial cells.[82] Furthermore, the homozygous loss of BRG1 in the lungs of the mice strongly potentiated the development of lung tumors after exposure to the carcinogen ethyl carbamate, which binds to DNA and generates DNA adducts. The observation of DNA adducts suggests that in the absence of a functional SWI/SNF complex, timely DNA repair is not guaranteed and, consequently, cells are inadequately protected from the deleterious consequences of DNA damage.

DNA METHYLATION

Of the covalent epigenetic marks, DNA methylation has been the most widely studied. The methyl group is deposited at the 5-position of cytosine, in the context of a small inverted repeat: a CpG dinucleotide. The palindromic nature of methylation allows the propagation of this modification following DNA replication. In the normal mammalian genome, some areas are heavily methylated, such as sections of the X chromosomes in females, pericentromeric regions, and parentally imprinted genes. Indeed, DNA methylation is essential for proper development and viability.[83] Methylation in mammals is carried out by at least three enzymes: the maintenance DNA methyltransferase *DNMT1* (which methylates daughter strands following DNA replication) and de novo DNA methyltransferases *DNMT3A* and *3B*.[84] All three genes are essential, as illustrated by mouse knock-out experiments.[84] A large number of DNMT splice isoforms exist, a number of which appear to target particular genes or areas of the genome and some of which are implicated in cancer.[85,86] Overexpression of DNMTs and the associated factor UHRF1 has been linked to lung cancer.[87–91] CpG dinucleotides exist in two general environments in normal cells: sparsely distributed, and clustered (Fig. 12.3).[1] On the one hand, CpGs are sprinkled throughout the genome, and

these CpGs are usually methylated. Spontaneous deamination of methyl-C results in thymine, which is less efficiently repaired than the uracil resulting from deamination of unmethylated cytosine. This has resulted in depletion over time of CpGs in areas that are usually methylated.[92] Thus, the remaining dense clusters of CpGs, called CpG islands,[93] are presumed to be normally unmethylated. It is estimated that about half of human genes contain such CpG islands in their promoter regions.[94]

In cancer, a profound disruption of DNA methylation is seen (Fig. 12.3).[1,10,95–98] Broadly stated, global hypomethylation occurs, in combination with local hypermethylation. Loss of DNA methylation has been thought to contribute to carcinogenesis in two possible ways: the transcriptional activation of previously methylated sequences and the loss of chromosome stability. In contrast, the local hypermethylation at promoter CpG islands has been assumed to contribute to carcinogenesis through gene inactivation, silencing a wide variety of growth control and tumor suppressor genes, such as genes involved in proliferation, adhesion, apoptosis, the cell cycle, differentiation, signaling, and transcription. Although these findings remain generally true, genome-wide assessment of DNA methylation has painted a more complex picture, in which gain of DNA methylation can be paired with increased gene expression, and DNA methylation loss can be associated with repression.[99] Genome-scale integration of DNA methylation and gene expression in lung cancer supports this observation.[28,100,101] Of key relevance is the location of the alteration with respect to neighboring genes (promoter, intron, coding region) or gene-distant regulatory elements (enhancer, genome organizer), and whether DNA methylation changes affect the binding of regulatory factors.[1]

One important reason for the extensive studies of DNA methylation to date is that relatively straightforward techniques exist to assess this modification.[102,103] Our ability to analyze DNA methylation patterns has increased dramatically, from studies of single genes at a time in the 1990s to current genome-wide approaches.[99,101,103] Given that methylation does not affect base pairing, and that DNA methylation information is lost following amplification by PCR, most DNA methylation assessing techniques employ a method to incorporate the DNA methylation information into the genomic sequence: bisulfite conversion. This process is a chemical treatment that converts unmethylated cytosines to uracil while methylated cytosines are protected;[104] it allows methylation information to be incorporated into the DNA sequence. Bisulfite-converted DNA can be analyzed by many methods.[103] Local bisulfite genomic sequencing, pyrosequencing, methylation-specific PCR, and its real-time version, MethyLight or its variation quantitative methyl-specific PCR, are still used to examine individual genes, but the development of increasingly powerful high-density bead arrays has provided a relatively low-cost way to interrogate hundreds of thousands of CpGs simultaneously.[105–107] Bisulfite genomic sequencing originally consisted of amplification followed by cloning and sequencing, providing information on the methylation status of all the Cs on the same DNA strand in the amplified area.[108] With the major advances in high-throughput sequencing, whole genome bisulfite sequencing has now become a reality, although it remains expensive and computationally challenging and, to our knowledge, has not yet been applied to entire lung cancer genomes.[99] It is anticipated that the application of genome-wide methods will continue to provide ever more detailed insight into DNA methylation alterations in lung cancer. This knowledge promises to change the way in which lung cancer is detected and treated. The biggest challenge that lies in our future is the analysis and interpretation of the wealth of information obtained from genomic methods. Just as with mutations in cancer, some DNA methylation changes are drivers of the cancer process, while others are passengers, occurring coincidentally as molecular changes accumulate in cancer cells. Thus, identifying common DNA methylation changes in lung cancer is only the very beginning; determining which of these changes are cancer drivers is the much bigger task, one for which we have barely scratched the surface.

DNA HYPOMETHYLATION IN LUNG CANCER

Because of the overall hypomethylation found in cancer cells, researchers originally assumed that the cancer-causing effect of methylation changes was based on loss of promoter CpG island methylation resulting in proto-oncogene activation.[109] Indeed, loss of methylation can promote the development of lung cancer in a murine model.[110] Although genes can be activated by hypomethylation,[100] they are not necessarily all considered canonical proto-oncogenes. One category of such genes is the parentally imprinted genes, genes for which either the maternally or paternally inherited allele is normally methylated. Hypomethylation can result in loss of imprinting, thereby contributing to cancer development; biallelic expression of the normally imprinted insulin-like growth factor 2, mesoderm-specific transcript, and H19 genes has been seen in lung cancer and is thought to contribute to the carcinogenic phenotype.[111,112] Another type of gene that can be activated by hypomethylation is the family of testis-specific antigens; these genes are usually methylated and silent in all somatic tissues but the testes.[113] Expression of testis-specific antigens has been noted in many tumor types including lung cancer, and these antigens are seen as potential immunotherapy targets.[113–116] Loss of methylation of transposable elements and repeats is also found in lung cancer[16,117] and can lead to mobility of such elements, causing further genetic damage.[97] In addition, read-through from such demethylated elements may result in the aberrant activation of neighboring genes. Hypomethylation might also play a role in the activation of microRNAs, many of which are deregulated in cancer.[8,118–120] For example, the normally methylated let-7a-3 microRNA was found to be hypomethylated in two of eight lung adenocarcinomas, and forced overexpression of this miRNA increased the oncogenic properties of lung cancer cell line A549.[121]

In addition to contributing to carcinogenesis through gene activation, a second consequence of hypomethylation is thought to be genomic instability. Mice genetically engineered to underexpress DNA methyltransferases show an increased frequency of loss of heterozygosity and an elevated incidence of hematopoietic malignancies.[122] Deletion of DNMT3A in a KRAS-dependent mouse of a lung cancer model was shown to promote tumor progression.[110] However, analysis of methylation of five human squamous cell lung carcinomas and normal matched tissue showed prominent hypomethylation of repetitive elements but little methylation loss in single-copy sequences.[117] This finding supports the notion that the effect of hypomethylation in lung cancer might be limited, which is important, because DNA methylation-blocking therapies are being widely explored, as will be discussed. These therapies appear to show promise in numerous cancers and are under investigation for lung cancer.[22] Importantly, leukemia-prone DNMT underexpressing mice show a lower incidence of intestinal cancer, pointing to a protective effect of hypomethylation in certain tumor types.[123] Indeed, treatment of a mouse xenograft model for human lung cancer with DNA methylation and histone deacetylation inhibitors suppressed tumor growth without apparent toxicity.[124] A similar treatment of a murine lung cancer model cut lung tumor development in half, emphasizing the potential of epigenetic drugs for lung cancer treatment.[125]

DNA Hypermethylation in Lung Cancer: Functional Implications

Although it would appear that the effects of hypomethylation in lung cancer are relatively modest, hypermethylation of promoter CpG islands is widely noted, with findings in lung cancer and

DNA methylation described in more than 1500 reports in Pub Med.[14,15,21,27,28,33,100,101,107,126–130] Hypermethylation can be associated with transcriptional shutdown.[83] This shutdown may happen directly, through steric interference of methylated cytosines with the binding sites for enhancer-binding proteins, transcription factors, cofactors, or chromatin organizers, or indirectly, through the attraction of methyl-binding proteins to the DNA, which in turn recruit histone deacetylase enzymes and other epigenetic modifiers (Figs. 12.1 and 12.3).[43]

Intensive investigation will be required to determine whether DNA methylation changes are driver or passenger events in the development and progression of cancer. For the purposes of prognostication or providing tailored therapies, it could be of great importance to know whether DNA methylation events have functional consequences. This idea is supported by the prognostic utility of expression arrays.[131] The first step in the approach to determine whether altered promoter CpG island methylation of a gene is functionally significant is the integration DNA methylation and gene expression information to identify genes showing concomitant changes in their DNA methylation and expression profiles (Fig. 12.5).[100,129,130] It has been frequently noted that only a minority of DNA methylation alterations show coincident changes in gene expression. This finding suggests that the rest are passenger events. However, there are other, as yet poorly explored, possibilities. For example, methylation changes may modulate binding of the chromatin organizer CTCF, thereby affecting alternative splicing events.[132] Changes in splicing may not immediately be obvious from gene expression analyses, depending on the platform used to examine expression. Another option is that some of these DNA methylation alterations affect the expression of distant genes by modifying regulatory elements such as enhancers. Proper investigation of these possibilities will require more detailed genome-wide knowledge concerning alternative splicing patterns and investigation of epigenetic regulatory elements in the different types of lung epithelial cells that constitute lung cancer precursors. The analysis of trans-effects of DNA methylation on distant genes is computationally and biostatistically challenging and is only just beginning.[133]

To obtain further circumstantial evidence that an epigenetically altered gene affected by cis-DNA methylation is a real target in cancer development and progression, it can be helpful to integrate other types of molecular profiles from cancer cells, such as copy number variation and mutational analyses;[28] a gene that is the target of numerous molecular changes is more likely to play a role in cancer. If lack of expression of a hypermethylated gene has been verified by mRNA and/ or protein analysis, DNMT inhibitors such as 5-azacytidine can be used to determine whether the gene can be reactivated in lung cancer cell lines. A potential caveat of such experiments is that reactivation could be the indirect consequence of demethylation of other genes. Next, reexpression of the gene in cancer cell lines in which the gene was silenced, and silencing of the gene in cells in which the gene is still expressed (e.g., through transfection of targeted inhibitory small hairpin RNAs), will help determine its role in cancer development and progression. In the silencing experiment, the choice of cells is important (primary, immortalized, transformed) and should be influenced by the perceived stage of cancer development at which the gene of interest is thought to play a role. Experiments such as these have implicated a variety of hypermethylated genes in lung cancer.[15,21,27,33,134,135] It should be noted that methylation of genes that were already silent in lung tissue may not be a functional event per se, but might still be informative, as it could provide hints to the origin of the cancer or the involvement of stem cells.[136]

Genes that appear to be silenced by methylation and that limit any aspect of the transformed phenotype when reactivated can be excellent targets for therapy but also could yield new tools for prognostication. Indeed, the testing of associations between

clinical data and DNA methylation status in patient populations could provide markers for survival or response to therapy. An important caveat of studies of associations between DNA methylation and clinicopathologic variables is that a correction should be applied for multiple hypothesis testing when multiple new loci and clinical parameters are examined.[137]

Many genes/loci silenced in lung cancer by DNA methylation have been studied to date, but only a handful have been analyzed in depth. The most intensive focus has been on *CDKN2A/p16*, a gene encoding an inhibitor of cyclin-dependent kinases 4 and 6, which in turn bind to cyclin D1 and promote the phosphorylation and inactivation of the retinoblastoma gene product, RB. RB is a key cell cycle regulator that is frequently inactivated in SCLC.[25] In contrast, in NSCLC it is *CDKN2A* that is inactivated in the majority of tumors, and in many cases, this inactivation occurs through promoter hypermethylation.[14,33,138–140] Methylation of the *CDKN2A* promoter CpG island appears to be a very early change in the development of squamous cell lung cancer as well as adenocarinoma.[16,126,141,142] In a cohort of high-risk long-term smokers from whom sputum was examined for seven DNA methylation markers, hypermethylation of *CDKN2A* was most strongly associated with lung cancer risk.[143] Indeed, the results of a study published in 2013 confirm a modest association between *CDKN2A* methylation and smoking.[140] These findings mesh with the idea that disruption of cell cycle regulation is an important early event in the transition from normalcy to cancer, an observation that is emphasized by the fact that human bronchial epithelial cells can be immortalized through CDK4 activation in combination with overexpression of telomerase.[144] It is intriguing that in NSCLC the *CDKN2A* promoter CpG island appears to be the weak link in the regulatory pathway, and it is tempting to speculate that this might be linked to occupancy of this region by polycomb complexes in stem cells.[145] Methylation of the gene appears to become more pronounced during progression[142] and is associated with an unfavorable prognosis in lung adenocarcinoma and an increased risk of recurrence of stage I NSCLC.[146,147] In the latter study, a several-fold increased risk of recurrence was predicted based on *CDKN2A* hypermethylation detected in tumors or regional or mediastinal nodes. The prognostic implications of *CDKN2A* hypermethylation were confirmed in several studies that were included in two meta-analyses published in 2013.[148,149]

A second gene that has been extensively studied in DNA methylation analysis is *MGMT*.[14,33] Mentioned previously as a target of epigenetic regulation that could promote further genetic changes, this DNA repair gene appears to be another hot spot for early methylation, showing increasing methylation as cells progress from a field defect to hyperplasia and then to adenocarcinoma.[126,142] Interestingly, methylation was also found to be associated with tumor progression and poor survival rates.[150,151] Reports about the preferential methylation of *MGMT* in smokers compared with nonsmokers have conflicted.[150,152]

Another hypermethylated gene of interest is the retinoic acid receptor beta (*RARB*). As mentioned in the section on chromatin remodellers, retinoids, including vitamin A and its analogs, play important roles in development, differentiation, proliferation, and apoptosis and have been considered strong candidates for chemoprevention of lung cancer.[153] This idea appears to be supported by hypermethylation of *RARB*.[88,89,154–160] Unfortunately, the outcome of retinoid chemoprevention clinical trials was an increase rather than decrease in the risk of lung cancer.[161] Nevertheless, the results of in vitro experiments suggest that retinoic acid can prevent the oncogenic transformation of immortalized human bronchial epithelial cells.[162] Hypermethylation of *RARB* was linked with retinoic acid resistance in a human bronchial epithelial cell line, and treatment with DNA methylation inhibitor azacytidine restored the cells' ability to respond to retinoic acid.[163] As with methylation of *MGMT*, *RARB* hypermethylation appears to be an early event in the development of lung adenocarcinoma,

showing low but detectable levels in the adjacent lung, and increasing methylation in hyperplasia and adenocarcinoma.[142,164]

RASSF1, encoding a putative RAS effector protein, has been reported to be frequently methylated in human malignancies, including lung cancer.[14,16,33,142,165] The gene has alternative first exons, alpha and gamma, each with a CpG island. The upstream island (*RASSF1A*) is hypermethylated in lung cancer, and its methylation strongly correlates with expression of the delta subfamily of the DNA methyltranseferase 3B.[166] This DNMT3B subfamily consists of at least seven splice variants. Knockdown of *DNMT3B4* in lung cancer cell lines resulted in reactivation of the *RASSF1A* but not the *CDKN2A* promoter, implying that *DNMT3B* isoforms could be involved in initiating promoter-specific DNA methylation. *RASSF1A* methylation is suggested to correlate with a poor prognosis, although this finding should be confirmed by an independent study.[167]

In addition to *CDKN2A*, *MGMT*, *RARB*, and *RASSF1*, many other genes may be of interest functionally or therapeutically. Genes worth mentioning briefly are *OPCML*, *CHD13*, and the *HOX* family.[16] *OPCML*, encoding an opioid-binding cell adhesion-like molecule, was suspected as a tumor suppressor gene many years ago by Minna et al.,[168] based on the apoptotic response of lung cancer cell lines to opioids, which antagonized the growth stimulatory effect of nicotine.[168] The frequent and high methylation of *OPCML* in both adenocarcinoma and squamous cell lung cancer also suggests that it might function as a pan-lung cancer marker.[169,170] Brock et al.[147] found that hypermethylation of CDH13, encoding the cell adhesion molecule heart cadherin, is associated with increased risk of recurrence of stage I NSCLC, and addition of *CDH13* methylation to *CDKN2A* methylation further increased the odds ratio for recurrence, particularly when methylation was assessed in tumors. However, to our knowledge, these data have not yet been translated to the clinic. Of interest is that a genome-wide study with similar goals identified a five-marker prognostic panel that did not include *CDKN2A* in the top genes and did not yield odds ratios as high as the ratios in the study by Brock et al.[171] This finding points to possible differences when different platforms are used and suggests that further studies are required to validate markers and obtain consistent results. One of the markers included in the five-marker panel was *HOXA9*. Members of the HOX family of genes, which encode homeobox–containing transcription factors important in the embryonic body patterns, have been reported to be methylated in numerous cancer types, including lung cancer.[16,100,172] Numerous other genes hypermethylated in lung cancer are under investigation, and much further work is required before we have full insight into the most common DNA methylation cancer driver events.

In addition to methylation of genes, the hypermethylation of microRNAs is also of great interest.[8] The miR-29 family of three RNAs is an example of microRNAs that are silenced by hypermethylation in lung cancer (in contrast to the activated let-7a-3 mentioned earlier).[173] Expression of these RNAs is inversely correlated with *DNMT3A* and *DNMT3B* in lung cancer, which appears to be mediated by targeting of miR-29 to the 3′ untranslated regions of the methyltransferase mRNAs. Reactivation of miR-29 could be one way in which methyltransferase expression and tumorigenic potential of lung cancer cells could be mitigated, as illustrated by the reduced tumor growth in nude mice of A549 lung cancer cells transfected with miR-29.[173] As with aberrantly methylated genes, much work remains to be done to fully characterize the role of epigenetically inactivated microRNAs in lung cancer.

From the data described previously, it is clear that progress is being made in understanding the functional consequences of changes in DNA methylation. Despite its promise, DNA methylation analysis has not yet become clinically implemented as a molecular assay applied to tumors. This finding may be related

to the fact that analysis of DNA methylation requires an additional chemical step (bisulfite conversion), or it may be because more work must be done to independently verify findings before they can lead to clinical implementation. The general reversal of methylation is already a clinical target though, with numerous drugs that counteract DNA methylation under development and being evaluated in clinical trials.[22,38]

DNA Hypermethylation in Lung Cancer: Application to Marker Development

One of the driving forces behind DNA methylation research is the desire to identify DNA methylation markers for early lung cancer detection.[14,21,33] DNA hypermethylation analyses could yield powerful candidate markers for lung cancer because only a small region of each gene needs to be interrogated, and DNA is a PCR-amplifiable substance that can be detected in bodily fluids.[14,21,33,174,175] Successful development of markers for cancer is a long process that should culminate in a randomized case–control study that demonstrates a reduction in mortality (Fig. 12.3).[176]

The vast majority of DNA methylation studies in lung cancer have focused on NSCLC, which makes up about 85% of all lung cancers.[14,15,21,27,28,33,100,101,107,126,129,177] A comparison of methylation profiles of SCLC and NSCLC cell lines and tumors indicates that hypermethylation profiles are distinct for these two groups.[178–180] Studies in SCLC are few as yet;[127,128] it is a very aggressive cancer associated with poor survival, and surgery is infrequent, limiting the accessibility of samples for profiling. In addition, SCLC is considered by many to be an unsuitable candidate for the development of early detection molecular markers due to the rapid progression of the disease. In contrast, important benefits would be gained if NSCLC could be detected at an early stage, as these lung cancers, which include adenocarcinoma (approximately 40% of lung cancers), squamous cell carcinoma (approximately 30%), large cell carcinoma (approximately 10%), and miscellaneous other histologic subtypes, such as carcinoids and neuroendocrine cancers (approximately 5%), usually lead to death.[181,182] In particular, DNA methylation markers could be useful to complement low-dose spiral computed tomography (CT) screening. Low-dose CT was shown to sensitively detect early lung cancer when applied to long-term smokers, leading to a 20% reduction in mortality, but has a specificity of less than 4%.[183]

Not surprisingly, differences between hypermethylation profiles of NSCLC histologic subtypes have been reported,[16,28,33,100,107,129,169,170,179,184–186] meshing with other molecular and clinicopathologic differences found in these tumor types.[187–190] This finding suggests that a panel of DNA methylation markers would be optimal and that this panel should include pan-lung cancer markers as well as ones for distinct histologic subtypes.[107,169,170,177]

The first step in molecular marker development is the identification of promising candidate markers.[176] In the case of DNA methylation markers for lung cancer, it is of high priority to identify frequently methylated genes or loci (we refer to the CpG island section we are probing as a locus, because a given gene can be probed in multiple areas within a single or even multiple CpG islands). These loci should also show substantially increased methylation levels over those found in healthy tissues. Thus, the initial focus should be on penetrance and DNA methylation levels. Because even a noncancerous lung from a long-term smoker may have accumulated substantial methylation due to age and environmental exposure,[186,191–194] many labs (including ours) have chosen to compare cancer tissues to this type of "high background" control tissue (referred to as adjacent nontumor lung). This finding ensures that identified hypermethylation markers are indeed cancer-specific and not merely indicative of environmental exposure. Although smoking has been implicated in increased DNA methylation, it appears that some DNA methylation alterations are consistent between smokers and nonsmokers, which means it should be possible to develop broadly applicable biomarker panels.[100,177]

Many of the genes studied early on did not show high methylation frequencies,[33] but more recent efforts by numerous groups to examine much larger collections of genes have yielded a number of panels that may deliver high sensitivity and specificity, based on the examination of tissues.[100,101,117,169,170,184,195–204] Some of these panels contain genes that were identified early on (such as *CDKN2A/p16*, *MGMT*, and *RASSF1*),[170,184,197,204] but many new loci have been added to the repertoire, including homeotic genes involved in development, such as members of the HOX and PAX families.[100,101,117,169,170,199,201,204] Whether the hypermethylation of potential DNA methylation markers is functional or not (i.e., leads to transcriptional silencing) is not relevant, as long as penetrance is high and hypermethylation is associated with the presence of cancer. Many of the marker panels must still be validated on independent tumor sets, and their ability to identify lung cancer independently of gender, histologic subtype, racial/ethnic group, and/or stages of cancer must be further scrutinized (Fig. 12.3, right panel). Once that is accomplished, the marker panels can be taken to the next phase of marker development: clinical assay validation.[176] In order for these panels to function in early lung cancer detection, they must be detectable in patient remote media: body fluids that could carry methylated DNA molecules from the cancer and that could be sampled relatively noninvasively.

Detection of DNA Methylation Markers in Body Fluids

Potential remote media for lung cancer detection are blood (plasma or serum[205]), coughed-up sputum (spontaneously collected from smokers or induced in never-smokers or ex-smokers), bronchioalveolar lavage ([BAL], a saline rinse that can be collected during bronchoscopy), bronchial brushings, and exhaled breath condensate (collected as condensation from breath using a cooling device).[21] DNA methylation markers have been detected in plasma, serum, sputum, and BAL, and data from an ever-growing number of studies are reported. One problem that authors report with many studies is the lack of control participants, which makes results difficult to interpret. In addition, authors of some studies cite frequencies based on the number of methylation-positive remote samples found in patients in which the tumor is positive. This finding is helpful to determine the experimental sensitivity of the test, but it does not provide a good estimate of clinical sensitivity.

There are two published reports of detection of DNA methylation markers in exhaled breath condensate.[206,207] Although sensitivity is low, these studies do show feasibility and may be further developed. The use of sputum as a source for DNA methylation has been more deeply investigated and has been reviewed.[174] A review of results to date indicates that sensitivity and specificity still need to be improved, variability in methodology between studies makes comparisons difficult, and that there is a need for further studies. One noted concern is frequent signal in the negative controls, perhaps related to the many amplification cycles.[143] In addition, sputum is considered to favor the detection of centrally located tumors.

Blood (plasma or serum) would be the easiest body fluid to obtain for screening, but analyses to date indicate this medium too lacks sensitivity. In addition, DNA methylation signatures may arise from anywhere in the body. However, the new high-throughput DNA methylation profiling technologies might make it feasible to identify lung cancer–specific DNA methylation signatures. This would require the profiling of DNA methylation in all other common types of cancer, a process that is ongoing in different laboratories and in The Cancer Genome Atlas Project.[208] Preliminary

analyses reported by investigators at the Laird-Offringa lab indicate that the markers with the highest sensitivity are not lung cancer–specific. Whether or not the signal should be unique to lung cancer will perhaps depend on how a resulting test is leveraged. If it is geared toward supplementary evaluation of a lesion detected by low-dose spiral CT, it may be less of an issue than when no other assays are available. It remains a question what size the tumor must be in order to shed sufficient DNA into the blood for remote detection. To date, the hunt for a blood-based marker panel with high sensitivity and specificity is ongoing.

Of the remote media tested, BAL appears the most promising, showing sensitivities for individual loci approaching 50% or higher. The combination of markers into panels will help increase sensitivity, as exemplified by studies of Grote et al.[157,209,210] The finding that combined methylation analysis of *CDKN2A* and *RARB* detects cases of lung cancer with a sensitivity of 69% and a specificity of 87% is highly encouraging.[157] The combination of *APC*, *CDKN2A*, and *RASSF1* also showed promise, detecting 63% of central cancers and 44% of peripheral cancers and exhibiting a very low background in one of 102 cases with benign lung disease.[210] Based on the detection of methylation in BAL from patients without cancer in a number of studies, it would be important to use quantitative measurements and to set a cut-off value for positive methylation.[157,209–212] The fact that the collection of lavage fluid can be directed to a particular area of the lung makes it especially suited to be combined with imaging approaches. This, in addition to the promising results obtained to date, suggests that analysis of DNA methylation in BAL might be the key to early detection of lung cancer.

In addition to their use for early detection, DNA methylation markers identified in body fluids could be applied to risk assessment and monitoring of recurrence. In the case of quantitative markers, cutoff values could be stratified to distinguish between methylation detected in normal tissue from nonsmokers, histologically normal tissue of cases prior to diagnosis, lung cancer, or recurring lung cancer. The authors of several studies have shown that methylation can be detectable long before the cancer becomes clinically apparent.[141,213,214] However, as noted previously, the sensitivity of the least invasive approaches (sputum, blood) have not been high, and use of BAL would require bronchoscopy.

EPIGENETIC THERAPY FOR LUNG CANCER

The cumulative role that DNA methylation, histone modifications, chromatin remodeling, and other epigenetic events play in the development of lung cancer has prompted investigations into targeting these changes therapeutically. Various strategies have been attempted or are ongoing to improve the treatment of patients with lung cancer by applying epigenetic approaches.

The ability to inhibit DNA methyltransferases and histone deacetylases gave rise to a flurry of drug development and preclinical studies, including ones using lung cancer cell lines.[38,215] The first identified epigenetic drug, 5-azacytidine, blocks DNA methylation. The DNA methyltransferase normally forms a covalent intermediate as it prepares to methylate cytosines, but when 5-azacytidine has been incorporated at that position, the 5 position is blocked and the methyltransferase becomes trapped and inactivated. In model systems, 5-azacytidine demonstrates intriguing antitumor activity. For example, in the H1299 lung cancer cell line implanted into nude mice, treatment with 5-azacytidine restored the expression of some hypermethylated genes and suppressed tumor growth.[124] However, although the 5-azacytidine derivative, decitabine (or 5-aza-2'-deoxycytidine), is used to treat myelodysplastic syndromes and acute myeloid leukemia,[216] clinical studies using hypomethylating agents alone for patients with lung cancer have been somewhat disappointing.

Histone deacetylase inhibitors are also currently used to treat hematologic malignancies.[217] However, clinical evaluations of HDAC inhibitors in patients with solid tumors have, in general, been only modestly successful. In NSCLC cell lines, several HDAC inhibitors were shown to induce cell death.[22] At least three different clinical trials have been undertaken with these inhibitors in NSCLC.[22] Although no major responses occurred in any of the patients, the major findings were stabilization of the disease in a subset of patients for a few months (Table 12.3). In this regard, the presence of alterations in genes encoding histone deacetylases (*HDAC1*, *HDAC2*, *HDAC6*, and *HDAC9*) in NSCLC is potentially of interest;[51] mutations in HDACs may determine the resistance or sensitivity to HDAC inhibitors. Of additional interest is the profiling of lung cancer cells to identify genes that modulate sensitivity to HDAC inhibitors.[218]

The modest success of clinical trials with either DNA methyltransferases or HDAC inhibitors as single agents has prompted their use in combination, either together or with other compounds. In a phase I/II trial of combined azacytidine and entinostat, an HDAC inhibitor, conducted in pretreated patients with recurrent metastatic NSCLC, the median survival for the entire cohort was significantly higher than that for existing therapeutic options. Among the patients who had a response to this combination treatment, one

TABLE 12.3 Clinical Trials Involving Epigenetic Agents in Lung Cancer[a]

Phase of Trial	Agent(s) (Type of Drug)	No. of Patients	Disease Characteristics	Effects
SINGLE AGENT				
I[239]	Decitabine (DNA-demethylating)	20	Stage III–IV NSCLC, refractory to standard therapies	Establishment of maximum tolerated doses; no objective responses
II[240]	Vorinostat (HDAC inhibitor)	14	Stage IIIB–IV NSCLC, progressive disease after traditional chemotherapy	No objective responses; stable disease in 57% of patients
II[241]	Romidepsin (HDAC inhibitor)	16	Recurrent SCLC, after platinum-based therapy	No objective responses; stable disease in 19% of patients
COMBINATIONS				
II (two randomized arms)[227]	Vorinostat/carboplatin/ paclitaxel (HDAC inhibitor/chemotherapy)	62 versus 32	Stage IIIB–IV NSCLC	Trend toward vorinostat enhancing the efficacy of chemotherapy
II (two randomized arms)[228]	Entinostat/erlotinib (HDAC inhibitor/tyrosine kinase inhibitor)	67 versus 66	Stage IIIB–IV NSCLC	Erlotinib and entinostat did not improve patient outcomes
I/II[219]	5-aza/entinostat (DNA demethylating/HDAC inhibitor)	45	Progressive, metastatic NSCLC	Objective responses in 4% of patients; antitumor activity was impressive in two patients

[a]Only trials that enrolled more than 14 patients with lung cancer are included.
HDAC, Histone deacetylase; *NSCLC*, non-small cell lung cancer; *SCLC*, small cell lung cancer.

patient had no evidence of disease for 1 year and another had stable disease for about 22 months and complete resolution of liver metastases, which remained undetectable more than 2 years after completion of therapy. This analysis also demonstrated the demethylation of four genes known to be associated with lung cancer, detectable in serial blood samples in these patients, which was associated with significantly improved progression-free and overall survival.[219] These promising results have given rise to other phase I and II clinical trials, and the excitement in the field is reflected by reviews published in 2013.[22,23] The combination of epigenetic therapies with other anticancer agents has also been investigated. HDAC inhibitors have been shown to be synergistic with cytotoxic agents, such as taxanes and platinum,[220,221] although in some cases it is not clear whether this is an effect of the HDAC inhibitor on histone tails or on other proteins that are acetylated, such as heat shock protein 90 (HSP90).[222] The HDAC inhibitor LBH589 increased HSP90 acetylation in lung cancer cells, thereby decreasing HSP90 protein chaperone ability, an activity that helps EGFR-mutant proteins maintain functionality.[223] These findings served as the rationale for the combination of inhibitors of EGFR signaling with HDAC inhibitors, an approach that showed promise in several studies using cancer cell lines.[224–226] Clinically, however, the combination of these agents has had little impact on patients' survival or response to treatment. A phase II study in advanced NSCLC suggested an improvement in response after the addition of the HDAC inhibitor, vorinostat, to a regimen of carboplatin and paclitaxel.[227] However, in another study, the combination of entinostat and erlotinib was not superior to erlotinib alone in an unselected NSCLC population.[228]

Another exciting combinatorial prospect is epigenetic therapy combined with immunotherapy, prompted by the finding that 5-azacytidine bolsters the expression of some immune modulators in lung cancer cell lines.[229] The combination of other standard therapies such as radiotherapy with HDAC inhibitors has also shown promise in preclinical models[230] and should be explored in clinical settings.

Lastly, a generation of novel drugs has been developed against bromodomains. Among these are the group of small molecule inhibitors of the bromo and extra terminal (BET) family of chromatin adaptors, which target the so-called BET proteins (e.g., BRD2, BRD3, BRD4, and BRDT). JQ1 is a BET inhibitor that suppresses cell growth in a variety of leukemia and lymphoma cell lines in the context of an activated MYC, either through chromosomal translocation or gene amplification.[231,232] In lung cancer, JQ1 has been tested only in lung adenocarcinoma cell lines, causing growth inhibition in about one-third of the cells. The exact mechanism for this inhibition is still not well understood, although it appears to be independent of MYC and may involve FOSL1.[233] The inhibitors of bromodomains may also have therapeutic applicability in the context of the SWI/SNF complex, depending on the genetic background of the cancer cell. Studies using interference RNAs have demonstrated that the inhibition of BRM in cells lacking functional BRG1 causes cell death.[234,235] Likewise, the inhibition of BRG1 is lethal in lung cancer cells, especially SCLC-carrying inactivation of the MYC-associated factor X gene, MAX.[236] These findings raise the possibility of using BRM or BRG1 as targeted therapeutics in lung cancers carrying genetic inactivation of BRG1 or MAX, respectively.[237] The coming years will witness the development of a variety of bromodomain inhibitors and other epigenetic-related drugs as well as the clinical trials that will test them. We anticipate that some of these new drugs will become valuable tools in the growing arsenal to treat patients with lung cancer.

CONCLUSION

Powerful tools are being honed for the epigenomic analysis of lung cancer, and these tools will continue to increase our understanding of the molecular underpinnings of the development and progression of lung cancer. In addition, they will provide molecular markers for detection, diagnosis, prognostication, and monitoring of recurrence. A key area that will require rapid development to make the most of these technologies is bioinformatics, because the staggering amount of data generated must be analyzed and interpreted. The combination of new epigenetic knowledge with novel epigenetic drugs, and insight into how these and other drugs function, has generated an aura of hope and excitement in the field of lung cancer. The possibility to build on existing therapies, such as EGFR inhibitors or radiotherapy, by combining them with inhibitors of HDACs and DNA methylation opens many new therapeutic avenues. With progress looming on the fronts of early detection as well as treatment, it can truly be said that epigenetics has given new breath to the fight against lung cancer.

13 Stem Cells and Lung Cancer: In Vitro and In Vivo Studies

Dean A. Fennell and David M. Jablons

SUMMARY OF KEY POINTS

- The use of mouse models to study the initiation and evolution of lung cancers has been crucial in advancing the field through the identification of putative stem cell niches within the lung.
- Bronchoalveolar stem cells (BASCs) are the putative cell of origin for lung adenocarcinoma.
- The tumor suppressor gene phosphatase and tensin homolog (PTEN) exerts a brake on BASC transformation to adenocarcinoma.
- Basal cells of the trachea are the putative cell of origin for squamous lung cancer.
- In small cell lung cancer (SCLC), a common neuroendocrine cell of origin may undergo RAS-driven transformation to a CD44-expressing non-neuroendocrine clone.
- Hedgehog (Hh) signaling persists in SCLC and is required for tumor growth in mouse xenograft models.

The cancer stem cell hypothesis, when applied to lung cancers, is underpinned by the concept of a cellular hierarchy in which a relatively rare somatic stem cell population with self-renewal capability, differentiation, and innate drug resistance gives rise to the bulk of the cancer.[1] Evidence of this concept has been reported in studies on hematologic malignancies and solid cancers.[2–5] Lung cancers, like other cancers, are heterogeneous with respect to histology and are spatially associated with the cellular origin of initiation.[6] With the advent of large-scale DNA sequencing, heterogeneity at the genetic level has been observed within these histologic subclasses, especially in adenocarcinomas.[7–11] This heterogeneity in adenocarcinomas indicates complexity in the mechanisms underlying cellular initiation and evolution of lung cancers as a result of specific mutational processes.[12] This chapter focuses on the evidence supporting the existence of spatially restricted initiator cell populations in lung cancer (cells of origin), including evidence for specific pathways involved in their maintenance, as well as the less well-supported evidence for cancer stem cells.

NORMAL LUNG

Over time, a model has been developed in which the lung is subdivided into regions associated with their own stem cell population capable of rapidly responding to lung injury, thus enabling cellular repopulation.[13] Accordingly, the trachea, bronchus, bronchioles, and alveolus exhibit their own complement of cells capable of repopulation following lung injury.

For the trachea and bronchus, these repopulating cells are the basal mucous secretory cells. Evidence supports the existence of a cellular compartment in the human airway surface epithelium that can restore the full repertoire of epithelial lining cells in a xenograft model in severe combined immunodeficiency mice.[14]

By contrast, the basal/parabasal origin of tracheal stem cells has been proposed based on data showing that a cytokeratin 5 (CK5), CK14-, and mindbomb E3 ubiquitin protein ligase 1-positive cell population comprising only 0.87% of lung cells accounts for 48% of proliferating cells with basal localization.[15] Tracheal gland ductal cells that express CK14 and CK18 have been shown to retain sulfur dioxide labeling up to 4 weeks after inhalation damage in adult mice and can repopulate the tracheal surface after injury.[16]

In the bronchioles and alveoli, the club cell (formally known as the Clara cell) and type II pneumocyte have been implicated in repopulation. Accordingly, specific depletion of club cells in rodent models by either intraperitoneal naphthalene or activation of the suicide substrate ganciclovir by Clara cell secretory protein (CCSP)-promoter-driven herpes simplex virus thymidine kinase in transgenic mice is sufficient to cause irreversible, fatal lung injury.[17] In rodent fetal lung, the existence of a possible bipolar stem cell (M3E3/C3) capable of differentiating into club or type II pneumocytes when grown in different media is supported by data from Finkelstein et al.[18] Bleomycin causes specific alveolar type I (AT1) cell injury, and it has been proposed that AT2 cells can repopulate and repair the alveolar epithelium.[19] A unique, naphthalene-resistant stem cell population has been identified at the bronchoalveolar junction and can repopulate the terminal bronchioles after club cell depletion injury. These cells express CCSP and are independent of the neuroepithelial body microenvironment, implicating a distinct stem cell niche.[20] Similarly, a so-called side population of cells (i.e., a rare cellular subset enriched for stem cell activity) exhibiting typical breast cancer-resistant protein-mediated Hoechst dye efflux has been identified in 0.03% to 0.07% of total lung cells.[21,22]

NONSMALL CELL LUNG CANCER

Adenocarcinoma and the Cells of Origin

Nonsmall cell lung cancer (NSCLC) can be subdivided into two distinct subtypes that reflect the histologic characteristics of distinct regions within the lung: 80% are adenocarcinomas and 20% are squamous cell carcinomas.[23] The adenocarcinoma subtype and adenoma precursors exhibit club and AT2 cell markers consistent with a peripheral or endobronchial origin,[24,25] whereas squamous cell carcinomas exhibit mature epithelial cell characteristics consistent with trachea and proximal airways origin. The AT2-specific marker surfactant protein has been shown to be expressed in lung adenocarcinoma and squamous cell carcinomas. Accordingly, Ten Have-Opbroek et al.[26] postulated that the AT2 cell may be the pluripotential cell for NSCLC in humans.

Isolation of a CD133-Positive Stem-Like Population in Lung Cancer

Rare populations of cells (<1.5%) have been shown to form colonies in soft agar and recapitulate features of the original lung cancer in athymic mice.[27] In a study that was aimed to isolate rare populations of cells from primary lung cancer specimens

expressing the marker CD133, an undifferentiated cell population was identified, capable of indefinitely growing as tumor spheres in serum-free medium containing epidermal growth factor and basic fibroblast growth factor.[28] This approach had previously been used to isolate a putative hemopoietic cell of origin in human acute myeloid leukemia.[29] These putative lung cancer stem cells were able to acquire specific lineage markers in tumor xenografts (which were identical to the original tumor) and differentiated to lose tumorigenic potential and CD133 expression. In association with aldehyde dehydrogenase 1A1, a marker of the stem cell phenotype, CD133 has been shown to be associated with a poor prognosis—related to shorter recurrence-free survival—for patients with lung cancer.[30,31]

In previous studies, CD133-positive cells have been isolated from cell lines. In one study, CD133-positive cells were found to coexpress octamer-binding transcription factor 4 (OCT-4), NANOG, alpha-integrin, and C-X-C chemokine receptor type 4, and these cells were found to be resistant to cisplatin.[32] In another study, following chemotherapy, cells with CD133 were isolated and then enriched in the surviving populations with CD133 positivity.[33] Consistent with the observation that isolated CD133-positive cells are resistant to cisplatin, selecting cells specifically for resistance to cisplatin over several months through long-term treatment led to enrichment of a CD133-positive/CD44-positive/aldehyde dehydrogenase-active clone that expresses NANOG/OCT-4/sex determining region Y-box 2 (SOX2).[34] However, isolation of CD133-positive cells from the A549 cell lines has also been shown to result in high potential for liver metastases,[35] and tumor growth factor-beta has been shown to increase the migratory capacity of these CD133-positive A549 cells in association with induction of epithelial to mesenchymal transition.[36]

The Cell of Origin in Conditional Oncogene-Driven Adenocarcinoma

Activating mutations of Kirsten rat sarcoma (KRAS) are identified in approximately 25% of adenocarcinomas. A Lox-Stop-Lox KRAS conditional mouse strain (LSL K-ras G12D) harboring an oncogenic KRAS under control of a removable transcriptional termination stop element by adeno-CRE infection has been reported as a model for monitoring the initiation of tumor formation over time through different stages of progression.[37,38] Three distinct types of lesions have been identified: atypical adenomatous hyperplasia (AAH), epithelial hyperplasia of the bronchioles, and adenomas. AAH is an atypical epithelial cell proliferation that grows along the alveolar septa but is noninvasive; it has been proposed by Kerr to be an adenoma-like precursor of adenocarcinoma.[39] Immunohistochemical analysis has shown negativity for the Clara cell-specific marker Clara cell antigen (CCA) and positivity for AT2 cell-specific marker prosurfactant apoprotein-C (pulmonary surfactant apoprotein C [SP-C]) consistent with AT2 cell origin. By contrast, epithelial hyperplasia lesions exhibit CCA positivity and SP-C negativity consistent with club cell origin. Importantly, endothelial hyperplasia lesions contiguous with AAH lesions exhibit double CCA/SP-C expression at the single-cell level, demonstrating a unique double-positive population that exhibits properties of both club and AT2 cells.[37] Monitoring progression following KRAS activation over time has demonstrated formation of adenomas (outnumbering AAH lesions) at 12 weeks after adeno-CRE infection, and adenocarcinomas that form at 16 weeks in the absence of AAH lesions suggest a precursor origin of these cancers.[37]

SP-C/CCA double-positive cells have been subsequently shown to be the putative cell of adenocarcinoma origin in the LSL-K-ras G12D model.[40] Such double-positive cells, which express markers of both AT2 and club cells, have been previously identified in mice.[41] In normal adult lungs, double immunofluorescence has been used to identify a subpopulation of cells that are positive for CCA and SP-C and that are restricted through localization to the bronchoalveolar duct junction; CCA is distributed in the columnar bronchial epithelium and SP-C in the AT2 cells. These double-positive cells respond to both naphthalene- and bleomycin-induced lung injury by proliferating, while club cell or AT1 cell loss occurs as a result of specific toxicities.[40]

Isolation of these double-positive cells has shown a putative stem cell population—termed BASCs—that reside at the bronchoalveolar duct junction and repopulate the bronchiolar or alveolar epithelium following damage. BASCs constitute 0.4% of the total lung cell population and exhibit an immunophenotype that is negative for platelet endothelial cell adhesion molecule (Pecam), CD45, and CD34 and positive for stem cell antigen 1 (Sca1). These cells are clonal, as evidenced by single-cell culture.[40] BASCs exhibit multipotent lineage potential and can give rise to AT2-like or club-like cells while undergoing self-renewal during culture.

During tumorigenesis in the LSL-K-ras G12D model, infection with adeno-CRE leads to an expansion of the BASC pool, coincident with the formation of AAH. The amount of BASC expansion correlates with the titer of adeno-CRE used to infect the LSL-K-ras G12D transgenic mice.

Loss of PTEN Expands the BASC Pool

BASCs require PTEN to prevent formation of lung adenocarcinomas.[42] PTEN is a tumor suppressor that inhibits the phosphoinositide 3 kinase (PI3K)/AKT survival pathway by dephosphorylating phosphatidylinositol-3,4,5-trisphosphate at the cell membrane, and it is required for maintenance of other organ-specific stem cells.[43] Loss of PTEN is a frequent occurrence in lung adenocarcinoma.[44–46] To study the effects of PTEN, bronchoalveolar epithelium-specific, PTEN-deficient mice were established. These mice had impaired lung morphogenesis, impaired alveolar epithelial cell differentiation, defective expression of the molecular markers (increased sprouty gene 2 [*Spry2*] and sonic hedgehog [Shh]), and bronchoalveolar epithelial hyperplasia.[42] Furthermore, loss of PTEN led to an increase in the numbers of BASCs and was sufficient to induce spontaneous adenocarcinomas, of which 33% were shown to exhibit secondary codon 61 KRAS mutations. By contrast, PI3K has been shown to mediate BASC expansion in oncogenic KRAS-induced lung cancer, demonstrating a critical role for this pathway in regulating the stem cell pool during formation of adenocarcinomas.[47] As with the PI3K pathway, Gata6-wingless-related integration site (wnt) signaling and B lymphoma Moloney murine leukemia virus insertion region 1 homolog (Bmi1) have been identified as regulators of BASC expansion.[48,49]

Maintenance of Stem Cell Populations: Notch and Wnt Signaling

Asymmetric cell division is a characteristic of stem cells that is regulated by the highly conserved notch signaling pathway, which, in turn, is mediated by cell–cell interactions. This pathway is involved in normal lung development, as evidenced by knockout of the downstream notch target hairy and enhancer of split 1 (Hes1), which is expressed in neuroendocrine cells and is associated with their expansion.[50] In RAS-transformed cells, RAS increases the level and activity of the notch pathway by increasing the levels of intracellular notch-1, and upregulating notch ligand delta-1 and p38 pathway-dependent processing of presenilin-1. This notch activation is essential for maintaining the neoplastic phenotype in vitro and in vivo.[51] Recently, it has been shown that Notch3 signaling in KRAS-driven adenocarcinoma is dependent on the oncogene protein kinase C iota (PKCiota), and simultaneous pharmacologic inhibition of both Notch and PKCiota

exhibits synergistic antagonism of KRAS-driven lung adenocarcinoma in vitro and in vivo.[52] The Wnt pathway activation is essential for maintaining the cancer stem cell phenotype and, although not commonly mutated in NSCLC, is constitutively activated. It has recently been shown that Wnt signaling is enhanced by microRNA 582-3p-mediated suppression of Wnt inhibitors axis inhibition protein 2, Dickkopf WNT signaling pathway inhibitor 3, and secreted frizzled-related protein 1. Inhibition of MiR582-3p results in suppression of Wnt and inhibition of both tumor initiation and in vivo xenograft progression, suggesting its potential as a therapeutic target.[53]

Squamous Cell Lung Carcinoma

Basal cells of the trachea have been implicated as possible cells of origin of squamous cell lung carcinoma. In mouse models, squamous cell lung carcinomas exhibit similar expression patterns of p63, CK5, and CK14, as well as spatial localization to intracartilaginous boundaries and mucosal junctions.[16,52] CK5-positive basal cells have self-renewal properties and are under the control of SOX2;[54] in squamous cell lung carcinomas, the *SOX2* gene is frequently amplified at chromosome 3q26.33.[55]

SMALL CELL LUNG CANCER

Neuroendocrine Airway Epithelia and the Origin of Small Cell Lung Cancers

SCLC arises from cells residing in the epithelial lining of the bronchi and exhibits a neuroendocrine phenotype.[56] Approximately 90% of SCLCs exhibit inactivating mutations in both p53 and retinoblastoma 1 (Rb1) tumor suppressor genes.[57–59] Accordingly, a transgenic mouse model has been established with use of Cre-Lox-mediated, epithelial-specific deletion of both Rb1 and p53.[60] Coincidental loss of these tumor suppressor genes leads to the formation of neoplastic lesions following intratracheal intubation. These lesions exhibit neuroendocrine differentiation, as evidenced by expression of synaptophysin (Syp) and neural cell adhesion molecule (Ncam1, also known as CD56), consistent with germline mutation of these genes in mice.[61] No proliferation of club or AT2 cells has been reported, despite these cells harboring p53/Rb1 mutations in the transgenic model, which suggests a specific genotype–phenotype interaction in the neuroendocrine cell pool. Similar to humans, transgenic mice harboring SCLC can express anti-Hu antibodies (14% compared with 16% of humans).[62]

Restricting the targeting Rb1/p53 loss to specific lung epithelial cell subsets has demonstrated that targeting of either neuroendocrine or AT2 cells can lead to the formation of SCLC (the latter with lower efficiency). By contrast, however, club cells are resistant to this path of transformation. This technique has enabled identification of the cell type of origin in pancreatic and prostate cancers.[63,64] The finding that club cells are resistant to neuroendocrine cells with respect to transformation by conditional p53/Rb1 loss implies that neuroendocrine cells are the predominant cell of origin associated with SCLC, although AT2 cells also have the capacity to transform.[65]

Neuroendocrine Hedgehog Signaling Mediates Airway Repair and SCLC

A naphthalene-induced acute lung injury model leads to loss of club cells approximately 24 hours after administration, with epithelial regeneration occurring within 72 hours, as well as an expansion of rare neuroendocrine cells.[66,67] During this regeneration phase, there is activation of widespread Hh pathway signaling, evidenced by upregulation of Hh signaling (Shh ligand and GLI protein). However, GLI is lost following neuroendocrine differentiation by day 4 after naphthalene-induced injury in nascent calcitonin gene-related peptide-positive epithelial cells.[68] Using a transgenic model to monitor Hh signaling by replacing one allele of Ptch (a transcriptional target of GLI proteins) with beta-galactosidase, it has been possible to show that during normal development, this pathway is activated in the airway epithelial compartment.[68]

Hh signaling persists in SCLC, as evidenced by GLI and Shh expression in 50% of primary SCLC specimens (in contrast to 23% in NSCLC).[66] SCLC cells and xenografts are dependent on Hh signaling for growth, as evidenced by sensitivity to cyclopamine and, conversely, their rescue by ectopic expression of GLI1, similar to medulloblastoma.[69] SCLC cells do not exhibit mutations in Ptch, but rather exhibit juxtacrine Hh signaling similar to that seen in development and airway repair.

Tumor Heterogeneity and SCLC

One of the unique clinical features of SCLC is initial sensitivity to chemotherapy, followed by recurrence and a marked acquisition of resistance, occasionally associated with a transformation to the NSCLC phenotype.[70] This behavior of SCLC probably reflects underlying tumor heterogeneity, with initial selection for a culture of clones that are resistant to chemotherapy. SCLC cell cultures derived from primary SCLC specimens grow as suspensions of small cellular aggregates, with some that attach to plastic dishes. This activity has also been noted for cells derived from disaggregation of tumors from Rb1/p53 transgenic mice harboring SCLCs.[71,72] In the latter model, attaching cells exhibit a large cell phenotype without expressing the neuroendocrine markers achaete-scute homolog 1 (Ash1) or Syp, in contrast to paired suspension cells from each tumor. Gene expression profiling data obtained from these paired cell lines have been analyzed by principal component analysis and demonstrated two groups: small cell clones (neuroendocrine) and large cell clones (non-neuroendocrine).[72] Only the neuroendocrine cell type is capable of generating SCLC tumors when injected into BALB/c NU/NU nude mice, whereas the large cell tumors generated by subcutaneous injection exhibit a mesenchymal phenotype expressing CD44. Neither cell type can regenerate the heterogeneity seen in the primary tumor; however, they exhibit a clonal relationship evidenced by spectral karyotyping and comparative genomic hybridization.[72]

H-Ras signaling has been shown to drive transition of SCLC to a dedifferentiated phenotype characterized by downregulation of neuroendocrine markers.[73,74] When neuroendocrine cells from SCLC cell lines obtained from Rb1/p53 transgenic mice are retrovirally transduced with RAS^{V12}, they undergo a transition to an adherent phenotype with downregulation of neuroendocrine markers Syp and Ash1 and expression of CD44, and a shift in gene expression, with clustering of non-neuroendocrine cells on principal component analysis. Mixing neuroendocrine and non-neuroendocrine clones leads to cell–cell crosstalk that confers metastatic potential. Together, these data suggest that a common neuroendocrine cell of origin may undergo RAS-driven transformation to a CD44-expressing non-neuroendocrine clone.

CONCLUSION

The use of mouse models to study the initiation and evolution of lung cancers has been crucial in advancing the field through the identification of putative stem cell niches within the lung. In addition, these models have increased our understanding of the pathways that regulate tumor evolution following conditional oncogene activation. Based on the genomic complexity associated with multiple putative driver mutations, the processes governing cancer

initiation are still relatively unclear. Furthermore, knowledge of the processes that drive genomic instability following tumor initiation, which lead to both spatial and temporal genomic complexity in lung cancer, will be essential for developing novel, more effective treatment paradigms, particularly in advanced disease.

14 Microenvironment and Lung Cancer

Tonya C. Walser, Elvira L. Liclican, Kenneth J. O'Byrne, William C.S. Cho, and Steven M. Dubinett

SUMMARY OF KEY POINTS

- There is untapped potential for targeted lung cancer prevention and therapy that requires, as a first step, a more clear delineation of the biology underlying the lung carcinogenesis process.
- The pulmonary microenvironment represents a unique milieu in which lung carcinogenesis proceeds in complicity with the four main components of the tumor microenvironment (TME): the field, cellular, soluble, and structural components.
- The literature now suggests that the adjacent histologically normal-appearing epithelium is a participant in the dynamic process of lung tumor initiation and carcinogenesis.
- Evidence continues to mount in support of the stromal compartment of the TME as an active participant in carcinogenesis, often driving the aggressiveness of tumors via its impact on the tumor cell secretome.
- Molecular signatures composed mainly of immune- and inflammation-related cytokines characterizing the cellular and soluble components of the TME correlate with important clinical parameters.
- The developing lung TME is populated by diverse cell types with both immune-protective and immune-suppressive potential—it is the balance of these effectors and their secretory products, along with their spatial and temporal context (i.e., the immune contexture), that often dictates clinical outcomes.
- One of the consequences of the inflammatory TME is suppression of antitumor immunity, thus recent strategies have been designed to specifically target the immune system.
- Dendritic cells are one of the cellular components of the TME that can be successfully utilized to redistribute soluble components of the TME (e.g., CCL21), ultimately redirecting the trafficking of immune cells into the tumor and enhancing immune activation.
- Two families of drugs directed at the immune system include pattern recognition receptor agonists (PRRago) and immunostimulatory monoclonal antibodies (immune checkpoint inhibitors).

Many questions central to a discussion of the influence of the lung tumor microenvironment (TME) on tumorigenesis and progression persist: the cells of origin for cancers arising in the proximal versus distal airways; the identities of key driver versus passenger mutations distinguishing histologically diverse tumors; the critical mass or combination of molecular and environmental events tipping the balance in favor of malignant conversion of the airway; and the order of events characterizing tumor initiation and systematic progression. Regardless of the answers to these questions, there is undoubtedly untapped potential for targeted lung cancer prevention and therapy that requires, as a first step,

a clearer delineation of the biology underlying the lung carcinogenesis process. Perhaps no clinical approach holds more potential than targeting the molecular underpinnings of the interplay between premalignant lesions and the developing lung TME. The opportunities for combination approaches that target multiple components of the TME simultaneously also abound and are extremely promising clinically. Past and present attempts to molecularly delineate lung carcinogenesis and to target the epithelial-TME interface are discussed in this chapter.

LUNG CARCINOGENESIS

The link between premalignancy and subsequent development of cancer is well established for some organ systems, but not for the lung.[1] For example, removal of premalignant lesions is the standard of care and has been shown to decrease cancer incidence and mortality in the case of cervical dysplasia and colorectal polyps. However, it has been difficult to demonstrate the link between premalignant histologic airway abnormalities and subsequent development of lung cancer.[2] Uncertainties about the clinical behavior of a premalignant lung lesion can lead to either inappropriate inaction or inappropriate aggressive treatment, both of which can result in harm to the patient.

The seminal autopsy studies of Auerbach et al.[3] from the early 1960s demonstrated multiple histologic abnormalities in nonmalignant bronchial epithelia of smokers with and without lung cancer. Because progressive sputum abnormalities have been shown to precede the development of lung cancer,[4] it has been suggested that the development of lung cancer proceeds in an orderly fashion through increasing grades of histologic abnormalities that culminate in metastatic carcinoma, as in cervical and colorectal cancer. Recent molecular findings support this stepwise lung tumor initiation model in which injury or inflammation leads to dysregulated repair by stem cells.[2] Tobacco smoking is a leading source of chronic injury and inflammation; thus, the majority of heavy smokers bear regions of airway epithelial dysplasia that are classified as premalignant lesions.[5] Additional genetic and epigenetic alterations prevent normal differentiation of cells in these lesions and facilitate proliferation and expansion of the field, gradually displacing the normal epithelium and giving rise to full-blown malignancy and metastatic behavior. The initiation and expansion of this premalignant field (i.e., field cancerization) appear to be critical steps in lung carcinogenesis that can persist even after smoking cessation.[6,7]

The originally proposed and still prevailing model of lung cancer progression, termed the linear progression model, places the focus on the fully malignant primary tumor and its size, and metastatic dissemination is conditional on both.[8,9] Conversely, the more recently posited parallel progression model proposes that metastases may also arise from the early dissemination of premalignant epithelial cells before their full malignant conversion or collective growth into a large primary tumor.[8,9] Cell invasion and metastasis are hallmarks of cancer that are mediated by epithelial-to-mesenchymal transition (EMT) and typically are associated with late-stage disease.[9–11] As per the linear progression model, EMT only occurs in rare cells at the leading invasive edge of advanced cancers, facilitating the final step (i.e.,

metastasis) in tumor progression. However, many groups have now demonstrated that EMT also drives malignant transformation and early dissemination of epithelial malignancies, including tobacco-related cancers.[9,12,13] In addition, consistent with the parallel progression model, it was recently proposed that EMT promotes dissemination of lung epithelial cells prior to, or concomitant with, their malignant conversion. These alternate models of tumor initiation and progression were highlighted by Sanchez-Garcia[9] in 2009, because they represented paradigm shifts in terms of our understanding of the protracted process of epithelial cell conversion from normal to cancer. Importantly, the parallel progression model may represent a more accurate model of lung cancer progression, given the clinical observation that 30% of patients with early-stage lung cancer who have surgery subsequently have metastatic disease, an indication that undetected micrometastatic disease may have already been present at the time of surgery.[14]

THE DEVELOPING LUNG TUMOR MICROENVIRONMENT

In the not-so-distant past, malignant epithelial cells were considered the tumor, and the adjacent histologically normal appearing epithelium, immune effector cells, inflammatory mediators, and the stroma were all considered irrelevant bystanders. Although genetic changes are critical for the malignant transformation of epithelial cells, we now understand that all components of the developing lung TME are active participants in the events precipitating lung cancer development. In fact, most tumors arise within, and are dependent on, a cellular microenvironment characterized by suppressed host immunity, dysregulated inflammation, and increased production of cellular growth and survival factors that induce angiogenesis and inhibit apoptosis. The pulmonary microenvironment, in particular, represents a unique milieu in which lung carcinogenesis proceeds in complicity with each of what we consider the four main components of the TME: the field, cellular, soluble, and structural components.

TME Field Component: Adjacent Histologically Normal-Appearing Epithelium

Slaughter et al.[15] initially coined the term "field cancerization" in 1953 to describe the histologically normal-appearing tissue adjacent to a neoplastic lesion that displays molecular abnormalities often identical to those in the tumor. The concept was seemingly rediscovered more than four decades later, when investigators renewed the effort to define the molecular mechanisms precipitating the development of an array of epithelial malignancies, including lung cancer.[2,16–18] In contrast to other common epithelial malignancies, there is not yet a clinical rationale to evaluate potential premalignant lesions in people at risk for lung cancer. Thus, carefully designed clinical investigations are required to harvest these clinical specimens that would not otherwise be collected from these individuals. Although knowledge regarding the molecular changes that occur in the airway in the setting of lung carcinogenesis is only fragmentary at present, it is generally accepted that there are alterations in the airway epithelium that mirror many of the changes seen in the primary lung tumor.

For example, in lung cancer, mutations in the Kirsten rat sarcoma viral oncogene homolog (*KRAS*) gene were described in nonmalignant histologically normal-appearing lung tissue adjacent to lung tumor.[16,19] Moreover, loss of heterozygosity events were frequent in cells obtained from bronchial brushings of normal and abnormal lungs from patients undergoing diagnostic bronchoscopy and were detected in cells from the ipsilateral and contralateral lungs.[20] Likewise, mutations in the epidermal growth factor receptor (*EGFR*) oncogene were reported in normal-appearing tissue adjacent to *EGFR*-mutant

lung adenocarcinoma and also occurred at a higher frequency at sites more proximal to the adenocarcinomas than at more distant regions.[21,22] Global mRNA and microRNA expression profiles were also described in the normal-appearing bronchial epithelium of healthy smokers,[23,24] and a cancer-specific gene expression biomarker was developed from the mainstem bronchus that can distinguish smokers with and without lung cancer.[25,26] In addition, modulation of global gene expression in the normal bronchial epithelium in healthy smokers was similar in the large and small airways, and the smoking-induced alterations were mirrored in the epithelia of the mainstem bronchus and the buccal and nasal cavities.[17,27,28]

Kadara et al.[29,30] advanced the field in 2013 with their investigation of the spatial and temporal molecular field of injury in individuals with early-stage nonsmall cell lung cancer (NSCLC), as determined by expression profiling of the large airways after definitive surgery. The normal airway epithelia were collected by endoscopic bronchoscopy brushings 12 months after surgical removal of the tumors, then every 12 months thereafter for up to 36 months. Although the study had key limitations, gene networks mediated by the phosphoinositide 3-kinase (*PI3K*) and *ERK* gene networks were upregulated in the airways adjacent to the resected tumor, suggesting that PI3K pathway dysregulation in the field of cancerization represents an early event in lung carcinogenesis that may persist even after resection of the primary tumor. In a follow-up study, the same researchers performed expression profiling of multiple normal-appearing airways various distances from tumors in conjunction with paired NSCLC tumors and normal lung tissues that were still in situ at the time of airway epithelial cell collection.[31] Site-independent profiles, as well as gradient and localized airway expression patterns, characterized the adjacent airway field of cancerization, suggesting they may be useful for distinguishing the large airways of people with lung cancer from those of cancer-free smokers. Such studies of the field of cancerization enrich our understanding of the molecular pathogenesis of lung cancer and have transformative clinical potential. Biomarker signatures within the field could be used for risk assessment, diagnosis, monitoring progression of disease during active surveillance, and predicting the efficacy of adjuvant therapies following surgery.

TME Cellular and Soluble Components: Immune Effector Cells and Cell-Secreted Inflammatory Mediators

Since the early 2000s, the authors of gene expression profiling studies of several tumor types have described molecular signatures associated with carcinogenesis and progression. The molecular signatures that emerged from the original gene sets were composed mainly of cytokine genes involved in immune and inflammatory responses. In a seminal study by Bhattacharjee et al.[32] in 2001, microarray-based expression profiling of resected tumor specimens allowed the investigators to discriminate between biologically distinct subclasses of adenocarcinomas, as well as primary lung adenocarcinomas and metastases of nonlung origin. Soon thereafter, Beer et al.[33] used expression profiling to predict survival among patients with early-stage lung adenocarcinomas. Likewise, an mRNA expression profile developed by Potti et al.[34] identified a subset of patients with early-stage NSCLC at high risk of recurrence. More recently, to inquire whether gene expression changes in the noncancerous tissue surrounding tumors could be used as a biomarker to predict cancer progression and prognosis, Seike et al.[35] conducted a molecular profiling study of paired noncancerous and tumor tissues from patients with adenocarcinoma. Many of the genes identified were part of an immune and inflammatory response signature previously reported in other cancers, but a unique subset of the genes was also predictive of lymph node status and disease prognosis

among patients with NSCLC.[36] Together, these studies provided the earliest indication of the potential for expression profiling and clear evidence that molecular signatures composed mainly of immune- and inflammation-related cytokines characterizing the cellular and soluble components of the TME correlate with important clinical parameters.

TME Structural Component: Stroma

As mentioned previously, the stroma was long thought to be the inert framework of the lung and irrelevant to the carcinogenesis process. Farmer et al.[37] were the first to report a major contribution of stromal genes to drug sensitivity, although not in the lung, in the context of a randomized clinical trial. These researchers used tumor biopsy specimens from individuals in the European Organization for Research and Treatment of Cancer 10994/BIG 00-01 trial with estrogen receptor-negative breast cancer treated with 5-fluorouracil, epirubicin, and cyclophosphamide and described a stromal gene signature that predicted resistance to preoperative chemotherapy. This study expanded the clinical significance of the identification of TME stroma-associated gene signatures, and it encouraged the development of antistromal agents as a new approach to overcome chemotherapy resistance.

An important translational study by Zhong et al.[38] also defined tumor cell and stromal cell interactions that inform the course of NSCLC progression. By coculturing a *KRAS*-mutant lung adenocarcinoma cell line with one of three lung stromal cells lines (macrophage, endothelial, or fibroblast) and subsequently profiling the secreted proteins, the group developed an in vitro model for evaluating the mechanisms by which stromal cells regulate the biologic properties of lung cancer cells. By two different proteomic approaches, the investigators concluded that stromal cells in the TME alter the tumor cell secretome, including proteins required for tumor growth and dissemination. Furthermore, they confirmed that the in vitro model robustly recapitulated many of the features of their *KRAS*-mutant murine model and human NSCLC specimens, suggesting its usefulness as a model of the lung TME.

Still more recently, Li et al.[39] demonstrated that mesenchymal stem cells (MSCs) recruited to the tumor stroma influence the phenotype of the tumor cells. Specifically, tumor cell-derived interleukin (IL)-1 induces prostaglandin E_2 (PGE_2) secretion by MSCs recruited to the tumor-associated stroma, which then acts in an autocrine manner to induce cytokine expression by the MSCs. The MSC-derived cytokines and PGE2 subsequently elicit a mesenchymal or stem cell–like phenotype in the tumor cells through activation of β-catenin signaling. Collectively, the results of these studies suggest that the stromal compartment of the TME is an active participant in carcinogenesis, often driving the aggressiveness of tumors via its impact on the tumor cell secretome. By extension, inhibition of specific interactions between tumor cells and the tumor-adjacent stroma holds significant potential in our search for novel lung cancer preventives and therapeutics.

PROTOTYPICAL CELL TYPES COMPRISING THE CELLULAR COMPONENT OF THE DEVELOPING LUNG TUMOR MICROENVIRONMENT

The developing lung TME is a unique and ever-changing milieu populated by diverse cell types with both immune-protective and immune-suppressive potential. The cell types are too numerous to describe in detail in the pages that follow. Thus, we discuss the induction, targeting, and potential pitfalls associated with attempting to harness three prototypical cell types characterizing the cellular component of the developing lung TME: cytotoxic and helper T cells, T regulatory cells (T regs), and dendritic cells.

Cytotoxic and Helper T Cells

The presence of tumor-infiltrating lymphocytes (TILs) has long been considered a manifestation of antitumor immunity. However, the prognostic significance of TILs was only appreciated after the development of markers that define the individual subsets of TILs.[40,41] Traditionally identified as a component of the cellular immune response to bacterial and viral infections, the integral role of cytotoxic CD8+ T cells (CTLs) in cell-mediated antitumor immune responses is now recognized. The reduced infiltration of CTLs, along with their reduced proliferation rate, increased susceptibility to spontaneous apoptosis, and impaired cytolytic activity against tumor cells, contributes to the immunosuppressive milieu that characterizes the developing lung TME.[42,43] Accordingly, a high infiltration of CTLs expressing granzyme B, the classic effector of CTL cytolytic activity, as well as the location of TILs in tumor cell nests, is associated with a good clinical outcome in several types of cancer, including colorectal cancer, ovarian cancer, and lung cancer.[44–50] Several reports have demonstrated that CTLs are associated with prolonged survival in lung cancer and positively correlated with favorable prognosis in patients with lung cancer.[43,46,51,52] However, more important than the number of CTLs present is the ratio of effector to regulatory TILs. In recent studies of patients with hepatocellular and ovarian cancer, it was shown that the ratio of CD8+ TIL:T regs was an independent prognostic factor, whereas the numbers of T regs and CD8+ TILs by themselves had lower or no predictive value, respectively.[53,54]

It is becoming increasingly clear that CD4+ helper T cells are also a critical determinant of effective antitumor immune responses. On stimulation, naïve CD4+ T cells differentiate into effector cells known as T helper (Th) cells, of which there are four subsets: Th1, Th2, Th17, and T regs. While T regs dampen antitumor immunity (discussed later), Th1 cells, characterized by production of interferon gamma and tumor necrosis factor-alpha, often lead to enhanced activation of CTLs, dendritic cells, and macrophages and beneficial downstream antitumor effects. In addition to assisting with the activation of other innate and adaptive immune cells, CD4+ helper T cells can induce apoptosis in tumor cells through Fas cell surface death receptor (FAS)- or tumor necrosis factor-related apoptosis-inducing ligand-dependent pathways.[55,56] Accumulating evidence also suggests that CD4+ helper T cells can acquire cytolytic activity.[57,58] As with CTLs, tumor-driven aberrant CD4+ T-cell differentiation and apoptosis, as well as Th dysfunction characterized by increased expression of the immune checkpoint molecule programmed death-1 (PD-1), contribute to the tolerogenic nature of the developing lung TME.[59] In this regard, immunotherapy strategies that aim to enhance the infiltration and/or activity of both CTLs and CD4+ helper T cells are found to have a synergistic effect in boosting antitumor immunity.

T Regulatory Cells

One major impediment to our efforts in both the prevention and treatment of lung cancer is our inadequate understanding of how lung cancer cells escape immune surveillance and inhibit antitumor immunity. Thus, identification of T regs in patients with cancer was a finding of great clinical importance. June et al.[60,61] were the first to document increased CD4+CD25+ T reg populations at the tumor site in patients with lung cancer. A subsequent examination of normal and tumor tissue from patients with NSCLC also indicated that tumor tissues have significantly higher expression of *FOXP3* mRNA than normal tissues, rendering CD4+CD25+FOXP3+ the more specific phenotypic marker of functional T regs at the time.[62] Next, investigators began to note increased numbers of T regs in the peripheral blood of patients with lung cancer relative to healthy volunteers and even patients with breast cancer.[63] Zhang et al.[64] made another key finding when they discovered that among

patients with NSCLC receiving paclitaxel-based chemotherapy, the mitotic inhibitor selectively decreased the size of the T reg cell population in the peripheral blood, but not the size of the effector T cell subsets. They went on to determine that the effect was mediated by the upregulation of the cell death receptor Fas (CD95) and selective induction of apoptosis of T regs. Although T reg cell function was significantly impaired, production of Th1 cytokines and expression of the CD44 activation marker were intact and even elevated within the helper and effector T cell subsets after treatment with paclitaxel. In addition to these studies in lung cancer, there are numerous reports of increased T regs in the peripheral blood coincident with increased TILs in the tumor bed in other malignant diseases.[65–68] These seminal findings are consistent with studies in murine models demonstrating that depletion of T regs can significantly augment the efficacy of cancer vaccination.[69] Together, these data suggest that T regs are selectively recruited to developing lung tumors, where they contribute to the immunosuppressive microenvironment that facilitates progression and metastasis. Likewise, the data suggest that T reg status can serve as an indicator of responsiveness to certain therapeutic regimens.

One of the first studies to link T reg cell recruitment and prognosis, although not for lung cancer, came from Curiel et al.,[70] who discovered that an increase in the number of tumor T regs was a significant predictor of increased risk for death and reduced survival in those with ovarian cancer. They also discovered that tumor cells and tumor-adjacent macrophages were contributors of the CCL22 chemokine that mediated trafficking of the T regs to the tumor. This was the first report of functional CCL22 within the lung TME and the earliest indication that blocking CCL22 in vivo reduces human T reg cell tumor trafficking. This report paved the way for those that followed seeking to develop novel immune-boosting strategies based on eradication of the T reg cell population in patients with cancer.

Lastly, our group reported on the phenomenon of cycloxygenase-2 (COX-2) and PGE$_2$ inhibition of immune responses in lung cancer via promotion of T reg activity. Numerous studies have now demonstrated that PGE$_2$ enhances the in vitro inhibitory function of T regs and induces a regulatory phenotype in T helper cells.[71–73] These and other basic and translational research investigations have informed our understanding of the role of CD4$^+$CD25$^+$ T regs in the developing lung TME, collectively suggesting that the development of clinical strategies to reduce the suppressive effects of these T regs in lung cancer is warranted. Efforts directed at ablating the suppressive activities of T regs have included clinical trials that use total lymphodepletion.[74–76] Others have evaluated immunotoxins to specifically ablate the T reg population,[77] and ongoing clinical investigations are assessing the role of celecoxib in controlling T reg numbers, activity, and differentiation in human NSCLC. While lymphodepletion or therapy with T reg immunotoxins may prove beneficial, COX-2/PGE$_2$ inhibition has additional potential benefits in the setting of NSCLC. In addition to the potential capacity to clinically decrease T reg cell function, COX-2 inhibition has been found to limit angiogenesis, decrease tumor invasiveness, and decrease tumor resistance to apoptosis in NSCLC.[78–80] These pathways and malignant phenotypes may be inhibited by several different agents in the class of nonsteroidal anti-inflammatory drugs.[81] Therefore, trials are evaluating COX inhibition in combination with other therapies.[80] Such studies will help further define the required interventions in this pathway and lead to more specifically targeted agents to diminish T reg cell activities in cancer. These agents could then be combined with other immune-based clinical therapies in an informed manner.

Dendritic Cells

In a seminal publication, Dieu-Nosjean et al.[46,82,83] identified ectopic lymph nodes or tertiary lymphoid structures within human NSCLC specimens and correlated their cellular content with clinical outcome. Specifically, the density of mature dendritic cells within these structures was a predictor of long-term survival in patients with lung cancer.[46] These findings were the first to suggest that ectopic lymph nodes participate in the host's antitumor immune response and are consistent with now abundant preclinical and clinical data.[84–88] For example, in murine tumor models, dendritic cells genetically modified to secrete CCL21 were reported to produce lymphoid cell aggregates and prime naïve T cells extranodally within a tumor mass, resulting in the generation of tumor-specific T cells and subsequent tumor regression.[85,89] Thus, the intratumoral approach may achieve tumor antigen presentation by utilizing the tumor as an in vivo source of antigen for the dendritic cells. In contrast to in vitro immunization with purified peptide antigen(s), autologous tumor has the capacity to provide the activated dendritic cells administered at the tumor site access to the entire repertoire of available antigens in situ. This may increase the likelihood of a response and reduce the potential for tumor resistance due to phenotypic modulation.

Dendritic cells are the most potent antigen-presenting cell capable of inducing primary immune responses.[90] Dendritic cells express high levels of major histocompatibility complex and costimulatory molecules, such as CD40, CD80, and CD86. Dendritic cells also release high levels of cytokines and chemokines into the TME that attract antigen-specific T cells in vivo. These properties, combined with efficient capture of antigens by immature dendritic cells, allow them to efficiently present antigenic peptides and costimulate antigen-specific naïve T cells.[90] Presentation of tumor-associated antigens by dendritic cells and their recognition by CTLs play an important role in the eradication of tumor cells.[91] Based on the importance of dendritic cells in tumor immunity, a variety of strategies have been used to exploit this cell type in cancer immunotherapy.[92–94] Advances in the isolation and in vitro propagation of dendritic cells, combined with identification of specific tumor antigens, have facilitated the start of clinical trials to evaluate dendritic cell-based vaccines,[92–94] and dendritic cell transfer has since been demonstrated to be a safe approach for clinical evaluation.[95–100]

Strategies involving the use of dendritic cells in immunotherapy have included pulsing isolated dendritic cells with tumor antigen peptides, apoptotic tumor cells, or tumor lysates ex vivo.[101–103] Dendritic cells have also been genetically modified with genes encoding tumor antigens or immunomodulatory proteins.[104–106] There is evidence that dendritic cells transduced with adenoviral vectors (AdV) have prolonged survival and resistance to spontaneous and Fas-mediated cell death, suggesting their utility in delivering immunotherapy more efficiently and robustly.[107] AdV transduction itself can also augment the capacity of dendritic cells to induce protective antitumor immunity.[108] In addition, enhanced local and systemic antitumor effects have been demonstrated when AdV-transduced dendritic cells expressing cytokine genes have been injected intratumorally.[109] AdVs are often used to transduce dendritic cells, because they efficiently induce strong heterologous gene expression in these cells.[108,109]

C-C motif chemokine ligand 21 (CCL21) is a cysteine-cysteine motif (CC) chemokine that belongs to a family of proteins involved in leukocyte chemotaxis and activation. Expressed in high endothelial venules and T cell zones of the spleen and lymph nodes, CCL21 exerts potent attraction of naïve T cells and mature dendritic cells, promoting their colocalization in secondary lymphoid organs and promoting cognate T cell activation.[110] Potent antitumor properties of CCL21 in murine cancer models have been reported.[111–113] CCL21 has also shown antiangiogenic activities in mice, thus strengthening its immunotherapeutic potential in cancer.[114,115] Based on the so-called ectopic lymph node concept posited by Dieu-Nosjean et al.[46] and the body of dendritic cell (DC)-CCL21 preclinical data available at the time,

our group initiated a phase I clinical trial at the University of California, Los Angeles in patients with advanced stage NSCLC. The trial consisted of intratumoral administration of autologous DCs transduced with a replication deficient adenoviral vector to express the CCL21.[116] In situ vaccination with DC-CCL21 was well tolerated and induced systemic tumor antigen-specific immune responses and enhanced CD8+ T cell infiltration of the primary tumor. This study is one clinically relevant approach by which to harness the cellular component of the TME and manipulate the soluble component of the TME to the advantage of patients.

PROTOTYPICAL CELL-SECRETED PRODUCTS COMPRISING THE SOLUBLE COMPONENT OF THE DEVELOPING LUNG TUMOR MICROENVIRONMENT

Chronic or dysregulated inflammation in the pulmonary microenvironment characterizes pulmonary diseases associated with the greatest risk for the development of lung cancer, such as emphysema, chronic obstructive pulmonary disease, and pulmonary fibrosis.[117–119] Here, we will discuss the induction, targeting, and potential/pitfalls associated with manipulating the following prototypical inflammatory mediators found in the developing lung TME: IL-2, IL-6, and transforming growth factor-beta (TGF-β).[120]

Interleukin-2

IL-2, produced by T cells during an immune response,[121] is necessary for the growth, proliferation, and differentiation of naïve T cells into effector T cells. The use of IL-2 is approved by the US Food and Drug Administration (FDA) for cancer immunotherapy, and it is currently in clinical trials for the treatment of chronic viral infection.[122] Combination treatment with IL-2 and anti-IL-2 monoclonal antibodies protects against tumor metastases in the lung,[123] and although pulmonary edema was a side effect, high-dose IL-2 led to an antitumor response against pulmonary tumor nodules.[124] IL-2 with a D20T mutation retains the antimetastatic activity of IL-2 via its interaction with the high-affinity IL-2 receptor, but it has a lower toxicity profile.[125] Of interest is a recent study demonstrating that acupoint stimulation elicited a pronounced immunomodulatory effect among patients with lung cancer, as shown by increased production of IL-2.[126] Collectively, these studies support the potential of harnessing IL-2 production for the benefit of patients.

Interleukin-6

IL-6 is a multifunctional cytokine that can act as both a proinflammatory and an anti-inflammatory mediator. It is secreted by T cells and macrophages to stimulate immune responses, and increased levels of IL-6 have been associated with trauma, infection, and elevated cancer risk. IL-6 function is mediated primarily through the Janus kinase-signal transducer and activator of transcription-zinc finger protein 1–2 signaling pathway, and an elevated level of IL-6 has been shown to increase the production of collagen and alpha-actin, which together induce interstitial lung disease. High levels of IL-6 are also responsible for enhanced neoangiogenesis, inhibition of cancer cell apoptosis, and dysregulation of other control mechanisms in the TME.[127] IL-6 has also been implicated in acquired resistance to EGFR inhibitors in patients with lung cancer. Furthermore, IL-6 is associated with poor prognosis and many of the debilitating symptoms that often affect patients with late-stage lung cancer, such as fatigue, thromboembolism, cachexia, and anemia. Consequently, a monoclonal antibody targeting IL-6 (ALD518) was recently developed to treat these IL-6-dependent morbidities. In preclinical, phase I, and phase II trials in advanced stage NSCLC, ALD518 appears to be well tolerated and to effectively ameliorate anemia and cachexia.[128]

Transforming Growth Factor-β

TGF-β is a cytokine that controls proliferation, cellular differentiation, and other functions in most cells. Secreted by many cell types, including macrophages, it plays a role in immunity and carcinogenesis. When a cell is transformed into a cancer cell, parts of the TGF-β signaling pathway are mutated, resulting in proliferation of the cancer cells and surrounding stromal cells (fibroblasts). Additionally, both cell types increase their production of TGF-β, which then acts on the surrounding stromal, immune, endothelial, and smooth-muscle cells to induce immunosuppression and angiogenesis and to make the cancer more invasive.[129] TME-derived TGF-β induces malignant phenotypes, such as epithelial mesenchymal transition (EMT) and aberrant cell motility, in lung cancer. TGF-β-induced translocation of β-catenin from E-cadherin complexes into the cytoplasm is involved in the transcription of EMT target genes.[130] Many studies have indicated that high levels of TGF-β characterize most tumor tissues, primarily released from tumor cells to maintain their metastatic potential and the protumorigenic TME.[131]

A TME enriched in TGF-β is broadly immunosuppressive, in part, due to its inhibition of natural killer cell function. Several studies have shown that miR-183-dependent repression of DNA polymerase III subunit tau (DNAX) activating protein 12 kDa (*DAP12*) transcription and translation in NSCLC is mediated by TGF-β.[132,133] TGF-β also converts effector T cells into T regs. Of interest, IL-6 enhances epithelial cell EMT and stimulates tumor progression by enhancing TGF-β signaling. Thus, IL-6 and TGF-β may play a contributing role in the maintenance of a paracrine loop between fibroblasts and NSCLC cells that facilitates tumor progression.[134] Like IL-6, TGF-β is a pleiotropic inflammatory mediator that interacts with premalignant lesions and the developing tumor in ways that are malleable and potentially manipulatable for the advantage of patients.

RECENT ATTEMPTS TO MOLECULARLY DEFINE THE FIELD COMPONENT OF THE LUNG TUMOR MICROENVIRONMENT

In our review of the recent translational research, several studies highlight the field's renewed appreciation for the urgent need to better define the key events driving lung carcinogenesis, if we are to ever achieve effective targeted lung cancer prevention. In the first of these studies, Ooi et al.[135] identified molecular alterations that characterize premalignant lesions and carcinogenesis in lung squamous cell carcinoma using a novel approach. In this first report of a gene expression profiling study of airway premalignant lesions and patient-matched normal tissue and squamous cell carcinoma samples, the authors discovered transcriptomic changes and identified genomic pathways altered with initiation and progression of squamous cell carcinoma within individual patients. Additionally, their analysis identified coordinate changes in the activity of upstream regulators and the expression of downstream genes within the same patient during early- and late-stage carcinogenesis, enhancing our understanding of the stepwise carcinogenesis of squamous cell carcinoma. In another study, by Perdomo et al.,[136] next-generation sequencing of small RNA from human bronchial airway epithelium identified miR-4423 as a regulator of airway epithelium differentiation and a repressor of lung carcinogenesis. Expression of miR-4423 is downregulated in the cytologically normal bronchial airway epithelium of smokers with lung cancer, which suggests that expression of miR-4423 and/or other miRNAs may be influenced by a field cancerization

effect and could be useful for the early detection of lung cancer in the relatively accessible proximal airway. Inflammation-induced upregulation of the zinc-finger transcription factor Snail has also been demonstrated to contribute to diverse aspects of lung carcinogenesis and progression, including EMT and angiogenesis.[137,138] Snail was previously shown to be upregulated in human NSCLC tissues, to be associated with poor prognosis in patients, and to have promoted cancer cell growth and progression in vivo.[138] More recently, we discovered that one mechanism by which Snail acts is via upregulation of secreted protein, acidic and rich in cysteine (*SPARC*), which drives SPARC-dependent invasion in a model of human lung premalignancy.[139]

The literature now suggests that the adjacent histologically normal-appearing epithelium is a participant in the dynamic process of lung tumor initiation and carcinogenesis. Work to define the interconnectedness of the field of cancerization to the other components of the TME and the developing or established primary tumor may be a rich source for biomarkers of initiation, progression, and targets for prevention and therapy. Development of more accurate in vitro and in vivo models of human premalignancy and lung carcinogenesis will further advance these efforts.

RECENT ATTEMPTS TO MANIPULATE THE CELLULAR (IMMUNITY) AND SOLUBLE (INFLAMMATION) COMPONENTS OF THE TUMOR MICROENVIRONMENT FOR LUNG CANCER CHEMOPREVENTION AND THERAPY

One of the consequences of the inflammatory TME is suppression of antitumor immunity, thus recent strategies have been designed to specifically target the immune system. As mentioned briefly, one approach to enhance immune responses is DC-based vaccines, in which DCs are used as a vehicle to intratumorally deliver chemokines and subsequently redirect the trafficking of immune cells into the tumor and enhance their activation.[82,116] Using two murine models of lung cancer, we demonstrated for the first time that intratumoral administration of recombinant CCL21 could lead to potent immune-dependent antitumor responses and, consequently, reduce tumor growth.[140] Importantly, CCL21-mediated antitumor responses were lymphocyte-dependent. Therapy did not alter tumor growth in severe combined immunodeficiency mice, whereas intratumoral injection of CCL21 led to a significant increase in CD4+ and CD8+ T lymphocytes and DCs infiltrating both the tumor and draining lymph nodes in immunocompetent mice. Further studies in *CD4* and *CD8* gene knockout mice determined that both CD4+ and CD8+ T cell subsets accounted for the CCL21-mediated tumor regression.[140] Intratumoral administration of CCL21 gene-modified DCs was also shown to generate systemic antitumor responses and confer tumor immunity via recruitment and activation of T effector cells in a transplantable and a spontaneous bronchoalveolar cell carcinoma model of lung cancer.[141,142] These studies additionally demonstrated that elaboration of CCL21 in the tumors by DCs promotes the CXCR3/CXCR3 ligand efferent arm of the immune response for the modulation of antitumor activity; i.e., neutralization of the CXCR3 ligands CXCL9 or CXCL10 inhibited the antitumor responses.[82,141]

As the number of circulating competent DCs is decreased in patients with lung cancer,[143] injecting DCs within the lung tumor site may be a particularly effective approach. In fact, there is a relationship between tumor-infiltrating DC aggregation and apoptosis in situ in human NSCLC.[144] To this end, intratumoral administration of clinical grade CCL21-transduced DCs was evaluated in a phase I clinical trial for late-stage NSCLC.[116] Patients with stage IIIB/IV NSCLC with a tumor accessible by computed tomography–guided or bronchoscopic intervention and disease refractory to standard therapy were selected. The objectives of the trial were to (1) determine the safety and

maximum tolerated dose of CCL21 gene-modified DCs (Ad-CCL21-DC) when administered into the primary lung cancer of patients with advanced NSCLC and (2) determine the local and systemic biologic activity of AD-CCL21 DC. Intratumoral vaccination with Ad-CCL21-DC was well tolerated and resulted in (1) induction of systemic tumor antigen-specific immune responses and (2) enhanced tumor CD8+ T cell infiltration accompanied by increased *PD-L1* expression.[82,116] Thus, DCs are a cellular component of the TME that can be utilized to redistribute soluble components of the TME (e.g., CCL21), ultimately redirecting trafficking of the immune cells into the tumor and enhancing specific immune activation. DC-CCL21 in situ vaccination will next be evaluated in combination with checkpoint inhibitor therapy.

Intratumoral immunization represents another avenue for reversing cancer-induced immunotolerance, allowing an antitumor response to occur.[145–147] This strategy has recently been supported by the positive results of clinical trials in metastatic melanoma, renal cell carcinoma, and NSCLC, cancers with low sensitivity to conventional cytotoxic therapies.[146] Two families of drugs that are currently directed at the immune system and in clinical development include pattern recognition receptor agonists (PRRago) and immunostimulatory monoclonal antibodies (immune checkpoint inhibitors). In contrast to conventional anticancer drugs, these immunostimulatory drugs can be directly delivered into the tumor and generate a systemic antitumor immune response. Furthermore, intratumoral delivery can potentially trigger more potent antitumor immune responses while causing less autoimmune toxicity.

PRRs constitute a growing family of receptors that recognize pathogen-associated molecular patterns, such as viral DNA or bacterial cell wall molecules, and damage-associated molecular patterns (DAMP) that are released upon cell death, stress, or tissue injury. PRRs are typically known for their role in the activation of immune responses against infectious pathogens, and evidence now suggests that activation of PRRs, such as toll-like receptors (TLRs) expressed by immune cells, also plays a role in immune responses against tumor cells.[146] In this regard, it has been demonstrated that TLR stimulation of antigen-presenting cells within mice and in the human TME modifies their phenotype from tolerogenic to immunogenic, with an upregulation of class II major histocompatibility complex, CD80, and CD86.[148,149] TLRs can also be expressed by tumor cells, and the direct activation of these TLRs can result in the death of the targeted tumor cell and/or upregulate antigen-presentation molecules.[150,151] Furthermore, with chemotherapy or tumor-targeted therapy, tumor cells can release DAMPs, which can then stimulate the immune cells surrounding the tumor cells. This is exemplified by high mobility group protein B1, an intracellular protein released in the TME upon tumor cell death that is subsequently recognized by TLR-4 expressed on tumor-infiltrating immune cells. Although the mechanism of the therapeutic effect of intratumoral PRRago is multifactorial, depending on the tumor cell type, the TME, and the PRRago used, a common feature is stimulation of tumor-infiltrating antigen-presenting cells, including B cells, DCs, tumor-associated macrophages, and other myeloid-derived suppressor cells. It should be noted, however, that although activation of tumor-infiltrating antigen-presenting cells is a prerequisite for mounting an efficient adaptive antitumor immune response against tumor-associated antigens, it does not address immunosuppressive tumor-infiltrating T regs and exhausted tumor-infiltrating CTLs.

Immunostimulatory monoclonal antibodies are designed to reverse tumor immunotolerance and stimulate antitumor immune responses by targeting checkpoints for T cell activation. Of the checkpoint inhibitors in clinical development, the anti-CTL antigen-4 (CTLA-4) monoclonal antibody ipilimumab has already been approved for metastatic melanoma.[146,147] CTLA-4 is a cell surface receptor constitutively expressed by FOXP3+ CD4+ T regs, and it is a critical negative immune checkpoint that limits the induction of potent CTL responses. In two randomized phase III clinical trials,

systemic intravenous therapy with ipilimumab generated long-lasting tumor responses in up to 20% of patients with refractory/relapsing melanoma.[152,153] However, this therapy was associated with major autoimmune toxicities requiring high-dose corticosteroids in about 60% of patients treated. The efficacy of anti-CTLA-4 has thus far been attributed to its ability to block the inhibitory interaction of CTLA-4 expressed on effector T cells with CD80/86 expressed by tolerogenic tumor antigen-presenting cells and, more recently, to intratumoral depletion of T regs rather than an interaction with CD4[+] effector T cells.[146,147,152,153] Intratumoral tumor-specific T regs express high levels of CTLA-4, which can be depleted by therapy with anti-CTLA-4 via FcγR[+] tumor-infiltrating cells.[146] Although no biomarkers exist to definitively predict which patients will benefit from anti-CTLA-4 therapy, there is a pattern in which a pretreatment gene signature demonstrating CD8 T cell infiltrates and CD8-attracting chemokines is, at least to some degree, positively correlated with benefit.[154] Current use of anti-CTLA-4 agents in NSCLC is still limited to phase I–III trials.

Based on the positive results of anti-CTLA-4 monoclonal antibodies, a second negative immune checkpoint mediated through interactions of PD-1 with its ligands PD-L1 and PD-L2 has been investigated as a target for cancer immunotherapy.[145–147] Monoclonal antibodies targeting the PD-1/PD-L1 axis have demonstrated strong and encouraging clinical activity in patients with metastatic melanoma, renal cell carcinoma, and NSCLC.[155,156] Late-phase clinical trials of these anti-PD-1 agents in patients with advanced lung cancers translated into improved clinical outcomes compared with standard-of-care chemotherapy.[157–161] Thus, two of the agents, nivolumab and pembrolizumab, are now FDA-approved for NSCLC in the second-line setting.[157,158] FDA approval for these agents as first-line therapy for NSCLC is anticipated. Importantly, preclinical models have demonstrated that the efficacy of immunostimulatory monoclonal antibodies may be potentiated when used in combination. Indeed, in murine models of melanoma, the combination of anti-PD-1 and anti-CTLA-4 monoclonal antibodies may be more effective than either agent alone, due to the complementary functional roles of these two negative immune checkpoints. Intratumoral injection of immunostimulatory agents is also postulated to have a potentiating effect. Local delivery, rather than systemic, allows concentration of the agent in the TME, limiting the toxicity of the monoclonal antibodies and increasing the efficacy of PRRago. This strategy relies on accessibility of the tumor site for injection, however, which can be an issue if repeated injections are needed.

As with anti-CTLA-4 therapy, no definitive predictive biomarkers exist for monoclonal antibodies targeting the PD-1/PD-L1 axis. However, transcriptomic profiling and whole-exome sequencing of melanoma from patients treated with anti-PD-1, a subset of whom had received prior mitogen-activated protein kinase inhibitor treatment, has given us insight into the relevance of transcriptomic changes and tumor mutations to therapeutic responsiveness.[162] Description of an innate anti-PD-1 resistance signature (IPRES) consisting of a set of coenriched genes in nonresponders is an important first step toward the identification of better biomarkers of response. With the approval of nivolumab and pembrolizumab for NSCLC, similar advances may soon be brought to bear against lung cancer as well. In addition to their report of a melanoma IPRES, Hugo et al.[162] also described a correlation between tumor mutational load and improved patient survival, but no statistically significant association between high mutational load and response to anti-PD-1 therapy was observed. Conversely, a number of other groups have reported a positive correlation between overall mutational load and both anti-CTLA-4 and anti-PD-1 treatment responsiveness.[162–166] There are still other preclinical reports suggesting that it is not mutational load in general that predicts response, but rather key driver mutations specifically upregulate PD-L1 for the purpose of immune evasion, thereby linking those specific mutations to anti-PD-1 treatment responsiveness.[145,167,168] For example, Akbay

et al.[145] suggest that EGFR-driven tumors may be characterized by host T cell exhaustion via upregulation of the PD-1/PD-L1 axis. Using a mouse model of EGFR-driven lung cancer, the authors demonstrated that administration of anti-PD-1 monoclonal antibodies reduced tumor growth and improved survival by enhancing T cell effector function and reducing the levels of tumor-promoting cytokines. Preclinical investigations of *KRAS* and *MYC* driver mutations also identify upregulation of PD-L1 by these oncogenic drivers, along with a concomitant increase in other key tumorigenic phenotypes.[167,168] Perhaps in alignment with these preclinical observations, Rizvi et al.[158,169] found that mutations in *KRAS* were evident in 7 of 14 tumors from NSCLC patients with partial or stable response >6 months compared with 1 of 17 in those that had no durable benefit from pembrolizumab. However, this finding may be explained by the association between *KRAS* mutations in NSCLC with smoking, given that smokers often harbor a substantially greater mutational load with each mutation serving as a potential source of neoantigens.[169,170]

CONCLUSION

Although the epithelial compartment remains central, investigators now understand that lung carcinogenesis proceeds in complicity with each of the four main components of the TME—the field, cellular, soluble, and stromal components. The epithelial and field compartments are definitively interconnected, but a more complete understanding of the molecular pathogenesis of lung cancer is required for the development of biomarker signatures, noninvasively obtained from the field, that are useful for risk assessment, diagnosis, disease monitoring, and predicting adjuvant therapy efficacy following surgery. Numerous cell types and cell-secreted products comprise the developing lung TME, and there are both advantages and disadvantages associated with attempting to harness each for the benefit of patients. Our review of the most recent translational and clinical literature highlights the field's evolving approach to the manipulation of these two particular TME components, including the rise of immunotherapeutics targeting the tumor-TME interface. On the whole, targeting the interplay between the epithelial compartment and the developing lung TME as a lung cancer prevention and therapy strategy has clear clinical potential that finally appears to be approaching fruition.

15 MicroRNAs as Biomarkers for Lung Cancer

William C.S. Cho

SUMMARY OF KEY POINTS

- The biologic roles of microRNAs (miRNAs) in lung cancer indicate their correlation with disease status, prognosis, and therapeutic outcome. The discovery of miRNAs has opened a new avenue for individualized disease diagnosis and treatment.
- Dysfunctions of miRNAs are frequently found in lung cancer. These noncoding RNAs have been recognized as some of the main regulatory gatekeepers of coding genes in the human genome.
- Owing to their high stability during storage and handling, miRNAs are optimal biomarkers presenting in blood, urine, and other body fluids.
- Early detection is a key to improve the survival of patients with lung cancer. Recent studies have suggested that circulating miRNAs may become promising biomarkers for risk assessment and diagnosis of lung cancer in blood and sputum.
- Some single nucleotide polymorphisms (SNPs) are significantly associated with an increased risk of nonsmall cell lung cancer (NSCLC) and its prognosis.
- Identification of specific miRNAs may provide accurate subclassification of NSCLC.
- Recent studies have demonstrated that miRNAs may serve as predictive biomarkers for the chemoresistance of lung cancer among patients treated with systemic chemotherapy and/or targeted therapies.
- Large prospective cohort studies and cross-validation are needed to consolidate the significant findings demonstrated by studies of miRNA profiling.
- In conjunction with genetic and proteomic signatures and other screening approaches, miRNA biomarkers may represent a new milestone in lung cancer theranostics.

miRNAs are a class of evolutionarily conserved, endogenous, small noncoding RNAs of about 21 to 23 nucleotides in length that participate in diverse biologic pathways and function as posttranscriptional gene regulators during tumorigenesis. These small molecules mainly bind imperfectly to the 3′ untranslated region (UTR) of target messenger RNAs (mRNAs). They are encoded in the genome and are generally transcribed by RNA polymerase II. miRNAs work via RNA-induced silencing complexes to target mRNAs in a sequence-specific manner, resulting in mRNA deadenylation followed by exonucleolytic decay, mRNA endonucleolytic cleavage, or translational inhibition. Deregulation of miRNAs is associated with epigenetic and genetic alterations, such as aberrant DNA methylation, amplification, deletion, and point mutation.[1] More than 1000 miRNAs exist in the human genome, and each one can potentially regulate hundreds of mRNAs. miRNAs therefore play an important role in many cellular processes, including apoptosis, differentiation, proliferation, and the stress response.[2]

Lung cancer is the leading cause of cancer mortality worldwide, yet few molecular markers are available for risk screening, subclassification, early diagnosis, survival prognosis, and prediction of treatment response. Researchers have suggested that aberrant miRNA expression profiles may act as oncogenes or tumor suppressors in many types of cancer, including lung cancer. The biologic roles of miRNAs in lung cancer indicate a correlation with disease status, prognosis, and therapeutic outcome. The discovery of miRNAs has opened a new avenue for individualized disease diagnosis and treatment.[3]

THE IMPORTANCE OF MICRORNAS IN LUNG CANCER

Implications of miRNAs in the Diagnosis of Lung Cancer

Identifying patients with early-stage lung cancer who will benefit the most from effective therapies may reduce the mortality of this deadly disease. Early detection is thus a key to improving the survival of patients with lung cancer. The results of investigational studies suggest that miRNAs may become promising biomarkers for risk assessment and diagnosis of lung cancer (Tables 15.1 and 15.2).

The let-7 family is a global genetic regulator important in controlling the expression of lung cancer oncogenes. Chin et al.[4] sequenced the let-7 complementary sites (LCS) in the Kirsten rat sarcoma (*KRAS*) 3′ UTR from 74 cases of NSCLC and identified a SNP at LCS6 significantly associated with an increased risk for NSCLC among moderate smokers (odds ratio, 2.3; 95% CI, 1.1–4.6). The LCS6 variant allele showed a 2.3-fold increase in risk for NSCLC among patients who smoked the equivalent of less than 40 pack-years.

A survey has reported that the SNP rs11614913 in miR-196a2 may affect mature miR-196a expression and target mRNA-binding activity and is significantly associated with survival from NSCLC. In a case–control study of 1058 patients with incident lung cancer and 1035 cancer-free controls in a Chinese population, Tian et al.[5] found that miR-196a2 rs11614913 variant homozygote CC was associated with a significant increase of approximately 25% (odds ratio, 1.25; 95% CI, 1.01–1.54) in the risk of lung cancer compared with the wild-type homozygote TT and heterozygote TC. To further determine whether any association exists between four common SNPs (miR-196a2 C>T, rs11614913; miR-146a G>C, rs2910164; miR-499 A>G, rs3746444; and miR-149 C>T, rs2292832) and the risk for lung cancer, He et al.[6] performed a meta-analysis of 40 published case–control studies. Their results demonstrated that the rs11614913 TT genotype was significantly associated with a decreased risk of lung cancer for an Asian population subgroup (TT vs. CC: odds ratio, 0.7; 95% CI, 0.57–0.85; *p* = 0.284). Squamous cell carcinoma is one major subtype of lung cancer for which biomarkers are urgently needed to aid patient management. Measuring the miRNA expression in cancerous and noncancerous tissue pairs collected from 60 Chinese patients with squamous cell carcinoma (stages I–III), Tan et al.[7] identified a panel of five miRNAs (miR-30a, miR-140-3p, miR-182, miR-210, and miR-486-5p) that distinguished squamous cell carcinoma from normal lung tissues with an accuracy of 94%. They also showed that high expression

TABLE 15.1 Single MicroRNAs (miRNAs) as Diagnostic Biomarkers for Lung Cancer

miRNAs	Deregulation in Cancer	Materials	Descriptions	References
let-7	Downregulated	Tissue/TTNA tissue	A SNP in a let-7 complementary site in the *KRAS* 3′ untranslated region increases NSCLC risk Profiling the let-7 family is a promising method for differentiating adenocarcinoma from squamous cell carcinoma, even in small specimens, such as those obtained with TTNA	[4,9]
let-7a	Downregulated	Serum	Expression levels show 0.74-fold change in cases vs. controls	[14]
miR-10b	Upregulated	Serum	High serum miR-10b value is associated with elevated level of tissue polypeptide antigen	[18]
miR-17-5p	Downregulated	Serum	Expression levels show 0.82-fold change in cases vs. controls	[14]
miR-25	Upregulated	Serum	The copy numbers of miR-25 are much higher in lung cancer than in healthy control samples	[16]
miR-27a	Downregulated	Serum	Expression levels show 0.87-fold change in cases vs. controls	[14]
miR-29c	Upregulated	Serum	The increased expression levels may reflect an increased systemic concentration of miR-29c in response to cancer processes	[14]
miR-106a	Downregulated	Serum	Expression levels show 0.87-fold change in cases vs. controls	[14]
miR-141	Upregulated	Serum	High serum miR-141 value is associated with elevated level of urokinase plasminogen activator	[18]
miR-145*	Downregulated	FFPE tissue	miR-145* inhibits cell invasion and metastasis	[22]
miR-146b	Downregulated	Serum	miR-146b is significantly decreased in lung cancer regardless of stage or histology	[14]
miR-155	Downregulated	Serum	Expression levels show 0.77-fold change in cases vs. controls	[14]
miR-196a2	Upregulated	Blood	Functional SNP rs11614913 in miR-196a2 can contribute to lung cancer susceptibility The rs11614913 TT genotype is associated with a significantly decreased risk of lung cancer for an Asian subgroup	[5,6]
miR-198	Downregulated	PE	Cell-free miR-198 from patients with lung adenocarcinoma may have diagnostic potential for differentiating malignant PE from benign PE	[19]
miR-205	Downregulated	FFPE tissue/TTNA tissue	miR-205 provides highly accurate subclassification of squamous cell carcinoma in NSCLC Profiling miR-205 is a promising method for differentiating adenocarcinoma from squamous cell carcinoma, even in small specimens such as those obtained with TTNA	[8,9]
miR-221	Downregulated	Serum	miR-221 is significantly decreased in lung cancer regardless of stage or histology	[14]
miR-223	Upregulated	Serum	The copy numbers of miR-223 are much higher in lung cancer than in healthy control samples	[16]
miR-328	Upregulated	FFPE tissue	miR-328 has a role in conferring migratory potential to NSCLC cells working in part through *PRKCA*	[21]

FFPE, formalin-fixed, paraffin-embedded; *NSCLC*, nonsmall cell lung cancer; *PE*, pleural effusion; *PRKCA*, protein kinase C, alpha; *SNP*, single nucleotide polymorphism; *TTNA*, transthoracic needle aspiration.

of miR-31 was associated with poor survival among patients with squamous cell carcinoma.

Recent advances in the treatment of lung cancer require greater accuracy in the subclassification of NSCLC. Using a high-throughput microarray to measure the miRNA expression levels in 122 samples of adenocarcinoma and squamous cell carcinoma, Lebanony et al.[8] identified miR-205 as a highly specific marker (96% sensitivity and 90% specificity) for squamous cell carcinoma. This standardized diagnostic assay may provide accurate subclassification of NSCLC. Fassina et al.[9] investigated the accuracy of miRNAs in differentiating squamous cell carcinoma from adenocarcinoma within scant and distorted specimens obtained by transthoracic needle aspiration. Quantification of the let-7 family and miR-205 expression levels in 18 adenocarcinoma and 13 squamous cell carcinoma specimens by quantitative reverse transcription-polymerase chain reaction (RT-PCR) showed a significant upregulation of the let-7 family and a significant downregulation of miR-205 in adenocarcinoma specimens (all, $p < 0.05$). Xing et al.[10] profiled miRNA expression signatures in 15 samples of lung squamous cell carcinoma and matched normal lung samples with an miRNA array (GeneChip; Affymetrix, Santa Clara, CA, USA). They identified three miRNAs (miR-205, miR-210, and miR-708) that distinguished the sputum samples of patients with stage I lung squamous cell carcinoma from

those of healthy individuals with 73% sensitivity and 96% specificity. Early detection is also the key to improving the survival of patients with lung adenocarcinoma. Using miRNA profiling on 20 paired samples of adenocarcinoma and normal lung tissue, Yu et al.[11] identified four miRNAs (miR-21, miR-200b, miR-375, and miR-486) that distinguished the sputum samples of patients with stage I lung adenocarcinoma from those of healthy individuals with 81% sensitivity and 92% specificity.

Other studies were designed to identify serum-based miRNAs with the ability to diagnose NSCLC at an early stage. Owing to their high stability during storage and handling, miRNAs are optimal biomarkers present in the blood, urine, and other body fluids.[12] Foss et al.[13] performed miRNA profiling on total RNA extracted from serum obtained from 11 patients with early-stage NSCLC and 11 controls. The authors found that the expression of miR-574-5p and miR-1254 was significantly increased in the samples of early-stage NSCLC with respect to the controls ($p = 0.0277$). Receiver operating characteristic curves plotting these two miRNAs were able to discriminate early-stage NSCLC from control samples with 82% sensitivity and 77% specificity. Using quantitative RT-PCR to measure the circulating levels of miRNAs in paired serum and plasma samples from 220 patients with early-stage NSCLC and 220 matched controls, Heegaard et al.[14] also demonstrated that the expression levels of let-7a,

TABLE 15.2 Combinations of MicroRNAs (miRNAs) as Diagnostic Biomarkers for Lung Cancer

miRNAs	Deregulation in Cancer	Materials	Descriptions	References
miR-20a	Upregulated	Serum	This 10-miRNA panel is correlated with the stage of NSCLC, especially in younger patients and patients who are current smokers	[15]
miR-24	Upregulated			
miR-145	Upregulated			
miR-152	Upregulated			
miR-199a-5p	Upregulated			
miR-221	Upregulated			
miR-222	Upregulated			
miR-223	Upregulated			
miR-320	Upregulated			
miR-21	Upregulated	Sputum	The combination of these four markers may improve the early detection of lung adenocarcinoma	[11]
miR-200b	Upregulated			
miR-375	Upregulated			
miR-486	Downregulated			
miR-28-3p	Downregulated	Plasma	These miRNAs in plasma may have a role as molecular predictors of lung cancer development and aggressiveness	[20]
miR-30c	Downregulated			
miR-92a	Upregulated			
miR-140-5p	Downregulated			
miR-451	Upregulated			
miR-660	Upregulated			
miR-30a	Downregulated	Tissue	This five-miRNA signature may be a new diagnostic classifier for squamous cell carcinoma among Chinese patients	[7]
miR-140-3p	Downregulated			
miR-182	Upregulated			
miR-210	Upregulated			
miR-486-5p	Downregulated			
miR-30a-30p	Upregulated	Plasma	This six-miRNA diagnostic test can discriminate between lung adenocarcinoma and granuloma	[17]
miR-100	Upregulated			
miR-151a-5p	Upregulated			
miR-154-3p	Upregulated			
miR-200b-5p	Upregulated			
miR-629	Upregulated			
miR-139-5p	Upregulated	Plasma	This four-miRNA screening test is useful to divide nodule and nonnodule groups	[17]
miR-200b-5p	Upregulated			
miR-378a	Upregulated			
miR-379	Upregulated			
miR-205	Upregulated	Sputum	The combination of these three markers may improve the early detection of lung squamous cell carcinoma	[10]
miR-210	Upregulated			
miR-708	Upregulated			
miR-574-5p	Upregulated	Serum	These two markers may be used as minimally invasive screening and triage tools for early-stage NSCLC	[13]
miR-1254	Upregulated			

NSCLC, nonsmall cell lung cancer.

miR-17-5p, miR-27a, miR-106a, miR-146b, miR-155, and miR-221 were significantly reduced in the serum of patients with NSCLC, whereas miR-29c was significantly increased (all, $p < 0.05$). Performing risk–score analysis to evaluate the diagnostic values of serum miRNA profiling among 400 patients with NSCLC and 200 controls, Chen et al.[15] showed that a panel of 10 serum miRNAs (miR-20a, miR-24, miR-25, miR-145, miR-152, miR-199a-5p, miR-221, miR-222, miR-223, and miR-320) accurately distinguished patients with NSCLC from controls even up to 33 months before the clinical diagnosis of NSCLC.

The levels of miRNAs in serum are stable, reproducible, and consistent among individuals of the same species. Chen et al.[16] used Solexa sequencing on serum miRNAs of human participants and obtained two miRNAs (miR-25 and miR-223) specific for NSCLC. The study conducted expression profiles of serum miRNAs in 21 healthy human patients and 11 NSCLC patients. Their results were validated in an independent cohort of 152 lung cancer patients and 75 healthy controls. The results of these analyses suggest that the copy numbers of these two serum miRNAs may serve as biomarkers for the detection of NSCLC. Cazzoli et al.[17] used exosome-based techniques to analyze the miRNAs of 30 plasma samples (10 lung adenocarcinomas, 10 lung granulomas, and 10 healthy smokers) and subsequently validated them on an independent group of 105 specimens. The results showed that a screening test of four miRNAs (miR-139-5p, miR-200b-5p,

miR-378a, and miR-379) was useful to divide the nodule and nonnodule groups (97.5% sensitivity, 72% specificity, and 90.8% area under the receiver operating characteristic curve [AUC]). The authors also developed a diagnostic test of six miRNAs (miR-30a-3p, miR-100, miR-151a-5p, miR-154-3p, miR-200b-5p, and miR-629) to discriminate between lung adenocarcinoma and granuloma (96% sensitivity, 60% specificity, and 76% AUC).

To examine whether circulating miRNAs have the potential to become suitable blood-based markers for the diagnosis and progression of lung cancer, Roth et al.[18] measured the concentrations of four miRNAs in the serum of 35 patients with lung cancer and seven patients with benign lung tumors. The levels of miR-10b ($p = 0.002$) and miR-141 ($p = 0.0001$) were significantly higher in patients with lung cancer than in patients with benign disease. High serum concentrations of miR-10b were also found to be associated with lymph node metastasis among patients with lung cancer. Circulating cell-free miRNAs in pleural effusion are also potential biomarkers for cancer. Using microarrays to screen miRNAs in 10 malignant pleural effusions associated with lung adenocarcinoma and 10 benign pleural effusions, Han et al.[19] showed that miR-198 was significantly downregulated in malignant pleural effusion compared with benign pleural effusion ($p = 0.002$). The results of miRNA microarray analysis were confirmed by quantitative RT-PCR using a validation set comprising 45 malignant pleural effusions associated with lung

adenocarcinoma and 42 benign pleural effusions. The AUC for miR-198 was 0.887.

Although early detection using chest x-ray and spiral computed tomography (CT) has resulted in a marked increase in the number of lung cancer diagnoses, these efforts may also lead to unnecessary treatments, and this possibility indicates the need for biomarkers of aggressive disease. Boeri et al.[20] explored the miRNA expression profiles of 74 plasma samples collected during the 5-year screening plan and identified 12 of 15 samples collected before lung cancer detection by spiral CT, with sensitivity of 80% and specificity of 90%. The 5-year screening plan was a longitudinal analysis of 3246 current or former smokers screened for lung cancer beginning in 1998 either in the United States or in Italy to assess whether CT screening might increase the frequency of lung cancer diagnosis. The median amount of follow-up from the initial CT evaluation to the mortality end point was nearly 5 years. The most frequently deregulated miRNAs were miR-28-3p, miR-30c, miR-92a, miR-140-5p, miR-451, and miR-660.

Brain metastasis affects approximately 25% of patients with NSCLC during their lifetime. Arora et al.[21] performed miRNA microarray profiling on samples from seven patients with NSCLC with brain metastasis and six without brain metastasis, and confirmed that the expression of miR-328 was able to correctly classify patients with and without brain metastasis. This miRNA may be incorporated into clinical treatment decision making to stratify patients with NSCLC who have a higher risk for brain metastasis. Profiling miRNAs extracted from 527 stage I NSCLCs on the human miRNA expression profiling panel, Lu et al.[22] found that miR-145* was associated with brain metastasis by virtue of inhibiting cell invasion and metastasis. This miRNA holds potential as a target for preventing and treating brain metastasis among patients with stage I NSCLC.

MicroRNAs as Prognostic Biomarkers for Lung Cancer

Despite the availability of effective treatments, recurrence is common even for early-stage lung cancer. Prognostic biomarkers that can predict tumor progression and survival are required to provide better guidance on postoperative surveillance and therapeutic decisions for patients with lung cancer. Recent evidence suggests that specific miRNAs with altered expression levels have great potential to serve as prognostic biomarkers for lung cancer (Tables 15.3 and 15.4).

Takamizawa et al.[23] reported that the expression of let-7 was able to classify 143 cases of human NSCLC into two major groups. Reduced expression of let-7 was significantly associated (p = 0.0003) with shorter postoperative survival, suggesting the potential prognostic impact of this miRNA alteration. Yanaihara et al.[24] also found that low expression of let-7a-2 and high expression of miR-155 correlated with poor survival of 65 patients with lung adenocarcinoma.

Evaluating the miRNA expression levels in 48 pairs of NSCLC tissue specimens by looped real-time RT-PCR, Markou et al.[25] detected a significant correlation (p = 0.027) between miR-21 overexpression and overall survival of patients with NSCLC. These results indicate that miRNA expression profiles may be prognostic markers of lung cancer. Saito et al.[26] also tested the expression of specific miRNAs by quantitative RT-PCR in tissues from 317 patients with lung adenocarcinoma. Elevated miR-21 was associated with worse cancer-specific mortality and worse relapse-free survival independent of other clinical factors in patients with stage I disease; these findings suggest that expression of miR-21 may contribute to lung carcinogenesis and serve as an early-stage prognostic biomarker for lung adenocarcinoma. Evaluating a combination four-gene panel (breast cancer 1 [*BRCA1*], hypoxia inducible factor 1, alpha [*HIF1A*], deleted in liver cancer 1 [*DLC1*], and exportin 1 [*XPO1*]) with miR-21

expression from 148 patients with stage I lung adenocarcinoma, Akagi et al.[27] found that the combination improved the association with prognosis. To synthesize the evidence of miR-21 as a prognostic biomarker in lung cancer, Yang et al.[28] conducted a meta-analysis for miR-21 with a median study size of 88 patients. The pooled hazard ratio suggested that high expression of miR-21 has a negative impact on relapse-free survival in lung adenocarcinoma and on overall survival in NSCLC. Their results also indicated that miR-21 can predict recurrence and poor survival in NSCLC.

Profiling 61 lung squamous cell carcinoma samples on miRNA bioarrays, Raponi et al.[29] showed that miR-146b and miR-155 have prognostic value in squamous cell carcinomas. Used alone, miR-146b had the strongest prediction accuracy, at approximately 78%, for stratifying prognostic groups in lung squamous cell carcinoma. Analyzing 140 pairs of NSCLC paraffin-embedded specimens and their corresponding adjacent noncancerous tissues, Cai et al.[30] discovered a uniform decrease in miR-186 expression correlating with poor survival, with median overall survival time of 63.0 or 21.5 months among patients with high or low levels of miR-186, respectively. Enforced overexpression of miR-186 in NSCLC cells inhibits proliferation by inducing G1-S checkpoint arrest. Their findings establish a tumor-suppressive role for miR-186 in the progression of NSCLC.

Profiling miRNA expression in 103 pairs of matched lung adenocarcinoma samples from never-smokers, Jang et al.[31] found that a high expression level of miR-708 in the tumors was strongly associated with an increased risk of death after adjustment for all clinically significant factors including age, gender, and tumor stage. This miRNA acts as an oncogene contributing to tumor growth and disease progression by directly down-regulating *TMEM88*, a negative regulator of the Wnt signaling pathway in lung cancer. Meng et al.[32] conducted genome-wide miRNA sequencing in primary cancer tissue from patients with lung adenocarcinoma and found that miR-31 was upregulated among patients with lymph node metastases compared with patients without lymph node metastases. This marker was validated in an external cohort of 233 cases of lung adenocarcinoma in The Cancer Genome Atlas (https://wiki.nci.nih.gov/display/TCGA/miRNASeq). Exploratory in-silico analysis showed that low expression of miR-31 was associated with excellent survival for T2 N0 patients.

Discovering prognostic markers that can predict relapse is a key part of cancer research. Campayo et al.[33] assessed miRNA expression in 70 resected NSCLC samples (TaqMan miRNA assays; Life Technologies, Carlsbad, CA, USA) and found that the mean time to relapse was 18.4 months for patients who had tumors with low levels of miR-145 and 28.2 months for patients who had tumors with high levels. The mean time to relapse was 29.1 months for tumors with low levels of miR-367 and 23.4 months for tumors with high levels. The expression levels of these miRNAs can be potential markers for relapse in surgically treated NSCLC.

The miR-34 family is part of the p53 network, and its expression is directly induced by p53 in response to DNA damage or oncogenic stress. In a study using stem-loop RT-PCR to analyze the expression of the miR-34 family in tumor tissues from 70 patients with surgically resected NSCLC, Gallardo et al.[34] found that low levels of miR-34a expression were correlated with a high probability of relapse. Patients with both *p53* mutations and low miR-34a levels had the highest probability of relapse. Nadal et al.[35] assessed the aberrant methylation and expression of miR-34b/c in 15 lung adenocarcinoma cell lines and a cohort of 140 patients with early-stage, surgically resected lung adenocarcinoma. They found that expression of miR-34b/c was significantly reduced (p = 0.001) in all methylated cell lines and primary tumors, especially in those harboring a *TP53* mutation. Patients who had tumors with high levels of miR-34b/c methylation had

TABLE 15.3 Single MicroRNAs (miRNAs) as Prognostic Biomarkers for Lung Cancer

miRNAs	Deregulation in Cancer	Materials	Descriptions	References
let-7	Downregulated	Tissue	Overexpression of let-7 in NSCLC cells inhibits cell growth in vitro	[23]
let-7a-2	Downregulated	Tissue	Low expression of let-7a-2 correlates with poor survival of patients with lung adenocarcinoma	[24]
let-7f	Upregulated	Plasma	Expression level of let-7f is associated with overall survival in NSCLC	[42]
miR-16	Downregulated	Serum	High expression of miR-16 is associated with significantly better survival in patients with advanced NSCLC	[44]
miR-21	Upregulated	Tissue	Overexpression of miR-21 is an independent negative prognostic factor for overall survival in NSCLC	[25,26,28]
			Inhibition of miR-21 inhibits cell growth in vitro and inhibits tumor growth in xenograft mouse models of lung adenocarcinoma	
			High expression of miR-21 has a negative impact on relapse-free survival in lung adenocarcinoma and overall survival in NSCLC	
miR-30c-1	Downregulated	Tissue	The expression of the host nuclear transcription factor Y gene is correlated with pri-miR-30c-1, but not with rs928508 genotypes among patients with NSCLC	[40]
miR-30e-3p	Downregulated	Plasma	The expression level of miR-30e-3p is associated with short disease-free survival in NSCLC	[42]
miR-31	Upregulated	Tissue	miR-31 represses DICER1 activity but not PPP2R2A or LATS2 in lung squamous cell carcinoma	[7,32]
			In vitro functional assays show that miR-31 increases cell migration, invasion, and proliferation in an ERK1/2 signaling-dependent manner in lung adenocarcinoma	
miR-34a	Downregulated	Tissue	A relation has been found between *MIRN34A* methylation and miR-34a expression in NSCLC	[34]
miR-34b	Downregulated	Tissue	Overexpression of miR-34b decreases the expression of *c-Met* in NSCLC cells	[36]
miR-34b/c	Downregulated	Tissue	Ectopic expression of miR-34b/c in lung adenocarcinoma cells decreases cell proliferation, migration, and invasion	[35]
miR-145	Downregulated	Tissue	miR-145 regulates *SOX2* and *OCT4* translation, and *p53* regulates miR-145 expression	[33]
miR-146b	Upregulated	Tissue	High expression of miR-146b correlates with poor overall survival for patients with lung squamous cell carcinoma	[29]
miR-149	Downregulated	Tissue	miR-149 may be involved in the pathogenesis of NSCLC	[41]
miR-155	Upregulated	Tissue	High expression of miR-155 correlates with poor survival of patients with lung adenocarcinoma	[24,29]
			High expression of miR-155 correlates with poor overall survival for patients with lung squamous cell carcinoma	
miR-186	Downregulated	Cell line	*Cyclin D1, CDK2,* and *CDK6* are each directly inhibited by miR-186, and restoring their expression levels reverses miR-186-mediated inhibition of cell cycle progression	[30]
miR-196a	Upregulated	Tissue	miR-196a may be involved in the pathogenesis of NSCLC	[41]
miR-196a2	Upregulated	Tissue	rs11614913 CC is associated with a significant increase in mature miR-196a expression, but not with changes in levels of the precursor for NSCLC	[39]
miR-367	Upregulated	Tissue	SOX2 and OCT4 transcription factors regulate the expression of miR-367	[33]
miR-651	Downregulated	Blood	The FAS:rs2234978 G allele is significantly associated with survival in early-stage NSCLC, and the *FAS* single nucleotide polymorphism created a miR-651 functional binding site	[45]
miR-708	Upregulated	Tissue	Forced miR-708 expression reduces *TMEM88* transcript levels and increases the rate of cell proliferation, invasion, and migration in culture	[31]

TABLE 15.4 Combinations of MicroRNAs (miRNAs) as Prognostic Biomarkers for Lung Cancer

miRNAs	Deregulation in Cancer	Materials	Descriptions	References
let-7a	Downregulated	FFPE tissue	Low expression of these five miRNAs is associated with up to fourfold excess mortality for male smokers with early-stage squamous cell carcinoma	[38]
miR-25	Downregulated			
miR-34a	Downregulated			
miR-34c-5p	Downregulated			
miR-191	Downregulated			
let-7a	Downregulated	Tissue	Patients with NSCLC and a high risk score for this five-miRNA signature have increased risk of cancer relapse and shortened survival	[37]
miR-137	Upregulated			
miR-182*	Upregulated			
miR-221	Downregulated			
miR-372	Upregulated			
miR-1	Downregulated	Serum	Patients with NSCLC carrying two or more of these high-risk miRNAs have significantly increased probability of cancer death in a dose-dependent manner compared with patients carrying zero or one high-risk miRNA	[43]
miR-30d	Upregulated			
miR-486	Upregulated			
miR-499	Downregulated			

FFPE, formalin-fixed, paraffin-embedded; *NSCLC*, nonsmall cell lung cancer.

significantly shorter disease-free survival ($p = 0.016$) and overall survival ($p = 0.027$) compared with patients who had tumors with unmethylated miR-34b/c or a low level of miR-34b/c methylation. Patients who had tumors with high levels of miR-34b/c methylation had significantly shorter disease-free survival and overall survival compared with patients who had tumors with unmethylated miR-34b/c or a low level of miR-34b/c methylation. Their results suggest that epigenetic inactivation of miR-34b/c by DNA methylation has independent prognostic value in early-stage lung adenocarcinoma. Mapping human miRNAs on autosomal chromosomes and selecting 55 miRNAs in silico, Watanabe et al.[36] found that miR-34b was silenced by the DNA methylation of its own promoter. The 5-aza-2′-deoxycytidine treatment of NSCLC cells resulted in increased miR-34b expression and decreased c-Met protein. The DNA methylation status of miR-34b was analyzed in 99 patients with primary NSCLC, and multivariate analysis showed that both miR-34b methylation ($p = 0.007$) and c-Met expression ($p = 0.005$) were significantly associated with lymphatic invasion. These results suggest that the DNA methylation of miR-34b may be used as a biomarker for an invasive phenotype of NSCLC.

Using real-time RT-PCR, Yu et al.[37] identified a five-miRNA signature (let-7a, miR-137, miR-182*, miR-221, and miR-372) that was associated with relapse and survival in 112 patients with NSCLC. Patients with a high-risk score for this five-miRNA signature in their tumor specimens had faster cancer relapse and shorter survival. These results suggest that miRNAs may play an important role in the clinical progression and prognosis of NSCLC. Landi et al.[38] analyzed miRNA expression in 125 tissue samples of squamous cell carcinoma from the Environment and Genetics in Lung Cancer Etiology study using a custom oligo array. This group also found that lower expression of five miRNAs (let-7e, miR-25, miR-34a, miR-34c-5p, and miR-191) strongly predicted poor survival for male smokers with stage I–IIIA squamous cell carcinomas. These miRNAs may have important implications for prognosis and treatment of this histologic subgroup of lung cancer.

SNPs in pre-miRNAs may alter miRNA processing, expression, and binding to target mRNA. In a systematic survey of common pre-miRNA SNPs among 893 patients with NSCLC, Hu et al.[39] found that SNP rs11614913 in miR-196a2 was associated with survival. Survival was significantly decreased for individuals who were homozygous CC at SNP rs11614913, indicating that the rs11614913 SNP in miR-196a2 may be a prognostic biomarker for NSCLC ($p = 0.033$). Hu et al.[40] further conducted a two-stage study to examine the impact of SNPs on the overall survival of 923 patients with NSCLC in China. They found that miR-30c-1 rs928508 was consistently a predictor of survival in NSCLC, and the protective role of rs928508 AG/GG genotypes was more pronounced among patients with stage I–II disease and patients treated with surgical procedures. Their data indicate that genetic polymorphisms in the pre-miRNA flanking region may be prognostic biomarkers of NSCLC. Using a PCR–restriction fragment length polymorphism assay, Hong et al.[41] evaluated the effects of four SNPs in pre-miRNAs of 363 patients with surgically resected early-stage NSCLC. The pre-miR-149 rs2292832 TC or CC genotype portended a significantly better overall survival (adjusted hazard ratio, 0.66; 95% CI, 0.47–0.92) and disease-free survival (adjusted hazard ratio, 0.64; 95% CI, 0.48–0.87) than the TT genotype, and the pre-miR-196a rs11614913 CT or TT genotype was associated with a significantly better overall survival (adjusted hazard ratio, 0.70; 95% CI, 0.49–0.99) and disease-free survival (adjusted hazard ratio, 0.66; 95% CI, 0.48–0.90) than the CC genotype. Their results suggest that miR-149 rs2292832 and miR-196a rs11614913 may be used as prognostic markers for patients with surgically resected early-stage NSCLC.

Human blood contains stably expressed miRNAs that may have great potential to predict survival. To identify tumor biomarkers using noninvasive procedures, Silva et al.[42] analyzed the plasma from 28 patients with NSCLC by low-density arrays (Taqman) and validated selected miRNAs by real-time PCR in the plasma from 78 samples of NSCLC. The plasma level of let-7f was associated with overall survival, and the plasma level of miR-30e-3p was associated with short disease-free survival. These two plasma vesicle-related miRNAs may serve as circulating tumor biomarkers with prognostic value. Using genome-wide miRNA expression analysis to test the levels of serum miRNAs among 243 patients with NSCLC, Hu et al.[43] also found four miRNAs (miR-1, miR-30d, miR-486, and miR-499) in the serum to be significantly associated with overall survival ($p \leq 0.001$). This four-miRNA signature may serve as a noninvasive predictor for the prognosis of NSCLC. Wang et al.[44] used quantitative RT-PCR to assay 35 miRNAs that have binding sites within the 3′ UTRs of 11 genes in the transforming growth factor-β signaling pathway to determine their associations with survival; the serum samples were from 383 patients with advanced NSCLC. The authors identified 17 miRNAs that were significantly associated with 2-year survival. Among them, high expression of miR-16 exhibited the most highly significant association with better survival (adjusted hazard ratio, 0.4; 95% CI, 0.3–0.5). A combined 17-miRNA risk score was created and showed that patients with a high risk score had a 2.5-fold increased risk of death compared with patients with a low risk score. Genotyping 240 miRNA-related SNPs in the blood of 535 patients with stage I and II NSCLC, Pu et al.[45] determined that the FAS (Fas cell surface death receptor:rs2234978) G allele was significantly associated with survival in early-stage NSCLC (hazard ratio, 0.59; 95% CI, 0.44–0.77). Luciferase assays showed that the FAS SNP created a miR-651 functional binding site. Their results indicate that miRNA-related polymorphisms may be associated with clinical outcomes among patients with NSCLC through altered miRNA regulation of target genes.

The Role of miRNAs in the Response to Treatment

Although most patients with lung cancer have a response to initial chemotherapy, chemoresistance can develop, leading to inferior outcomes. Predictive biomarkers are needed to aid researchers in designing clinical trials that better stratify patients and in identifying new treatments for specific subpopulations. Recent studies have demonstrated that miRNAs may serve as predictive biomarkers for chemoresistance of lung cancer among patients treated with systemic chemotherapy and/or targeted therapies (Table 15.5).

Platinum-based chemotherapy is the backbone of current combination strategies for the treatment of small cell lung cancer (SCLC). However, more than 95% of patients with SCLC eventually die of cancer. Ranade et al.[46] performed miRNA microarray profiling on 34 diagnostic SCLC tumor samples and analysis by a data integration and discovery tool (XenoBase; Van Andel Research Institute, Grand Rapids, MI, USA) showing that higher levels of miR-92a-2* in the tumors were associated with chemoresistance. This miRNA may have an application in screening patients with SCLC at risk for de novo chemoresistance in an effort to design more tailored clinical trials for SCLC.

Researchers have also hypothesized a role of miRNAs in the resistance to platinum-based chemotherapy for NSCLC. Investigating the expression profiles of serum miRNAs in 260 patients with inoperable, advanced NSCLC treated with cisplatin-based chemotherapy, Cui et al.[47] showed that miR-125b was significantly associated with therapeutic response, with higher expression levels in the tumors of patients who did not have a response to treatment ($p = 0.003$). These results suggest that miR-125b is a potential predictive biomarker for NSCLC and may aid in the development of targeted therapeutics to overcome chemotherapeutic resistance in NSCLC. Employing a

TABLE 15.5 Single MicroRNAs (miRNAs) as Predictive Biomarkers for Treatment Response in Lung Cancer

miRNAs	Deregulation in Cancer	Materials	Descriptions	References
miR-10a	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-21	Upregulated	Tissue/plasma	Transfection of NSCLC cells with anti-miR-21 increases the expression of *PTEN* and decreases *Bcl-2*	48
miR-22	Upregulated	Blood	Significantly higher miR-22 expression is found in patients who have progressive NSCLC	49
miR-24-2	Downregulated	Serum	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-25*	Upregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-30a	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-30c-2*	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-92a-2*	Upregulated	FFPE tissue	Higher tumor levels of miR-92a-2* are associated with chemoresistance and with decreased survival in patients with small cell lung cancer	46
miR-125b	Upregulated	Serum	High level of miR-125b is significantly correlated with poor therapeutic response in patients with inoperable, advanced NSCLC treated with cisplatin–based chemotherapy	47
miR-155	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-195	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-200c	Downregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction. Treatment with TGFβ1 changes the expression of miR-200c and proteins involved in the epithelial-to-mesenchymal transition and modulates migration in lung cancer cells	50,54
miR-203	Upregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50
miR-221	Upregulated	Cell line	High expression level of miR-221 is needed to maintain the TRAIL-resistant phenotype in NSCLC	51
miR-222	Upregulated	Cell line	High expression level of miR-222 is needed to maintain the TRAIL-resistant phenotype in NSCLC	51
miR-885-5p	Upregulated	Cell line	Genes with significantly altered expression and putatively mediated by the expression-changed miRNAs are mainly enriched in chromatin assembly, antiapoptosis, protein kinase, and small GTPase-mediated signal transduction	50

FFPE, formalin-fixed, paraffin-embedded; *GTP*, guanosine triphosphate; *NSCLC,* nonsmall cell lung cancer; *PTEN*, phosphatase and tensin homolog; *TGF*, transforming growth factor; *TRAIL*, tumor necrosis factor-related apoptosis-inducing ligand.

microarray to compare the expression levels of miRNAs, Gao et al.[48] found that increased expression of miR-21 also significantly increased the resistance of NSCLC cells to platinum, whereas reduced expression of miR-21 decreased the resistance of NSCLC cells ($p = 0.007$). This finding was further validated in the tissue samples of 58 patients and matched plasma samples. These data suggest that the expression level of miR-21 in tumor tissue and plasma may be used as a biomarker to predict the response to adjuvant platinum-based chemotherapy in patients with NSCLC.

Pemetrexed has been widely used in patients with advanced NSCLC. Franchina et al.[49] evaluated the expression levels of circulating miRNAs possibly involved in the folate pathway in 22 patients with NSCLC treated with pemetrexed. They found a correlation between high expression of miR-22 in whole blood and a lack of response in these patients. Their results indicate that miR-22 may represent a predictive biomarker for pemetrexed-based treatment.

Gemcitabine is also one of the most widely used drugs for the treatment of advanced NSCLC. Applying miRNA expression chips to determine biomarkers for gemcitabine sensitivity, Zhang et al.[50] found that miR-10a, miR-24-2*, miR-30a, miR-30c-2*, and miR-155 were upregulated in sensitive cells, whereas miR-25*, miR-195, miR-200c, miR-203, and miR-885-5p were increased in resistant cells. Their results may provide potential biomarkers for the prediction of gemcitabine sensitivity and putative targets to overcome gemcitabine resistance in patients with NSCLC.

NSCLC cells show differential sensitivity to therapy with tumor necrosis factor-related apoptosis-inducing ligand (TRAIL). Performing genome-wide expression profiling of miRNAs, Garofalo et al.[51] showed that high expression levels of miR-221 and miR-222 were needed to maintain the TRAIL-resistant phenotype in NSCLC. These miRNAs may thus be used as diagnostic tools for TRAIL resistance in NSCLC. In addition, miRNAs have been reported to have significant associations with epidermal growth

factor receptor (*EGFR; p* < 0.05), and epithelial-to-mesenchymal transition may predict resistance to EGFR inhibitors and metastatic behavior.[52,53] Using a model system for an NSCLC cell line, Bryant et al.[54] found that ectopic expression of miR-200c altered the expression of proteins responsible for the epithelial-to-mesenchymal transition, sensitivity to erlotinib, and migration in lung cancer cells. Their data suggest that the tumor microenvironment may stimulate miR-200c, which then induces resistance to anti-EGFR therapy and drives lung tumor cells to the epithelial-to-mesenchymal transition, invasion, and metastasis.

FUTURE PERSPECTIVES

Dysfunctions of miRNAs are frequently found in lung cancer.[55] These noncoding RNAs have been recognized as some of the main regulatory gatekeepers of coding genes in the human genome. For the most part, miRNAs silence gene expression by binding imperfectly matched sequences in the 3′ UTR of target mRNAs.[56] By targeting and controlling the expression of mRNAs, miRNAs may control highly complex signal transduction pathways and other biologic pathways.[57] Rapid advances in platform technologies, such as SNP analysis, genome-wide transcriptional profiling, miRNA microarrays, next-generation sequencing, and other so-called omics technologies, offer the potential for revolutionary developments in the study of miRNAs in lung cancer.[58]

Studies since the early 2000s have shown the oncogenic and tumor suppressive characteristics of miRNAs and have inspired researchers to begin elucidating the specific roles of miRNAs as potential biomarkers for the diagnosis and prognosis of lung cancer.[59] Numerous studies have documented the implications of miRNAs in nearly every carcinogenic process of lung cancer, including tumor growth and apoptosis, progression and metastasis, and resistance to anticancer agents.[60–64] These small molecules are produced in a tissue-specific manner, yet they are also found to be stable in human blood. By exploiting the unique characteristics of miRNAs in solid tumors and circulating samples, including their tissue specificity, stability, ease of detection, and ready manipulation, clinicians come ever closer to achieving the goal of personalized cancer therapy.[65,66] Furthermore, using circulating miRNAs in blood and/or sputum as noninvasive diagnostic biomarkers may create a breakthrough in the early detection of lung cancer.[67]

Early detection and swift treatment can significantly affect the prognosis of patients with lung cancer. However, massive screening may lead to overdiagnosis and eventually overtreatment. A number of studies have reported that specific miRNAs are able to differentiate benign from malignant lung lesions. Combining these molecular biomarkers with massive screening may reduce the risk of overdiagnosis in lung cancer.[68] On the other hand, the utility of some protein-encoding gene biomarkers has already been exploited in routine clinical practice. The translational study of miRNAs may provide complementary or superior information to these existing biomarkers to enhance the diagnostic, prognostic, and predictive power of molecular characterization of lung cancer.[69] Indeed, an emerging trend is to combine several miRNAs into a panel biomarker to improve sensitivity and specificity. Similarly, the combination of miRNA biomarkers with other molecular markers (such as SNPs and methylation signatures) may also help to better diagnose or predict the treatment outcomes of individual patients.[70]

Although the identification of miRNA-based signatures in lung cancer has shown promising results in recent years, no single biomarker has made the transition into the clinic. Further efforts are essential to fully realize and define common procedures, standards, and controls so as to translate valuable laboratory findings into clinically relevant procedures for patients with lung cancer.[71] Large prospective cohorts and cross-validation are needed to consolidate the significant findings demonstrated by studies of miRNA profiling. Over time, in conjunction with genetic and proteomic signatures and other screening approaches, miRNA biomarkers may represent a new milestone in lung cancer theranostics.[72]

16 Humoral and Cellular Immune Dysregulation and Lung Cancer

Anish Thomas, Julie R. Brahmer, and Giuseppe Giaccone

SUMMARY OF KEY POINTS

- Humoral and cellular immune dysregulation in the tumor microenvironment contributes to immune evasion, a key hallmark of lung cancer.
- Immunosuppressive mechanisms observed in lung cancer include defective antigen presentation, secretion of immunosuppressive tumor-derived soluble factors, and immunosuppressive cells infiltrating the tumors.
- Suppression of antigen-presenting machinery in lung cancer results from several mechanisms including deficiencies in expression of antigen-processing genes and haplotype loss of human leukocyte antigen (HLA) class I antigens.
- Immune inhibitory cytokines secreted by the tumor cells impair T-cell survival and help avoid T cell-mediated immune responses.
- Immune checkpoints expressed on the surface of T lymphocytes modulate the immune response to antigens via inhibitory or stimulatory signaling to T cells.
- Tobacco smoke markedly influences the immune microenvironment in lung cancer.

Advances in the understanding of cellular immunology and tumor–host immune interactions have led to the development of promising immunotherapies in lung cancer.[1] This chapter provides a review of the current understanding of the basic immunologic abnormalities in lung cancer. Clinical trials of immunotherapy in lung cancer are discussed in Chapter 50.

Although lung cancer was traditionally thought to be a nonimmunogenic tumor unlike melanoma or renal cell cancer,[2] accumulating evidence suggests both cellular (T lymphocyte-mediated) and humoral (antibody-mediated) immune antitumor responses even in patients with advanced lung cancer.[3,4] Despite the immune responses, spontaneous tumor regressions rarely occur, indicating the ability of the tumor cells to escape an immune response. In fact, lung cancer is among the many tumors that are known to promote immune tolerance and escape host immune surveillance. It is thought that the immune system actively inhibits the formation and progression of transformed cells and ultimately "shapes" nascent tumors by forcing the selective evolution of tumor cells that can evade the immune response, a phenomenon called tumor immunoediting.[5] Tumors also utilize numerous other pathways to inhibit immune responses, including local immune suppression, induction of tolerance, and systemic dysfunction in T-cell signaling.[6–9] Although these immunosuppressive mechanisms are categorized discretely, the clinically observed deficits are interrelated (Fig. 16.1).

SUPPRESSION OF THE ANTIGEN-PRESENTING MACHINERY

An adaptive immune response requires two signals between the antigen-presenting cells (APCs) and the effector T cell. The first signal is mediated by the T-cell receptor and the specific antigenic peptide presented in the context of major histocompatibility complex (MHC) class I or class II molecules expressed on the APC surface. The second signal is mediated through constitutively expressed costimulatory molecules on the T cell (CD28) and the APC (B7-1/CD80 or B7-2/CD86; Fig. 16.1). The presence of both signals trigger intracellular events resulting in the activation and interleukin-2 (IL-2)-dependent clonal proliferation of T cells.

The MHC class I molecules are essential components of the adaptive immune system and are crucial to the immune recognition of tumor cells. MHC class I molecules report on cellular transformation to CD8+ cytotoxic T lymphocytes (CTLs) through a multistep process of antigenic peptide acquisition, tagging them for destruction by ubiquitylation, proteolysis, delivery of peptides from cytosol to the endoplasmic reticulum via the heterodimeric transporter associated with antigen processing (TAP) 1 and TAP2 subunits, binding of peptides to MHC class I molecules, and displaying of peptide–MHC class I complexes on the cell surface.[10]

Under physiologic conditions, the components of MHC class I antigen-processing machinery (APM) are constitutively expressed in all adult nucleated cells (except immune privileged tissue). Their expression is regulated by cytokines that can alter the surface expression of MHC class I molecules. Aberrant MHC class I expression has been conclusively demonstrated as an important immune escape mechanism in cancers. MHC class I abnormalities have been frequently found in a variety of human cancers, are associated with unfavorable prognoses in some tumor types, and have a negative impact on the outcome of T cell-based immunotherapy.[11–13] Marked deficiency or lack of expression of MHC class I molecules has been demonstrated in lung cancer.[14,15]

The molecular mechanisms of MHC class I expression loss are diverse and include structural alterations or dysregulations of genes encoding the classical MHC class I antigens and/or components of the MHC class I APM. The dysregulation of APM components may occur at the epigenetic, transcriptional, or posttranscriptional level.[11] Mechanisms underlying the aberrant expression of MHC class I antigens in lung cancer include deficiencies in the expression of antigen-processing genes (e.g., genes that encode proteasome subunits and the peptide transporters), which result in defective peptide transport to the cell surface from the endoplasmic reticulum.[15–18] Haplotype loss of HLA class I antigens is another mechanism of abnormal HLA expression in lung cancer and has been demonstrated in about 40% of lung cancer cell lines.[19–21] Structural alterations such as β2-microglobulin gene abnormalities resulting from loss of messenger RNA and

The blockade of immune checkpoints in cancer immunotherapy.* Nat Rev Cancer. *2012;12(4):252–264.)*

point mutations are less common mechanisms of altered MHC class I expression in lung cancer.[19,22]

Studies in which lung cancer cell lines with haplotype loss of HLA class I antigens are used indicate that tumor cells with a normal HLA class I expression may be killed by CTLs at an early stage of carcinogenesis, and only immunoselected tumor cells that lack HLA class I expression can escape this immune attack and develop into cancer.[23] Furthermore, some defects in MHC class I expression in lung cancer, for example, deficiencies in expression of antigen-processing genes and not β2-microglobulin gene abnormalities, may be reversible with cytokines. Interferon-γ (*IFN-γ*) gene transfection into HLA-deficient small cell lung

cancer (SCLC) was able to restore its ability to present endogenous tumor antigens to CTL with a concomitant increase in cell-surface expression of class I molecules.[15,18,24]

The results of immunohistochemical studies of surgically resected samples with monoclonal antibodies against a common framework determinant of HLA class I antigens have shown deficient expression in HLA class I antigens in 25% to 33% of nonsmall cell lung cancer (NSCLC).[25–28] As evident from studies of transfected tumor cells lacking expression of these antigens, MHC class I molecules are required for presentation of antigens on tumor cells to the CTL. Thus tumor cells that have lost MHC class I antigens have the advantage of being able to escape lysis by CTL.[29] In lung cancers, the absence of expression of HLA class I molecules has been associated with poor differentiation and aneuploidy, suggesting that lung cancers with abnormal HLA expression may be biologically more aggressive.[25–27] Taken together, these findings may suggest that tumors with aberrant expression of HLA class I molecules are associated with a poorer prognosis. However, the prognostic implications of HLA class I antigen downregulation in NSCLC are not clear.[25–27,30]

Despite expressing antigens recognizable by the host immune system, tumors are very poor at initiating effective immune responses. However, antigen presentation alone is insufficient to activate T cells. In addition to T-cell receptor engagement of an antigenic peptide bound to MHC molecules, additional costimulatory signals are necessary for T-cell activation. The most important of these costimulatory signals is provided by the interaction of CD28 on T cells with its primary ligands B7-1 (CD80) and B7-2 (CD86) on the surface of APCs.[31]

Cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), a member of the immunoglobulin super family and homolog of CD28, binds members of the B7 family with a much higher affinity than CD28. In effect, CTLA-4 competes with CD28

for binding to the B7 family. Upregulation of surface CTLA-4 follows clonal expansion of T cells and regulates the immune response by inducing inhibitory signals in effector T cells that lead to the dampening of the effector T-cell response.[32] CTLA-4 is thus one of the endogenous immune checkpoints that normally terminate immune responses after antigen activation. These T cells are eventually eliminated via apoptosis. CTLA-4 may also contribute to the immune-suppressive function of T-regulatory cells. Upregulation of CTLA-4 on the surface of T-regulatory cells results in suppression of activation and expansion of effector cells specific for both normal self-antigens and tumor antigens.[33,34] CTLA-4 is constitutively expressed in NSCLC cell lines, where it induces apoptotic cell death on engagement with soluble B7-1 and B7-2 recombinant ligands.[35] Furthermore, CTLA-4 expression in resected early-stage NSCLC was shown to be a good prognostic indicator in a retrospective analysis that was limited by a small number of patients.[36]

Programmed cell death 1 (PD-1) is another key immune checkpoint receptor that is structurally similar to CTLA-4, but with distinct biologic functions and ligand specificity that is expressed by activated T cells and mediates immunosuppression. PD-1 functions primarily in peripheral tissues, where T cells may encounter the immunosuppressive PD-1 ligands PD-L1 (B7-H1) and PD-L2 (B7-DC), which are expressed by tumor cells, stromal cells, or both (Fig. 16.2).[37] The immune inhibitory signals mediated by CTLA-4 and PD-1 are different, as evidenced by the early mortality of CTLA-4 knockout mice compared with modest late-onset strain-specific and organ-specific autoimmunity of PD-1 knockout mice.[38]

Most lung cancer samples, but not samples with normal alveolar cells, express high levels of PD-L1, which is limited to the tumor plasma membrane or cytoplasm.[39] Dendritic cells (DCs) isolated from tumoral and nontumoral lung tissues express low,

although significantly higher, levels of B7-1 and B7-2 molecules compared with blood DCs.[40] In surgically resected NSCLC, no relationship was found between the expression of PD-L1 or PD-L2 and clinicopathologic variables, such as histology, stage, or postoperative survival.[41] In a limited subset of patients, fewer tumor-infiltrating lymphocytes (TILs) were identified in PD-L1-positive tumor regions than in PD-L1-negative tumor regions. Tumor-infiltrating and circulating CD8+ T cells from patients with NSCLC showed increased PD-1 expression compared with peripheral blood mononuclear cells from normal volunteers, but showed impaired immune function, including reduced cytokine production capability and impaired capacity to proliferate.[42] Blocking the PD-1 and PD-L1 pathway by anti-PD-L1 antibodies increased cytokine production and proliferation of PD-1+ tumor-infiltrating CD8+ T cells.[42]

TUMOR-DERIVED SOLUBLE FACTORS

Tumor cells avoid lymphocyte-mediated immune responses by secreting immune inhibitory cytokines in the tumor milieu. In addition to secreting immune-suppressive mediators, tumor cells may also signal surrounding inflammatory cells to release immune-suppressive mediators, augment the trafficking of suppressor cells to the tumor site, and promote the differentiation of effector lymphocytes to a T-regulatory phenotype.[43,44] Tumor-derived soluble factors also impair T-cell survival. NSCLC cell line supernatants contribute to enhanced activation-induced T-cell apoptosis in the tumor environment. The increased T-cell apoptosis after mitogen stimulation is due to the inhibition of nuclear factor-κB activation in the tumor milieu.[45]

Interleukin-10

Human bronchial epithelial cells constitutively produce IL-10, which regulates the local immune response in normal lungs.[46] Although the precise role of IL-10 in carcinogenesis remains controversial,[47] results of several studies suggest that IL-10 is a potent immunosuppressive molecule that may promote lung cancer growth by suppressing T-cell and macrophage function and enabling tumors to escape immune detection.[48–50] In vitro, human lung tumors produce greater amounts of IL-10 than normal lung tissue.[51,52] Tumor cells also induce T lymphocyte-derived IL-10 via a prostaglandin E_2 (PGE$_2$)-mediated pathway.[50] In vivo, lung carcinoma cells grow more rapidly in IL-10 transgenic mice compared with controls.[53] *IL-10* transgenic mice also demonstrate a reduced capacity for antigen presentation, CTL generation, and type 1 cytokine production, reflecting defects in both T-cell and APC function.[48] Increased IL-10 expression of tumor-associated macrophages in patients with NSCLC correlates with late-stage disease and other adverse prognostic features, suggesting its potential role in the progression of NSCLC.[54,55] Furthermore, in patients with advanced-stage NSCLC receiving platinum-based chemotherapy, an elevated baseline serum IL-10 level was an independent predictor of poorer survival.[56] In patients with early-stage NSCLC, an elevated *IL-10* messenger RNA level was associated with worse survival.[57]

However, preclinical and clinical models suggest that IL-10 possesses an immunostimulating property that favors immune-mediated rejection of cancer.[47] In patients with NSCLC, the percentage of CD8+ cells expressing IL-10 was higher in cancerous tissue than in cancer-free tissue and correlated with both early-stage tumors and better survival rates.[58] In clinical studies, lack of tumor IL-10 expression was associated with a worse disease-specific survival rate in patients with early-stage NSCLC.[59,60]

Conflicting evidence on the immune regulatory function of IL-10 likely reflects its pleiotropic ability to positively or negatively influence the function of innate and adaptive immunity, resulting in immunostimulation or immunosuppression depending on its source (tumor compared with tumor-infiltrating immune cells) and on the interactions with factors found in the tumor microenvironment.[47,61]

Transforming Growth Factor-β

Transforming growth factor-β (TGF-β) is a member of a family of multifunctional proteins that through complex cell signaling pathways regulate cell proliferation, differentiation, and angiogenesis.[62] Three highly conserved and tissue-specific *TGF-β* isoforms, namely, *TGF-β1*, *TGF-β2*, and *TGF-β3*, signal through heteromeric complexes of three cell-surface receptors, that is, the type III TGF-β receptors: TβRIII, TβRII, and TβRI.[63] TGF-β ligands initiate signaling by binding to and bringing together TβRI and TβRII receptor serine and threonine kinases on the cell surface. This process allows TβRII to phosphorylate the TβRI kinase domain, which propagates the signal through phosphorylation of the small mothers against decapentaplegic (SMAD) proteins, which then translocate into the nucleus and interact in a cell-specific manner with transcription factors to regulate specifically the transcription of a multitude of *TGF-β*-responsive genes. While *TGF-β* acts as a tumor suppressor via its effects on proliferation, replication potential, and apoptosis, it also acts as a tumor promoter via its effects on migration, invasion, angiogenesis, and the immune system.[64] TGF-β enables tumors to evade immune surveillance and kill through various mechanisms, most of which converge on the impairment of tumor cell killing by immune effector cells.[65]

Normal bronchial epithelial cells have high-affinity receptors for TGF-β. TGF-β inhibits proliferation and induces differentiation of normal bronchial epithelial cells.[66] TGF-β secreted by tumor cells mediates conversion of CD4+CD25− T cells to regulatory T (T-reg) cells. Neutralization of TGF-β abrogates this conversion both in vitro and in vivo.[67] Cigarette smoking promotes tumorigenicity partly by abrogating *TGF-β*-mediated growth inhibition and apoptosis by reducing expression of SMAD3.[68] Both SCLC and NSCLC overexpress TGF-β, and high levels of TGF-β are also detected in the serum of patients with lung cancer compared with normal individuals.[69,70] Elevated plasma levels of TGF-β confer a poorer prognosis for patients with lung cancer.[71]

A variety of other tumor-derived soluble factors contribute to the immunosuppressive milieu including vascular endothelial growth factor, PGE$_2$, soluble phosphatidylserine, soluble Fas, soluble Fas-L, and soluble MHC class I–related chain A proteins.[72] Although deposited at the primary tumor site, these factors can extend immunosuppressive effects to local lymph nodes and the spleen, thereby promoting invasion and metastasis.[73]

TUMOR-INFILTRATING T LYMPHOCYTES

The lymphocyte population that infiltrates the tumor is quite heterogeneous and consists of many different clones of lymphocytes that contain a variety of cell surface markers. The protumor and antitumor effects of interactions between tumor and immune cells in the tumor microenvironment are influenced not just by the type of immune cells (CD8+, CD4+, CD20+, and forkhead box P3 [FoxP3+]), but also by their density and location within the tumors.[74] In NSCLC, tumor stroma inflammatory cells are mainly lymphocytes (approximately two-thirds, and among them 20% B cells and 80% T cells) and tumor-associated macrophages (approximately one-third), with a low percentage of DCs and a very low percentage of natural killer (NK) cells.[75] Although the cell surface markers and distribution among various lymphocyte subtypes are similar, TILs are functionally different

from lymphocytes that are found in regional lymph nodes and peripheral blood. TILs are markedly suppressed in their functional capacity based on assessments of their proliferative and cytotoxic activities. In addition, tumor-infiltrating NK cells have markedly diminished activity compared with peripheral blood lymphocytes.[76]

Using genetically engineered mouse lung adenocarcinoma into which exogenous antigens were introduced to mimic tumor neoantigens, DuPage et al.[77] showed that endogenous T cells responded to and infiltrated tumors early during tumor development, substantially delaying malignant progression. However, despite continued antigen expression, T-cell infiltration did not persist and tumors ultimately escaped immune attack. Moreover, very few tumor-reactive T cells in the lungs were functional, as evidenced by their limited capacity to produce both IFN-γ and tumor necrosis factor-alpha (TNF-α). Immunohistochemical analysis in patients with NSCLC demonstrated significantly higher CD8+ T-cell counts within the tumor when compared with the invasive margin.[78] However, the number of peritumoral CD8+ T cells correlated with the IFN-γ production, whereas this association was not observed intratumorally, suggesting that CD8+ T cells are able to infiltrate the tumor, but they are not able to mount a robust antitumor response once within the tumor nest.

Although TILs are associated with a favorable prognosis in many malignancies,[79] the association between CD8+ T-cell infiltration and prognosis is controversial in lung cancer.[80] However, high numbers of CD4+ T cells within cancer cell nests positively correlated with a favorable prognosis, suggesting that CD4+ T cells may be required for initiating and maintaining antitumor immune responses, as without CD4+ T-cell help, the resultant CD4-unhelped CD8+ T cells do not differentiate into sustainable memory cells.[81]

Although TILs accumulate in lung cancer tissues, they fail to mount an immune response to tumor cells,[82] in part because high proportions of NSCLC TILs are T-reg cells.[83] TILs that are CD4+CD25+, the activated phenotype of T-reg cells, inhibit T-cell proliferation and prevent the host from mounting an immune response to tumor antigens.[84] A preponderance of these T-reg cells could lead to a failure of tumor immunosurveillance or to enhanced tumor growth. In patients with NSCLC, T cells derived from the tumor show considerably increased proportions of CD4+CD25+ T cells that produce TGF-β.[85] These cells uniformly express high levels of CTLA-4 on their cell surface. In addition, CD4+CD25+ T cells isolated from tumors mediate potent inhibition of the proliferation of autologous peripheral blood T cells stimulated by anti-CD3 or anti-CD3 and anti-CD28.[83] An increased pool of CD4+CD25+ T-reg cells with potent immunosuppressive features also exists in the peripheral blood of patients with NSCLC.[86]

Although the activation of T-reg cells is considered antigen specific, their immunosuppressive function is nonspecific and results from inhibition of multiple phases and events in the immune response from antigen presentation to effector functions.[87] Secretion of immunosuppressive cytokines such as TGF-β may play a role in the immune-suppressive function of T-reg cells.[88] However, TGF-β may not be required for inhibition of proliferation of T-reg cells in patients with lung cancer: TGF-β neutralization did not abrogate the suppressive effect of CD4+CD25+ T cells on autologous T-cell proliferation.[83]

FoxP3, a forkhead transcription factor family member encoded on the X chromosome, is a critical control gene for the development and function of natural CD4+CD25+ T-reg cells. In lung cancer cells, tumor-derived cyclooxygenase-2 (COX-2)/PGE$_2$ induced expression of *FoxP3* and increased T-reg cell activity.[89] In vivo, inhibition of COX-2 reduced T-reg activity, attenuated *FoxP3* expression in TILs, and decreased tumor burden. In stage I to III NSCLC, tumor-infiltrating FoxP3+ T-regs

correlated with COX-2 expression and an increased tumor recurrence.[90]

MYELOID-DERIVED SUPPRESSOR CELLS

Myeloid-derived suppressor cells (MDSCs) are a phenotypically heterogeneous population of cells of myeloid origin that expand during cancer, inflammation, and infection, characterized by their immature state and ability to suppress T-cell responses.[91,92] Unlike the physiologic state where immature myeloid cells generated in bone marrow quickly differentiate into mature granulocytes, macrophages, or DCs, in cancer, a partial block in the differentiation of immature myeloid cells into mature myeloid cells results in an expansion of MDSCs. MDSCs express the common myeloid marker CD33, but lack the expression of markers of mature myeloid and lymphoid cells and the MHC class-II molecule HLA-DR11.[91] Two main subsets of MDSCs that suppress antigen-specific T-cell proliferation to an equal extent, despite their different mechanisms of action, have been identified: a granulocytic subset and a monocytic subset.[93] The MDSC population is influenced by several different factors. The factors that are known to induce MDSC expansion in lung cancer include granulocyte-macrophage colony-stimulating factor,[94] granulocyte colony-stimulating factor,[95] and prostaglandins.[96] The signaling pathways in MDSCs that are triggered by most of these factors converge on Janus kinase protein family members and signal transducer and activator of transcription 3 (STAT3), which are involved in cell survival, proliferation, differentiation, and apoptosis.[91]

The immune-suppressive activity of MDSC is thought to be a result of several mechanisms including upregulated expression of immune-suppressive factors, such as arginase and inducible nitric oxide synthase, and an increase in the production of NO and reactive oxygen species.[91] Arginase, which metabolizes L-arginine to L-ornithine, plays an important role in T-cell suppression through depletion of arginine, which is required for T-cell proliferation and cytokine production.[97] Using the 3LL mouse lung carcinoma model, Rodriguez et al.[98] showed that arginine depletion in the microenvironment by arginase I–producing MDSCs inhibited T-cell receptor CD3 expression and blocked T-cell functions. Arginase I in MDSC was induced by COX-2, and inhibition of COX-2 blocked arginase I induction in vitro and in vivo.[96] Furthermore, blocking arginase I expression using COX-2 inhibitors elicited a lymphocyte-mediated antitumor response.[96]

Further evidence supporting the immunosuppressive effect of MDSCs is derived from experiments of antibody-mediated depletion of MDSC in 3LL tumor-bearing mice. MDSC depletion increased APC activity and augmented the frequency and activity of NK and T-cell effectors that led to reduced tumor growth, enhanced therapeutic vaccination responses, and conferred immunologic memory.[99] MDSC numbers are increased in the peripheral blood of patients with NSCLC compared with healthy volunteers and these cells are capable of directly inhibiting antigen-specific T-cell responses.[100–105] As with many other cancers, MDSC levels correlate with clinical cancer stage and response to therapy in NSCLC.[102,105] In patients with advanced NSCLC, higher peripheral blood MDSC numbers were associated with poor response to cisplatin-based chemotherapy and predicted shorter progression-free survival.[100,105] In patients with early-stage NSCLC, peripheral blood MDSC numbers declined after removal of the tumor.[105] A negative association existed between the population of circulating MDSCs and the frequency of CD8+ T lymphocytes.[105] In a small study of patients with advanced NSCLC who received erlotinib, circulating MDSCs were substantially decreased in patients who had a partial response compared with patients who had progressive disease, and there was a negative correlation between the progression-free survival

and MDSC numbers.[106] The prognostic significance of MDSCs in the tumor microenvironment of patient samples in lung cancer is not clear.

MDSC gene expression varies in different tumor types, and an understanding of its clinical significance requires the full characterization of these cells. Despite the lack of consensus over the definition and phenotype of MDSCs, and considerable heterogeneity in how they are defined clinically, their immunosuppressive properties are clear in NSCLC. The mechanisms by which MDSC functions are regulated within the tumor microenvironment, and how they differ from MDSCs that operate at peripheral sites, remain unclear.

CIGARETTE SMOKING AND IMMUNE DYSFUNCTION

Tobacco smoke has been shown to exert proinflammatory effects. For example, smoking increases production of several proinflammatory cytokines, such as TNF-α, IL-1, IL-6, and IL-8, and decreases anti-inflammatory cytokines such as IL-10. DC maturation is inhibited by cigarette smoking, as demonstrated by reduced cell-surface expression of MHC class II and the costimulatory molecules CD80 and CD86. Consequently, DCs from cigarette smoke–exposed animals show reduced capacity to stimulate and activate antigen-specific T cells in vitro. Reduced antigen-specific T-cell proliferation is also found in smoke-exposed mice.[107] Activation of CD8+ T cells is also impaired in the presence of cigarette smoke in mouse models.[108,109] CD8+ T-cell predominance is a characteristic of smoking-related chronic obstructive pulmonary disease and has been implicated in the progression of emphysema.[110,111]

CONCLUSION

Although traditionally thought to be a nonimmunogenic tumor, both cellular and humoral immune antitumor immune responses are found in lung cancer. Despite this finding, spontaneous tumor regressions rarely occur, indicating the ability of the tumor cells to escape the immune response. Immune dysregulation at multiple levels has been noted in experimental lung cancer models. These include defective antigen presentation, secretion of immunosuppressive tumor derived-soluble factors, and immunosuppressive cells infiltrating the tumors. Immune evasion mechanisms in other solid tumors may not play a major role in lung cancer as a result of the proinflammatory and immunosuppressive effects of tobacco smoke,[112] the major risk factor for lung cancer. In this context, it is important to consider that findings in a particular cancer model may not be broadly applicable to all immune–tumor interactions because immune response and tumor response are likely to vary greatly depending on the originating tissue and the genetic pathology of the disease. An understanding of the complex issues surrounding cancer immunosurveillance, immunoediting, the role of host cellular networks in lung tumorigenesis, and tumor-mediated immunosuppression will offer additional therapeutic opportunities in lung cancers.

17 Classic Anatomic Pathology and Lung Cancer

Ignacio I. Wistuba, Elisabeth Brambilla, and Masayuki Noguchi

SUMMARY OF KEY POINTS

- A clinically relevant pathologic classification of lung cancer is essential for accurate diagnosis and for patients to receive appropriate therapy.
- Although classification of the majority of lung cancers is straightforward, areas of controversy and diagnostic challenges remain.
- The current lung cancer classification is applicable to surgically resected tumors and small biopsy specimens.
- Pathologists play a critical role in properly handling tissue and cytology specimens for molecular testing of lung cancer.
- The recently developed classification and approaches for lung cancer diagnosis are aligned with current clinical practice and open new avenues for research.

Lung cancer continues to be the most common and deadly malignancy worldwide.[1] The main challenge to improve the poor survival rate (5-year survival approximately 15%) of this disease is to develop better strategies for stratifying high-risk populations for early diagnosis and for selecting adequate treatment for different subsets of lung cancer. The mortality associated with this disease is high primarily because most lung cancers are diagnosed at advanced stages, when options for treatment are mostly palliative. Accurate pathologic classification and diagnosis of lung cancer are essential for patients to receive appropriate therapy.[2] Although classification of the vast majority of lung cancers is straightforward, areas of controversy and diagnostic challenges remain.

From pathologic and biologic perspectives, lung cancer is a highly complex neoplasm with several histologic types.[3] Although most lung cancers are associated with smoking, a significant proportion of them (approximately 15%) occur among never-smokers, mostly with adenocarcinoma tumor histology. Lung tumors are the result of a multistep process in which normal lung cells accumulate multiple genetic and epigenetic abnormalities and evolve into cells with malignant biologic capabilities.[3] Recent advances in understanding the complex biology of nonsmall cell lung carcinoma (NSCLC), particularly activation of oncogenes by mutation, translocation, and amplification, have provided new treatment targets and allowed the identification of subsets of NSCLC tumors with unique molecular profiles that can predict response to therapy in this disease.[4] The identification of a specific genetic and molecular abnormality using tumor tissue specimens, followed by administration of a specific inhibitor to the target, is the basis of personalized cancer treatment. In this new paradigm for lung cancer, making a precise pathologic diagnosis and properly handling tissue and cytology samples for molecular testing are becoming increasingly important. These changes in the paradigms of lung cancer diagnosis and treatment have posed multiple new challenges for pathologists to adequately integrate both routine histopathologic analysis and molecular testing into

the clinical examination for tumor diagnosis and subsequent selection of the most appropriate therapy.

In this chapter we describe the pathologic features of the major types of lung cancer and the diagnostic tools available for their diagnosis, with special emphasis on the challenges involved in classifying lung cancer using small tissue biopsies and cytology specimens. In Table 17.1 we summarize the current approach for the histologic classification of surgically resected tumors in lung cancer as described in the new lung cancer classifications from the World Health Organization.[5]

NONSMALL CELL LUNG CARCINOMA

The generally denominated NSCLCs are by far the most common type (representing approximately 85%) of lung cancer. Although NSCLC displays numerous histologic patterns, most tumors can be grouped into three main categories: squamous cell carcinoma (30%), adenocarcinoma (40%), and large cell carcinoma (3–9%).[6] Traditionally, the NSCLC designation was used for tumors that had histologic and cytologic features different than small cell carcinoma (SCLC). However, more recently, with the use of new therapeutic strategies and molecular diagnostic testing, it has become imperative to provide a more specific diagnosis of lung cancer, and the histologic subtypes must be part of the pathology report. As explained later, pathologists are more often required to perform a panel of immunohistochemical staining in biopsy and cytology specimens when the histologic subtype is not clear.

Adenocarcinoma

Adenocarcinoma is a malignant epithelial tumor with glandular differentiation or mucin production, showing various growth patterns, with expression of either mucin or thyroid transcription factor-1 (TTF-1). A significant change in pathologic classification of lung cancer occurred in 2011 with the publication of the revised classification of lung adenocarcinoma under the sponsorship of the International Association for the Study of Lung Cancer (IASLC), the American Thoracic Society (ATS), and the European Respiratory Society (ERS). This new classification of adenocarcinoma outlined many paradigm shifts that affect clinical diagnosis and management and open new avenues for research.[7] A major point in this classification was the concept that personalized medicine for patients with advanced lung cancer is determined by histology and genetics and that strategic tissue management of small biopsy specimens is critical for pathologic and molecular diagnosis. This publication was a multidisciplinary effort rather than one primarily addressed by pathologists; clinicians, radiologists, molecular biologists, and surgeons were involved. This collaboration led to an emphasis on correlations between pathology and clinical, radiologic, and molecular characteristics. In addition, the experts recognized that 70% of patients with lung cancer present with advanced-stage disease, which is usually diagnosed based on small biopsy and cytology specimens. Because the previous (2004) classifications from the WHO focused on lung cancer diagnosis in resection specimens, which are obtained in only 30% of cases, a major new effort was

	  – Dysplasia
	  – Carcinoma in situ
	• Keratinizing
	• Nonkeratinizing
	• Basaloid carcinoma

LARGE CELL CARCINOMA	

Neuroendocrine tumors	• Preinvasive lesion
	  – DIPNECH
	• Carcinoid tumors
	  – Typical carcinoid
	  – Atypical carcinoid
	• Large cell neuroendocrine carcinoma
	• Small cell carcinoma

ADENOSQUAMOUS CARCINOMA	
Sarcomatoid carcinoma	• Pleomorphic • Spindle cell • Giant cell carcinoma • Carcinosarcoma • Pulmonary blastoma
Other and unclassified carcinomas	• Lymphoepithelioma-like carcinoma • NUT carcinoma
Salivary gland tumors	• Mucoepidermoid carcinoma • Adenoid cystic carcinoma • Epithelial–myoepithelial carcinoma • Pleomorphic adenoma
Papillomas	• Squamous cell papilloma • Glandular papilloma • Mixed squamous cell and glandular papilloma
Adenomas	• Sclerosing pneumocytoma • Alveolar adenoma • Papillary adenoma • Mucinous cystadenoma • Pneumocytic adenomyoepithelioma • Mucous gland adenoma
Mesenchymal tumors Lymphohistiocytic tumors Tumors of ectopic origin Metastatic tumors	

DIPNECH, diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.

TABLE 17.2   Classification of Lung Adenocarcinomas in Resection Specimens[a]

Category	Description

Preinvasive lesions	• Atypical adenomatous hyperplasia
	• Adenocarcinoma in situ (≤3 cm, formerly solitary BAC)
	  – Nonmucinous
	  – Mucinous
	  – Mixed mucinous/nonmucinous

Minimally invasive adenocarcinoma (≤3-cm lepidic predominant tumor with ≤5-mm invasion)	• Nonmucinous • Mucinous • Mixed mucinous/nonmucinous
Invasive adenocarcinoma	• Lepidic predominant (formerly nonmucinous BAC pattern with >5 mm invasion) • Acinar predominant • Papillary predominant • Micropapillary predominant • Solid predominant
Variants of invasive adeno-carcinoma	• Mucinous adenocarcinoma (including formerly mucinous BAC) • Colloid • Fetal (low-grade and high-grade) • Enteric

[a]Classification of the International Association for the Study of Lung Cancer, American Thoracic Society, and European Respiratory Society (IASLC/ATS/ERS).[6]
BAC, bronchioloalveolar carcinoma.

made in this new classification to define terminology and criteria to be used in small biopsies and cytology specimens.[8,9] Therefore, this classification is divided into two sections based on the diagnostic modalities of lung cancer (Table 17.2). These changes have been reflected in the recently released 2015 WHO Classification of Lung Cancer.[5] Resection specimens apply for patients with early-stage disease who are eligible for surgical resection, and small biopsy and cytology specimens for patients with advanced-stage lung cancer.

Several important modifications were made to the 2004 WHO classification concerning specimens in the 2011 IASLC/ATS/ERS and 2015 WHO classifications. The most significant change is the discontinuation of the term bronchiolo–alveolar cell carcinoma (BAC). This term had been used for at least five different entities with disparate clinical and molecular properties, leading to great confusion in routine clinical care and research.[7,8] To address two of these entities, the concepts of adenocarcinoma in situ (AIS) and minimally invasive adenocarcinoma (MIA) were proposed for small (no more than 3 cm), solitary adenocarcinomas with a lepidic pattern that either lack invasion (AIS) or only show small foci of invasion measuring no more than 0.5 cm (MIA). AIS and MIA should define patients with either 100% or near 100% 5-year disease-free survival if the tumor is completely resected. The term mixed subtype was discontinued, and invasive adenocarcinomas were classified according to their predominant subtype. Using this approach, the proportions of each of the histologic subtypes should be estimated in a semiquantitative manner and a predominant pattern designated. The term lepidic predominant adenocarcinoma was proposed for nonmucinous tumors classified formerly as mixed subtype where the predominant subtype consists of the former nonmucinous BAC. Micropapillary adenocarcinoma was introduced as a major histologic subtype as multiple studies have shown that patients with such tumors have a poor prognosis.[10–13] The tumors formerly classified as mucinous BAC are now reclassified as mucinous AIS or MIA or invasive mucinous adenocarcinoma; these tumors on computed tomography (CT) scan frequently show nodules of consolidation with air bronchograms and a multinodular and multilobar distribution. Finally, clear cell and signet ring adenocarcinomas were discontinued as major subtypes because they represent cytologic features that can occur in multiple histologic patterns of adenocarcinoma; however, now these features can be recorded when any amount is present.[7,14]

In the new classification, tumors formerly regarded as BAC included a wide spectrum of entities with varied clinical behavior such as AIS, MIA, lepidic predominant adenocarcinoma, overtly invasive adenocarcinoma with a lepidic component, and invasive mucinous adenocarcinoma. AIS should not be equated with tumors previously classified as BAC, particularly in registry databases such as Surveillance, Epidemiology, and End Results Program (SEER).[15] Such data could be misleading as AIS is the rarest lung adenocarcinoma, representing only 0.2% to 3% of cases in white populations and up to 5% in a Japanese series.[16–18] Most cases previously classified as BAC represent tumors with invasive components. Since the publication of the 2011 IASLC/ETS/ERS classification, a series of studies validated various aspects of the classification in resection specimens. Studies from Australia,[17] Europe,[19] Asia,[18] and North America have demonstrated that the proposed subtyping has prognostic value.[16,20]
Fig. 17.1. Early lesions of lung adenocarcinoma. (A) Atypical adenomatous hyperplasia (*AAH*), (B) adenocarcinoma in situ (*AIS*), (C) microinvasive carcinoma (*MIA*), and (D) acinar growth pattern of the invasive component in the scar of a MIA (H&E stain).

Atypical Adenomatous Hyperplasia

Atypical adenomatous hyperplasia (AAH) is considered to be a precursor of adenocarcinoma.[21,22] AAH is a discrete parenchymal lesion in the alveoli close to terminal and respiratory bronchioles. Because of their size, AAH cells are usually incidental histologic findings, but they may be detected grossly, especially if they are 0.5 cm or larger. The increasing use of high-resolution CT scans for screening purposes has led to an increasing awareness of AAH, which remains one of the most important differential diagnoses of air-filled peripheral lesions (so-called ground-glass opacities). AAH maintains an alveolar structure lined by rounded, cuboidal, or low columnar cells (Fig. 17.1A). The postulated progression of AAH to adenocarcinoma with predominant lepidic growth features, apparent from the increasingly atypical morphology, is supported by the results of morphometric, cytofluorometric, and molecular studies.[22,23] The origin of AAH is still unknown, but the differentiation phenotype derived from immunohistochemical and ultrastructural features suggests an origin from the progenitor cells of the peripheral airways, such Clara cells and type II pneumocytes.[24,25]

Adenocarcinoma in Situ

AIS was added to the group of preinvasive lesions along with AAH (Table 17.2).[7,8,14] AIS is defined as a localized, small (no more than 3 cm) adenocarcinoma consisting of neoplastic pneumocytes growing along preexisting alveolar structures (lepidic growth), lacking stromal, vascular, or pleural invasion (Fig. 17.1B). No papillary or micropapillary patterns should be present, and intra-alveolar tumor cells are absent. AIS is typically nonmucinous, consisting of type II pneumocytes and/or Clara cells, but rare cases of mucinous AIS do occur. The concept of AIS was proposed with the intention of defining lesions that should correlate with a 100% disease-free survival if completely resected. This proposal was supported by retrospective observational studies in tumors measuring either 2 cm or less or 3 cm or less.[7] In the setting of multiple tumors, the criteria for AIS as well as MIA should be applied only if the other tumors are regarded as synchronous primaries rather than intrapulmonary metastases.

Minimally Invasive Carcinoma

MIA is defined as a small (no more than 3 cm), solitary adenocarcinoma with a predominantly lepidic pattern and invasion of no more than 5 mm in greatest dimension (Fig. 17.1C–D).[26,27] MIA is usually nonmucinous, but it may rarely be mucinous.[16] Measurement of the invasive component of MIA should include the following: (1) histologic subtypes other than a lepidic pattern (i.e., acinar, papillary, micropapillary, and/or solid) or (2) tumor cells infiltrating myofibroblastic stroma. MIA should not be diagnosed if the tumor invades lymphatics, blood vessels, or pleura or contains tumor necrosis. More details about measuring invasive size are explained elsewhere.[7,9] The concept of MIA was introduced to define a population of patients who should have a 100% or near 100% 5-year disease-free survival rate if the lesion is completely resected. Although less evidence was found to support the concept of MIA compared with AIS,[26,27] all published cases using these criteria have shown a 5-year disease-free survival rate of 100%.[16–18,20]
Fig. 17.2. Invasive adenocarcinoma. (A) Invasive lung adenocarcinoma with mixed patterns, including central acinar and peripheral lepidic components. Examples of invasive lung adenocarcinoma patterns: (B) acinar; (C) lepidic; (D) papillary; (E) micropapillary; and (F) solid with mucin. (A–C, E, H&E stain; D–F, mucin stain.)

The diagnosis of AIS or MIA requires that the tumor be completely sampled histologically (i.e., the patient has undergone a surgical resection). Both lesions should also have a discrete circumscribed border without miliary spread of small foci of tumor into adjacent lung parenchyma and/or with lobar consolidation. Review of CT scans may be helpful in evaluating pathologic specimens because the extent of ground-glass (usually lepidic) and solid (usually invasive) patterns can guide pathologists in assessing whether the lesion has been properly measured and/or sampled. For lesions suspected to be AIS or MIA larger than 3 cm, the term lepidic predominant adenocarcinoma is best applied, along with a comment that an invasive component cannot be excluded,

because the data are insufficient to show that such patients will have 100% 5-year disease-free survival.

Invasive Adenocarcinoma

Because of the rarity of AIS and MIA, overtly invasive adenocarcinomas represent more than 70% to 90% of surgically resected lung adenocarcinomas. These tumors typically consist of a complex, heterogeneous mixture of histologic patterns, thus explaining the former category of adenocarcinoma, mixed subtype (Fig. 17.2). The major subtypes of invasive adenocarcinoma are now classified according to the predominant component, after

performing comprehensive histologic subtyping (Fig. 17.2B–F, and Table 17.2). Comprehensive histologic subtyping is performed by making a semiquantitative estimation of each of the patterns in 5% increments. It is useful to record in diagnostic reports each adenocarcinoma subtype that is present with the respective percentages. This approach may also provide a basis for architectural grading of lung adenocarcinomas.[16,28,29] Since the 2011 classification was initially published, a growing number of studies of resected lung adenocarcinomas have demonstrated its utility in identifying significant prognostic subsets and molecular correlations according to the predominant patterns.[17–19,28,30–32]

Lepidic Predominant Invasive Adenocarcinoma. This subtype consists of a proliferation of bland type II or Clara cells growing along the surface of alveolar walls, similar to the morphology defined in the earlier section on AIS and MIA (Fig. 17.2C). Invasive adenocarcinoma is present in at least one focus measuring more than 5 mm in greatest dimension. Invasion is defined as follows: (1) histologic subtypes other than a lepidic pattern (i.e., acinar, papillary, micropapillary, and/or solid); (2) myofibroblastic stroma associated with invasive tumor cells; (3) vascular or pleural invasion; and (4) spread through alveolar spaces (STAS).[33–35] Lepid predominant adenocarcinoma is diagnosed rather than MIA if the cancer invades lymphatics, blood vessels, or pleura or contains tumor necrosis. Several recent studies of early-stage adenocarcinomas published since 2011 have demonstrated that lepidic predominant tumors have a favorable prognosis, with 5-year disease-free survival rates of 86% to 90%.[17–19] The term adenocarcinoma with lepidic pattern corresponds to some cases previously referred to as adenocarcinoma with BAC features. The term lepidic predominant adenocarcinoma should not be used in the context of invasive mucinous adenocarcinoma with predominant lepidic growth; these tumors should be classified as mucinous adenocarcinomas.

Acinar Predominant Invasive Adenocarcinoma. This subtype shows a major component of glands that are round to oval with a central luminal space surrounded by tumor cells (Fig. 17.2B).[6] The neoplastic cells and/or glandular spaces may contain mucin. Cribriform structures can be found in the acinar pattern, are considered to be high grade, and are associated with poor prognosis.[36] Tumor cells may form aggregates of polarized cell without clear lumen, which is still recognized as an acinar pattern.

Papillary Predominant Adenocarcinoma. This subtype shows a major component of a growth of glandular cells along central fibrovascular cores (Fig. 17.2D).[6] If a tumor has lepidic growth, but the alveolar spaces are filled with papillary or micropapillary structures, the tumor is classified as papillary or micropapillary adenocarcinoma, respectively.

Micropapillary Predominant Adenocarcinoma. This subtype has tumor cells growing in papillary tufts or florets that lack fibrovascular cores (Fig. 17.2E).[6] These may appear detached and/or connected to the alveolar walls. The tumor cells are usually small and cuboidal with minimal nuclear atypia. STAS is a newly suggested pattern of invasion, often seen with the micropapillary pattern; it can occur with micropapillary clusters, solid nests, or single cells. STAS probably contributes to the high recurrence rate for patients with small stage I adenocarcinomas who undergo limited surgical resections and the poor prognosis observed by others.[12,33]

Solid Predominant Invasive Adenocarcinoma. The solid subtype with mucin production consists of a major component of polygonal tumor cells forming sheets but without any clear acinar, papillary, micropapillary, or lepidic growth (Fig. 17.2F).[6] If the tumor is 100% solid, intracellular mucin should

be present in at least five tumor cells in each of two high-power fields, confirmed with histochemical stains for mucin.[6,9] Tumors formerly classified as large cell carcinomas that have immunohistochemical expression of TTF-1 and/or napsin A, even if mucin is not identified, are now classified as solid adenocarcinomas. Solid adenocarcinomas must be distinguished from nonkeratinizing squamous cell carcinomas and large cell carcinomas, both of which may show rare cells with intracellular mucin. Neuroendocrine markers, such as neural cell adhesion molecule (NCAM)/CD56, dense core granule associated protein chromogranin A, and synaptic vesicle protein synaptophysin should be performed only if neuroendocrine morphology is present, to allow the diagnosis of large cell neuroendocrine carcinoma (LCNEC).

Variants of Invasive Adenocarcinoma

Four variants of clinically relevant invasive lung adenocarcinomas are recognized: (1) invasive mucinous adenocarcinoma, with tumor cells that have a goblet or columnar cell morphology with abundant intracytoplasmic mucin (Fig. 17.3A); (2) colloid adenocarcinoma, with abundant mucin pools filling alveolar spaces; (3) fetal adenocarcinoma, resembling fetal lung; and, (4) enteric adenocarcinoma, an adenocarcinoma of the lung resembling enteric adenocarcinoma.

Invasive Mucinous Adenocarcinoma. Multiple studies have shown major differences in clinical, radiologic, pathologic, and genetic features between invasive mucinous adenocarcinomas and the tumors formerly classified as nonmucinous BAC.[37–42] Invasive mucinous adenocarcinomas have tumor cells with a goblet or columnar cell morphology with abundant intracytoplasmic mucin and aligned, basally located nucleoli (Fig. 17.3A). This pathognomonic cellular feature can be recognized in small lung samples. Similar to nonmucinous tumors, invasive mucinous adenocarcinomas may show the same heterogeneous mixture of lepidic, acinar, papillary, micropapillary, and solid growth, which will not be described in detail and quantified for this specific subtype. Although invasive mucinous adenocarcinomas frequently show lepidic predominant growth, extensive sampling usually shows invasive foci. Therefore, reports on biopsy specimens should include a remark such as mucinous adenocarcinoma with lepidic pattern. However, if a resection specimen of the mucinous tumor fulfills the diagnostic criteria of AIS or MIA, the tumor should be diagnosed as mucinous AIS or MIA, respectively, although such tumors are extremely rare. In some cases, mucinous adenocarcinoma appears in CT scans and pathology specimens with a pseudo-pneumonia growth pattern (Fig. 17.3B–C).

Colloid Adenocarcinoma. This subtype shows abundant extracellular mucin in pools, which distend the alveolar spaces and destroy their walls, showing an overtly invasive growth pattern into the alveolar spaces. Mucin deposits enlarge and dissect the lung parenchyma, creating pools of mucin-rich matrix, while tumor elements consist of foci of tall columnar cells with goblet-like features growing in a lepidic fashion. Tumor glands often float into the mucoid material, becoming poorly recognizable and then requiring extensive tumor sampling.

Fetal Adenocarcinoma. This subtype consists of complex glandular structures composed of glycogen-rich, nonciliated cells resembling a developing epithelium in the pseudoglandular phase of the fetal lung, with low nuclear atypia and morule formation.[43]

Primary Pulmonary Adenocarcinoma With Enteric Differentiation. This term is used to indicate a primary lung cancer resembling colorectal adenocarcinoma metastatic to the lung.[44–46]
Fig. 17.3. Variants of invasive adenocarcinoma with mucinous histology. (A) Mucinous invasive adenocarcinoma, (B) mucinous invasive adenocarcinoma with pseudopneumonic alveolar pattern, and (C) higher magnification of a mucinous growth with lepidic features. (A–C, H&E stain.)

Its histologic characteristics include eosinophilic tall columnar cells with brush border, vesicular nuclei, central geographic or dotted necrosis, occasional central scar and pleural indentation, and papillo–tubular (or gland-like) structure. The histologic resemblance to colorectal cancer is a hallmark of this tumor. Although some tumors have enteric differentiation with positive immunohistochemical expression of CDX-2 (which encodes for an intestine-specific transcription factor) and cytokeratin (CK) 20, and negative expression of CK7, others have only enteric morphology.

Immunohistochemistry of Adenocarcinomas

The immunohistochemical expression of lung adenocarcinomas varies somewhat based on the subtype and degree of differentiation. TTF-1 and napsin A are nearly specific markers for lung adenocarcinoma, except that thyroid cancer expresses TTF-1 and renal cell carcinoma expresses napsin A. Approximately 75% of invasive adenocarcinomas are positive for TTF-1 (Fig. 17.4), and none of the squamous cell carcinomas express TTF-1. Among the adenocarcinoma subtypes, most lepidic and papillary predominant tumors are positive for TTF-1, as are the lepidic components of AIS and MIA, whereas positive frequency is lower in cases of solid predominant cancer.[32,47] The sensitivity of napsin A is comparable to that of TTF-1, but its specificity is far lower.[48] CK7 is another marker for lung adenocarcinoma, and its sensitivity, but not its specificity, is higher than that of TTF-1 and napsin A. Furthermore, tumor protein p63, which has been used as a marker for a squamous cell carcinoma, is also positive in some lung adenocarcinoma (up to 38%),[49] and a portion of these adenocarcinomas are positive for anaplastic lymphoma kinase (*ALK*) gene rearrangement.[50–52] In contrast, protein p40, an isoform of p63,[50] is never positive in adenocarcinomas except for those contained in adenosquamous carcinomas. Some adenocarcinomas may show a squamous appearance. In these cases, phenotyping with a limited panel of immunomarkers (including p40, and TTF-1) and mucin stain is necessary.[7,49,53,54]

Histologic and Molecular Correlations

Despite the discovery of multiple molecular abnormalities in lung adenocarcinoma, no significant, specific histologic and molecular correlations have been found. A number of driver gene alterations are now known to exist in lung adenocarcinomas including mutations of EGFR, KRAS, BRAF, and ERBB2/HER2, and rearrangements of ALK, RET, ROS1, NTRK1, and NRG1.[55–61] Among these mutations, EGFR and ALK are clinically relevant because molecular targeted drugs can be used in patients whose tumors have these molecular abnormalities. Adenocarcinomas with BRAF, HER2, ROS1, and NTRK1 abnormalities share clinicopathologic features with the EGFR-mutant and ALK-rearranged tumors in terms of involvement that is nearly specific to adenocarcinoma in lung cancer, particularly frequent in TTF-1–positive expression, and preferentially present in never-smokers and in women. The frequent finding of KRAS mutation and consistent lack of EGFR mutation in invasive mucinous adenocarcinoma is the strongest histologic and molecular correlation found in lung cancer. Most histologic subtypes of adenocarcinoma harbor EGFR and KRAS mutations, as well as ALK rearrangement. EGFR mutations are encountered most frequently in nonmucinous adenocarcinomas with a lepidic or papillary predominant pattern, whereas KRAS mutations tend to be found in solid predominant adenocarcinomas. ALK rearrangement has mostly been associated with an acinar pattern including a cribriform morphology and with signet-ring cell features, particularly in those tumors with TTF-1 and p63 coexpression.[51,62,63]

Impact of the New Classification on Tumor, Node, Metastasis Staging

The 2011 IASLC/ATS/ERS classification of adenocarcinoma can affect tumor, node, metastasis (TNM) staging in several ways. First, it may help in comparing histologic characteristics of multiple lung adenocarcinomas to determine whether they are intrapulmonary metastases or separate primaries. Using comprehensive histologic subtyping along with other histologic characteristics has been shown to correlate well with molecular analyses and clinical behavior.[64,65] Second, it may be more meaningful clinically to measure tumor size in lung adenocarcinomas that

Diagnosis of lung cancer in small biopsies and cytology: implications of the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society classification. *Arch Pathol Lab Med.* 2013;137(5):668–684.

[b]*IASLC/ATS/ERS*, International Association for the Study of Lung Cancer, American Thoracic Society, and European Respiratory Society; *NSCLC-NOS*, nonsmall cell lung cancer, not otherwise specified. Pattern can be seen not only in large cell carcinomas, but also when the solid, poorly differentiated component of adenocarcinomas or squamous cell carcinomas does not express immunohistochemical markers or mucin; *TTF-1*, thyroid transcription factor-1; *WHO*, World Health Organization.

have a lepidic component by using the invasive size rather than total size to determine the final size of the tumor for TNM staging. It is possible that in the next edition of the TNM, AIS may be regarded as tumor carcinoma in situ (Tis) and MIA may be regarded as tumor microinvasive (Tmi).

Small Biopsy and Cytology Samples

In the past, NSCLCs were lumped together without attention to more specific histologic typing (e.g., adenocarcinoma, squamous cell carcinoma, etc.).[8] One of the major new proposals in the IASLC/ATS/ERS classification was the development of standardized criteria and terminology for the pathologic diagnosis of lung cancer in small biopsy and cytology specimens (Table 17.3).[8,9]

In addition to the criteria and terminology, two paradigm shifts have emerged for pathologists in terms of tumor classification and management of specimens. The first is the need to perform immunohistochemistry to further classify tumors formerly diagnosed as NSCLC not otherwise specified (NOS). Because the distinction between histologic types of lung cancer, particularly adenocarcinoma and squamous cell carcinoma, is so important, the new classification recommends that pathologists use special stains to try to further subtype carcinomas that are difficult to classify by light microscopic evaluation of histologic sections alone.

For tumors with classic morphologic features the diagnostic terms adenocarcinomas and squamous cell carcinomas can be used (Table 17.3). The morphologic features of these tumors are described in detail elsewhere.[6,7,9] If an NSCLC does not show

clear glandular or squamous morphology in a small biopsy or cytology specimen, it is classified as NSCLC-NOS.[7,66] Tumors with this morphologic appearance should be studied with a limited special stain workup in an attempt to classify them further. It is recommended to use a single adenocarcinoma marker (e.g., TTF-1), a single squamous marker (e.g., p40), and/or mucin stain.[66,67] Tumors that are positive for an adenocarcinoma marker or mucin are classified as NSCLC, favor adenocarcinoma. Tumors that are positive for a squamous cell carcinoma immunohistochemical marker with negative adenocarcinoma markers are classified as NSCLC, favor squamous cell carcinoma. Cytology is a powerful diagnostic tool that can accurately subtype NSCLC in most cases,[66] and immunohistochemistry is readily available when cell blocks are prepared for the cytology samples.[68]

Squamous Cell Carcinoma

Squamous cell carcinoma is thought to arise from the airway epithelium and is characterized histologically by keratinization and/or intercellular bridges. If these morphologic hallmarks are absent, a diagnosis can be established only by positive immunohistochemical staining for markers such as p40 and CK5/6.

Squamous cell carcinoma usually arises in a main or lobar bronchus, but more peripheral locations are not uncommon. The centrally located hilar-type occasionally shows intraepithelial spread that may extend to the cut end of the resected bronchus; therefore, frozen sections of the mucosa at the resected end must be examined during surgical procedures. In comparison with adenocarcinoma, many peripherally located squamous cell carcinomas are only locally invasive, and pleural carcinomatosis is rare. The spread of squamous cell carcinoma is similar to that of other NSCLCs. Staging of squamous cell carcinoma, as for other malignant epithelial tumors of the lung, is performed according to the TNM system. Uncommonly, squamous cell carcinoma manifests as a superficial spreading tumor on the bronchial mucosa. Squamous cell carcinoma tends to be locally aggressive, involving adjacent structures through direct invasion.

Preinvasive Lesions

The histopathologic sequence of preinvasive lesions of squamous cell carcinoma has been identified and is characterized for different degrees of squamous dysplasia and carcinoma in situ (Fig. 17.5).[69] The criteria for squamous dysplasia and carcinoma in situ are similar to those for lesions occurring in the uterine cervix and oral cavity. However, the histologic appearance of these lesions is not uniform, because bronchial dysplasia originates from pseudostratified columnar epithelium and is not deeply associated with human papilloma virus (HPV) infection.

In a dysplastic lesion, the ciliated respiratory epithelium is replaced by thick, stratified squamous epithelium with moderate nuclear atypia, but still retaining the capacity for squamous differentiation. Angiogenic squamous dysplasia is a specific phenotype of dysplasia characterized by proliferation of small blood vessels in the submucosa; this subtype shows high proliferative activity and is associated with high-risk smokers.[70] Carcinoma in situ is composed of stratified epithelium (more than 10 cells thick) with an increased nuclear-to-cytoplasmic ratio and severe nuclear atypia, but it does not show invasive growth.

Early Invasive Squamous Cell Carcinoma

Centrally located (hilar-type) early invasive squamous cell carcinoma is defined as a tumor that arises in areas up to the subsegmental bronchus, is confined to the bronchial wall, and shows no lymph node metastasis. Early invasive squamous cell carcinoma is associated with a 5-year survival rate of more than 90% and

can be divided into the following subtypes: (1) polypoid type, frequently arising at the bronchial spar; (2) nodular type, arising at any bronchus and having a tendency to form a localized tumor showing vertical invasive growth; and, (3) superficially infiltrating type, showing in situ and microinvasive growths, often involving a wide area but exhibiting little tendency to produce bronchial stenosis and obstruction.

In comparison with the hilar-type, little is known about the peripheral type of squamous cell carcinoma. A unique subtype of squamous cell carcinoma with alveolar space filling (ASF) has been proposed.[71,72] Peripheral-type squamous cell carcinoma can be divided into two distinctive subtypes, the ASF-type and the expanding or destructive-type, based on the condition of the elastic fiber framework. The ASF-type shows growth that fills the alveolar space without destruction of the existing alveolar structure or elastic fiber network (Fig. 17.6A). It has been suggested that ASF growth represents an in situ lesion with an extremely favorable prognosis.

Invasive Squamous Cell Carcinoma

Invasive squamous cell carcinoma arises in both the major (main to segmental) bronchus and the peripheral parenchyma. The former type shows both endobronchial and invasive growth into the peribronchial soft tissue, lung parenchyma, and nearby lymph nodes. Squamous cell carcinoma growing in the endobronchial region sometimes blocks the bronchus, resulting in secondary changes to the distal lung, such as collapse, lipid pneumonia, and bronchopneumonia. On the other hand, squamous cell carcinoma arising in the peripheral region shows two different tumor growth types: the ASF-type and the compression-type. In comparison with the hilar-type, the peripheral squamous cell carcinoma frequently possesses mucin-containing cells and shows glandular cell charactertistics. Therefore, many tumors diagnosed as peripheral-type squamous cell carcinomas are actually adenosquamous cell carcinomas in the strict sense.

Invasive squamous cell carcinomas are grouped in three major histologic types, including the common types keratinizing and nonkeratinizing, and the basaloid type.

Keratinizing and Nonkeratinizing Squamous Cell Carcinoma. Most invasive squamous cell carcinomas are moderately or poorly differentiated. The well-differentiated carcinoma is not common in comparison with squamous cell carcinoma of stratified squamous epithelial origin, such as that of the oral cavity, pharynx, and esophagus. Squamous cell carcinoma arising from a major bronchus frequently shows an intraepithelial, in situ type of extension along the bronchus. Histologically, invasive squamous cell carcinoma shows geographic nests composed of polygonal cells with intercellular bridges and keratinization (Fig. 17.6B–C). As stated, the common type of squamous cell carcinoma is divided into two classes: keratinizing and nonkeratinizing. The keratinizing type is well to moderately differentiated and easy to diagnose as squamous cell carcinoma, whereas the nonkeratinizing type is sometimes difficult to diagnose if it does not contain intercellular bridges (Fig. 17.6D).

Keratinization and intercellular bridges are the hallmarks for the differential diagnosis of squamous cell carcinoma from other NSCLCs. However, if a tumor is poorly differentiated and differentiation is unclear, immunohistochemical analysis using a limited panel of markers and mucin staining is necessary. The most important diagnostic immunohistochemical marker of squamous cell carcinoma is p40 (Fig. 17.6F), which is more specific than p63 (Fig. 17.6E).[73,74] These markers are positive in the tumor cell nuclei and are fundamental markers for basal cells of the bronchial mucosa. CK5/6 is a less reliable marker of squamous cell carcinoma.[75] TTF-1, which is a very specific marker for adenocarcinoma, should be negative.[76] If
Fig. 17.5. Histopathologic sequential changes involved in the pathogenesis of squamous cell carcinoma of the lung. (A) Normal bronchial epithelium; (B) basal cell hyperplasia; (C) squamous metaplasia of bronchial epithelium; (D) moderate dysplasia; (E) carcinoma in situ; and (F) invasive squamous cell carcinoma. (A–F, H&E stain.)

the immunostaining profile is the only evidence for a diagnosis of squamous cell carcinoma, such cases should be diagnosed as tumor with squamous cell carcinoma nonkeratinizing type. It is sometimes difficult to differentiate pulmonary squamous cell carcinoma from metastatic squamous cell carcinoma of other sites, such as the head and neck, esophagus, or cervix. Genotypic fingerprinting for *TP53* mutation, loss of heterozygosity, or HPV genotyping has been reported to be useful for the differential diagnosis.[77] Despite the discovery of multiple molecular abnormalities in squamous cell carcinoma,[78,79] no significant, specific histologic and molecular correlations have been found in this tumor type.

Immunohistochemistry of Squamous Cell Carcinoma. Squamous cell carcinoma has traditionally been defined as a tumor that shows keratinization, pearl formation, and/or intercellular bridges. Immunohistochemistry is not needed in these tumors. As intercellular bridging may be scarce in nonkeratinizing squamous cell carcinoma, immunohistochemistry is needed to distinguish theses tumors from large cell carcinoma with a null immunophenotype in surgical resections, and NSCLCs with adenocarcinoma or NSCLC-NOS phenotype on small biopsies. For such tumors, diffuse positive staining with p40, p63, and/or CK5 or CK5/6 confirms their squamous phenotype and classification as a nonkeratinizing squamous cell carcinoma.
Fig. 17.6. Squamous cell carcinoma (SCC). (A) SCC of the alveolar space filling-type, with tumor cells preserving the elastic fiber framework; (B) SCC of the keratinizing type showing keratinization; (C) SCC of the keratinizing type showing cellular keratinization at higher magnification; (D) SCC of the nonkeratinizing type; (E) p63 immunohistochemical expression; and (F) p40 immunohistochemical expression. (A, elastic stain; B–D, H&E stain).

Both TTF-1 and mucin stains should be negative or only focally positive (for TTF-1, less than 10% of cells with faint staining).

Basaloid Carcinoma. Basaloid carcinoma is a variant of squamous cell carcinoma (Fig. 17.7). This is a poorly differentiated tumor that displays lobular architecture and peripheral palisading of nuclei at the edge of tumor nests and lacks squamous differentiation. The tumor cells are relatively small with scanty cytoplasm and absent or focal nucleoli. The mitotic rate is high (15–50 per 2 mm^2) and the proliferation index is high as assessed by Ki-67 (approximately 50–80%). In the 2004 WHO classification, this tumor was classified as the basaloid variant of large cell carcinoma; however, as it is usually positive for p40 immunohistochemical expression, recently it has been reclassified as a variant of squamous cell carcinoma (Fig.
Fig. 17.7. Basaloid carcinoma. (A) Histology (H&E stain) and (B) p40 immunohistochemical staining.
Fig. 17.8. (A) Adenosquamous carcinoma and (B) sarcomatoid carcinoma, spindle cell. (A and B, H&E stain.)

17.7B).[80] Tumors with keratinizing or nonkeratinizing squamous cell carcinoma features that have more than 50% basaloid component are classified as basaloid carcinoma. These changes were introduced to the new 2015 WHO classification.[5] Tumor spread and staging of basaloid carcinoma are similar to those of other squamous cell carcinomas of the lung.

Immunohistochemistry of Basaloid Carcinoma. Basaloid carcinoma is a specific subtype of nonkeratinizing squamous cell carcinoma that requires differential diagnosis with SCLC and LCNEC, with which it might be confused in the case of crushed artifact due to small cell size or the presence of rosettes and palisading with centrolobular necrosis. Basaloid carcinoma consistently shows diffuse and strong expression of p63 and its isoform p40 (Fig. 17.7B). CK5/6 and the cytokeratins included in the antibody 34βE12 (CKs 1, 5, 10, and 14) are also expressed in all cases, sometimes in a less diffuse fashion. TTF-1 is never expressed.[50,81] Neuroendocrine markers (NCAM/CD56, chromogranin A, and synaptophysin) are usually negative.

Adenosquamous Carcinoma

This tumor is characterized by the presence of both squamous cell and adenocarcinoma differentiations. A carcinoma showing histologic characteristics of each component in at least 10% of the tumor should be categorized as adenosquamous carcinoma (Fig. 17.8A). However, a situation where less than 10% of each histologic differentiation is present should be reported because recent molecular analyses have suggested that tumors with mixed features can reflect the genetic status of either component regardless of their proportion in the tumor.[82] The frequency of adenosquamous carcinoma is estimated at 0.4% to 4% of lung cancers.[6] Typically, adenosquamous carcinomas are located in the peripheral pulmonary parenchyma, but they have also been reported to arise centrally.[83] The clinical characteristics are similar to those of other NSCLCs. The outcome of adenosquamous carcinoma is significantly poorer than that of adenocarcinoma and squamous cell carcinoma, particularly in stages I and II.[84] The amount of each component does not affect the survival rate.

Immunohistochemistry of Adenosquamous Carcinoma

Although adenosquamous carcinoma is diagnosed on the basis of morphologic features, immunohistochemistry is sometimes useful for distinguishing the relatively poorly differentiated components, including solid adenocarcinoma and nonkeratinizing squamous cell carcinoma. TTF-1 (a hallmark of adenocarcinoma differentiation) and p40 (a hallmark of squamous cell carcinoma differentiation) are the two best markers for immunohistochemical analysis.[74] Only uniformly, diffusely, and clearly stained areas should be judged as positive immunostaining for p40.

Sarcomatoid Carcinoma

This category encompasses a heterogeneous group of uncommon tumors, including pleomorphic, spindle, and giant cell carcinomas, as well as carcinosarcomas and pulmonary blastomas.

Pleomorphic, Spindle, and Giant Cell Carcinomas

These tumors represent poorly differentiated NSCLCs, namely adenocarcinoma, squamous cell carcinoma, or large cell carcinoma containing at least 10% spindle cells (Fig. 17.8B) and/or giant cells.[85,86] A specific and definite diagnosis may be made only on a resected tumor. The specific histologic components should be mentioned in the diagnosis. In small biopsy specimens, the sarcomatoid elements should be described. Pure spindle cell carcinoma and giant cell carcinoma are very rare. The most common presentation is a large peripheral mass, usually in an upper lobe.[87] These are aggressive tumors with spread similar to that of other NSCLCs, and distant metastases are commonly found. Tumors are staged according to the TNM classification.

Immunohistochemistry is useful for highlighting the differentiation characteristics of the tumor cells. Evidence of keratin expression in the spindle or giant cell components is not required if carcinoma is clearly present. Various kinds of genetic alterations have been reported, but no specific mutations, rearrangements, and amplifications are found in this type of tumor.[86]

Carcinosarcoma

Carcinosarcoma is a malignant tumor consisting of a mixture of carcinoma and sarcoma containing heterologous elements such as rhabdomyosarcoma, chondrosarcoma, and osteosarcoma.[47] Carcinosarcoma arises either in the major bronchi or in the peripheral lung. The diagnosis of carcinosarcoma is difficult using small biopsy samples, and immunohistochemistry may be helpful for confirming clear epithelial and sarcomatous differentiation. Although most carcinosarcomas contain conventional NSCLC, some cases may have a component of high-grade fetal adenocarcinoma. This type of tumor may be referred to as the blastomatoid variant of carcinosarcoma. However, carcinosarcoma lacks the component of low-grade fetal adenocarcinoma and the primitive stroma of pulmonary blastoma.

Pulmonary Blastoma

Pulmonary blastoma is a biphasic tumor composed of low-grade fetal adenocarcinoma and primitive mesenchymal cells showing various degrees of differentiation. Foci of specific mesenchymal differentiation (e.g., immature cartilage) may exist, but they are not required for diagnosis. Pulmonary blastoma and well-differentiated fetal adenocarcinoma contain missense mutations in exon 3 of the beta-catenin gene, which result in activation of the Wnt pathway and aberrant nuclear localization of beta-catenin. Therefore, nuclear localization of beta-catenin is a unique diagnostic marker of pulmonary blastoma.[83,84] Because pulmonary blastoma is a biphasic tumor, it expresses both epithelial and mesenchymal immunomarkers.

Immunohistochemistry of Sarcomatoid Carcinoma

Although these tumors are diagnosed by morphologic features, immunohistochemistry may highlight the different cell components. The differentiated epithelial elements show the expected immunophenotypes. Cytokeratin expression is not required in the spindle or giant cell component if carcinoma is clearly present. The pleomorphic, spindle, or giant cell components express vimentin and fascin.[85,88–90] Cytokeratins and differentiation-associated markers such as napsin A,[91,92] TTF-1, p63, and CK5/6 are variably expressed in sarcomatoid elements.[88,93]

Large Cell Carcinoma

Large cell carcinoma is defined as an undifferentiated NSCLC that lacks the cytologic, architectural and immunohistochemical features of adenocarcinoma or squamous cell carcinoma. The diagnosis requires a thoroughly sampled resected tumor and can be made only on resected specimens and not in small biopsy specimens or cytology samples. Even if squamous or adenocarcinoma differentiation cannot be detected in biopsy material both morphologically and immunohistochemically, a diagnosis of large cell carcinoma cannot be made, because the tumor may contain squamous cell carcinoma and/or adenocarcinoma with a large cell component. Therefore, in that event, the tumor should be diagnosed NSCLC-NOS (Table 17.3). Many tumors previously classified as large cell carcinoma according to the 2004 WHO classification are now reclassified as per the 2015 WHO classification as adenocarcinoma, solid subtype (positive for TTF-1, napsin A, or mucin) or squamous cell carcinoma, nonkeratinizing subtype (positive for p40 or p63) based on use of immunohistochemistry and mucin stains.[5]

Historically, large cell carcinoma has accounted for about 10% of all lung carcinomas.[94] However, recent data from the SEER database in the United States have shown that the frequency has decreased from 9.4% to 2.3%. This change is explained by the more precise diagnosis of NSCLC subtypes using immunohistochemical staining. The average patient age at diagnosis is around the 7th decade, and the male-to-female ratio is 4:1 or 5:1, which lies between the ratios for squamous cell carcinoma and adenocarcinoma.[69] Large cell carcinoma arises more frequently in the periphery of the lung. It usually forms a spherical tumor with well-defined borders, and it has a bulging, fleshy, homogeneous, rather sarcomatous appearance. Necrosis is often found, but cavitation is rare. Some large cell carcinomas resemble poorly differentiated adenocarcinoma or squamous cell carcinoma grossly. On histological examination, most large cell carcinomas are composed of solid nests of polygonal cells with vesicular nuclei, prominent nucleoli, moderately abundant cytoplasm, well-defined cell borders, and a scant fibrovascular stroma (Fig. 17.9A). These histologic features suggest a poorly differentiated carcinoma in which differentiation to squamous cell carcinoma or adenocarcinoma cannot be confirmed.

The 2004 WHO classification listed five histologic variants of large cell carcinoma: LCNEC, basaloid carcinoma, lymphoepithelioma-like carcinoma, clear cell carcinoma, and large cell carcinoma with rhabdoid phenotype.[6] However, in the recently released 2015 WHO classification, LCNEC will be reclassified into the new category of neuroendocrine tumor, and basaloid carcinoma is included as a variant of squamous cell carcinoma (Table 17.1).[5] Pure large cell carcinomas with clear cells or rhabdoid phenotypes are quite rare, and they are not considered a variant of cell carcinoma. If these components are detected in a large cell carcinoma, their presence should be added in the histologic description.

Immunohistochemistry of Large Cell Carcinoma

Large cell carcinoma is an undifferentiated carcinoma from the aspects of both morphology and immunohistochemistry. Therefore, if a resected tumor cannot be diagnosed as adenocarcinoma or squamous cell carcinoma morphologically, immunohistochemical analysis should be performed.[75,76] Many immunohistochemical differentiation markers have been reported, but based on analyses of sensitivity and
Fig. 17.9. Large cell carcinoma. (A) Histology (H&E stain); (B) negative for immunohistochemical marker TTF-1; and (C) negative for immunohistochemical marker p40.

specificity, the most useful are p40 and CK5/6 for identifying squamous differentiation, and TTF-1 and napsin A for identifying adenocarcinoma differentiation. Practically, if no morphologic differentiation can be detected in the resected specimen, immunohistochemical analysis should be done, and if squamous markers (p40 and/or CK5/6) are positive and adenocarcinoma markers (TTF-1 and/or napsin A) are negative, the tumor should be diagnosed as nonkeratinizing squamous cell carcinoma. On the other hand, if adenocarcinoma markers (TTF-1 and/or napsin A) are positive and squamous markers (p40 and/or CK5/6) are negative, the diagnosis should be of adenocarcinoma, solid subtype. A tumor that is negative for both adenocarcinoma and squamous cell carcinoma markers can be finally diagnosed as large cell carcinoma (Fig. 17.9B–C). However, if immunohistochemistry is not applicable, a comment should be included in the pathology report, such as diagnosed without immunohistochemical analysis or diagnosed by histology only.

NEUROENDOCRINE TUMORS

Neuroendocrine tumors account for approximately 15% of lung cancers. Neuroendocrine neoplasms of the lung are ubiquitous tumors composed of malignant cells showing neuroendocrine differentiation and representing a wide spectrum of clinical, biologic, and histopathologic features. Four major types of neuroendocrine tumors of the lung are recognized: typical and atypical carcinoids, considered low- and intermediate-grade tumors, respectively; and LCNEC and SCLC, considered high-grade malignancies.[95]

The precursor lesions for the most common type of neuroendocrine carcinoma of the lung, SCLC, are unknown.[21,23] However, a rare lesion called diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH) has been associated with the development of typical and atypical carcinoids.[21,96,97] DIPNECH lesions include local extraluminal proliferations in the form of tumorlets. Carcinoid tumors are arbitrarily separated from tumorlets if the neuroendocrine proliferation is 0.5 cm or larger. The findings of more widespread and more extensive genetic damage in normal and hyperplastic bronchial epithelium among patients with SCLC, as compared with NSCLC, suggest that SCLC may arise directly from histologically normal or mildly abnormal epithelium without passing through a more complex histologic sequence.[98]

Carcinoid Tumors

Carcinoid tumors are thought to be derived from neuroendocrine cells known to exist in normal airways. However, in contrast to most other lung cancers, these tumors have no relationship to smoke exposure.[95] Compared with typical carcinoids, atypical carcinoids are larger and have a higher rate of metastases, and survival of patients with this type of tumor is significantly reduced.[99] The 5-year survival rates for metastatic typical and atypical carcinoids are approximately 90% and 60%, respectively; rates are higher for resectable tumors.[99]

Carcinoids are located centrally and peripherally in the lung.[100] When the tumor is centrally located, it commonly shows bronchial involvement, has a sessile and pedunculated shape, and often fills the bronchial lumen. An endobronchial component is found more frequently in typical than in atypical carcinoids. For staging, the current edition of the TNM classification is used. As with other types of lung cancer, tumor spread through lymphatics or the bloodstream may occur with metastasis in mediastinal lymph nodes, liver, and bones; as stated earlier, metastases are more common in atypical than in typical carcinoids.

Histologically, carcinoid tumors are characterized by an organoid growth pattern, uniform cytologic features, and immunohistochemical expression of neuroendocrine markers, such as chromogranin A, synatophysin, and NCAM/CD56.[101] Recent molecular data support the notion that carcinoids are genetically and phenotypically independent neuroendocrine tumors and they are not early progenitors of high-grade neuroendocrine tumors, such as SCLC and LCNEC tumors.[102]

Typical carcinoids are characterized by growth patterns suggesting neuroendocrine differentiation (Fig. 17.10A). Several growth patterns and a variety of cell features have been described, including, among others, spindle, mucinous, and clear cells. The tumor cells are usually uniform in appearance with polygonal shape, finely granular nuclear chromatin, inconspicuous nucleoli, and scant to moderately abundant eosinophilic cytoplasm. In general, atypical carcinoids show the same histologic patterns as typical carcinoids. By definition, atypical carcinoids have 2 to 10 mitoses per 2 mm^2 and/or foci of necrosis (often punctuate), whereas typical carcinoids show fewer than 2 mitoses per 2 mm^2 and lack necrosis (Fig. 17.10B).[103] The findings may be focally distributed, so careful examination of a resected tumor is necessary for accurate diagnosis.
Fig. 17.10. Neuroendocrine tumors. (A) Typical, and (B) atypical (arrows indicate mitosis) carcinoids; (C) histology of large cell neuroendocrine carcinoma; (D) immunohistochemical expression of cytoplasmic chromogranin A; (E) membranous NCAM/CD56; and (F) histology of SCLC. (A–C and F, H&E.)

Although no immunohistochemical marker is available to subtype carcinoids, the finding of a low Ki-67 (approximately 10–20%) labeling index is valuable in small biopsy or cytology samples, particularly with crush artifact, to avoid misdiagnosing carcinoid tumors as high-grade neuroendocrine carcinomas.[104] However, the role of Ki-67 in discriminating between typical and atypical carcinoids has not been completely validated.[105]

Immunohistochemistry of Carcinoid Tumors

Immunohistochemical staining may be required to confirm neuroendocrine and epithelial differentiation, especially in small biopsy or cytology samples. An antibody panel approach including chromogranin A and synaptophysin (both with cytoplasmic expression) is recommended. NCAM/CD56 is mostly expressed in the cell membrane.[101,103] Most carcinoids are also reactive for

low-molecular-weight cytokeratins, with negative cases mostly limited to a few peripheral tumors.[106] Pulmonary carcinoids may express several types of polypeptides such as calcitonin, gastrin-related peptide/bombesin, and adrenocorticotropic hormone similar to neuroendocrine tumors of the digestive tract.

Large Cell Neuroendocrine Carcinoma

LCNEC is a malignant epithelial tumor composed of large cells showing histologic features of neuroendocrine differentiation and immunohistochemical expression of neuroendocrine markers. In the 2004 WHO classification of lung tumors, LCNEC was considered a variant of large cell carcinoma.[6] However, the new 2015 WHO classification indicates that it should be categorized as a neuroendocrine carcinoma.[5]

Clinically, LCNEC is considered to be a high-grade neuroendocrine tumor. This tumor is commonly located in the periphery of the lung, but a central location occurs in approximately 20% of cases.[107] LCNEC harbors the potential to spread to many sites, mainly the thoracic lymph nodes, contralateral lung, liver, brain, and bones. Staging is similar to that of other NSCLCs. The tumor often invades the pleura, chest wall, and adjacent structures.[107]

Histologically, LCNEC shows neuroendocrine histologic patterns and is composed of large cells with moderate to abundant cytoplasm and often prominent nucleoli (Fig. 17.10C). Mitotic counts should be greater than 10 (average of 75) per 2 mm^2, and the count is rarely less than 30 per 2 mm^2. The Ki-67 proliferation index ranges from 40% to 80%. Necrosis usually consists of large zones, but it may be punctate. Rarely, these tumors look like atypical carcinoid, but if the mitotic rate exceeds 10 per 2 mm^2 they are classified as LCNEC. The diagnosis is difficult in small biopsy specimens unless all morphologic and immunohistochemical criteria are met; in this setting, the suggested diagnosis is NSCLC, suspect LCNEC.[108]

The neuroendocrine differentiation separates LCNEC from poorly differentiated NSCLC.[108] However, about 10% to 20% of typical lung squamous cell carcinomas, adenocarcinomas, and large cell carcinomas demonstrate neuroendocrine differentiation upon immunohistochemistry and/or electron microscopy analysis. These tumors are referred to as NSCLC with neuroendocrine differentiation on small biopsy specimens, or the specific subtype of NSCLC with neuroendocrine phenotype on resection samples. The clinical implications of this tumor category for response to therapy or survival are still unclear, so these subtypes are not here recognized as specific entities.

A LCNEC associated with components of adenocarcinoma, squamous cell carcinoma, and sarcomatoid carcinoma features is categorized as combined LCNEC. Combinations with SCLC also occur, but such tumors are classified as combined SCLC.

Immunohistochemistry of LCNEC

The diagnosis of LCNEC requires immunohistochemistry for confirmation of neuroendocrine differentiation.[109] In decreasing order of frequency, NCAM/CD56 stains 92% to 100% of LCNEC cases, followed by chromogranin A in 80% to 85%, and synaptophysin in 50% to 60% (Fig. 17.10 D–E).[110] Chromogranin A and synaptophysin are the most reliable stains for diagnostic accuracy in separating LCNEC from nonneuroendocrine tumors, and one positive marker is enough if the staining is clear.[110,111] About half of LCNEC tumors express TTF-1, a figure that is generally lower than that of SCLC,[49,110–112] but all LCNECs demonstrate reactivity to low-molecular-weight cytokeratin or CK7.[110] More than 70% of LCNEC also express CD117 (KIT protein) immunoreactivity,[113,114] which may be associated with reduced survival and increased recurrence rate.[114]

Small Cell Lung Cancer

SCLC is commonly located centrally in the major airways but may occur peripherally in the lungs in about 5% of cases. SCLCs are typically situated in a peribronchial location with infiltration of the bronchial submucosa and peribronchial tissue.[115] The tumors are large masses with extensive necrosis. SCLC can present as a solitary pulmonary nodule in less than 5% of cases.[116] Extensive lymph node metastases are common.[117] Staging is based on the TNM classification, which parallels the anatomic extent of the disease. The tendency toward widespread dissemination at presentation has sometimes led to the staging of SCLCs as limited or extensive disease rather than using the TNM system. However, the TNM classification is preferred because it separates different prognostic groups lumped together as limited disease.

On histologic examination, SCLC is characterized by small epithelial tumor cells with scant cytoplasm, round nuclei with finely granular chromatin, and absent or inconspicuous nucleoli (Fig. 17.10F).[115] Single cell necrosis is frequent and extensive, and the mitotic count is high (usually more than 10 per 2 mm^2). Although no precise upper limit of size has been specified for a cell to be defined as a small cell, it has been suggested that cells should measure approximately the diameter of two or three small mature lymphocytes.[118] In some areas, the histology is that of spindle cell with oval nucleoli. The diagnosis of SCLC is often more evident on cytology specimens than in biopsy specimens. Small biopsy samples are characterized by crush artifact and few viable cells. In larger specimens, the cell size may be larger with more abundant cytoplasm and scant pleomorphic malignant cells. Fewer than 10% of SCLCs demonstrate a mixture of other histologic types, usually adenocarcinoma, squamous cell carcinoma, large cell carcinoma, LCNEC, and, less commonly, spindle cell carcinoma or giant cell carcinoma; these tumors are referred to as combined SCLCs.[115,119] Interestingly, SCLC differentiation has been detected in tumors with acquired resistant to EGFR tyrosine kinase inhibitors therapy, and that before therapy exhibited adenocarcinoma histology and harbored an EGFR TKI sensitizing mutation.[120]

The diagnosis of SCLC is usually based on routine histologic and cytologic features; however, immunohistochemistry may be required to confirm the neuroendocrine nature of the tumor cells. Immunohistochemical expression of neuroendocrine markers, including NCAM/CD56, chromogranin A, and synaptophysin, is regularly present in SCLCs;[118,121] however, less than 10% of SCLCs are negative or focally positive for neuroendocrine markers, probably because of the lack of overt neuroendocrine differentiation.

In small biopsy specimens, the differential diagnosis of SCLC includes LCNEC, typical and atypical carcinoids, lymphoid infiltrates, the Ewing sarcoma family of tumors, and metastatic carcinomas. If examination shows marked expression of a neuroendocrine marker or a high proliferation index determined by Ki-67 immunohistochemical expression, the possibility of a lower-grade neuroendocrine carcinoma as an alternative for SCLC should be carefully excluded.[104]

Immunohistochemistry of SCLC

As stated earlier, SCLC can be diagnosed reliably on routine histologic and cytologic preparations, but immunohistochemistry may be required to confirm the neuroendocrine nature of the tumor cells. Broad reactivity to cytokeratin antibody mixtures is detected in essentially all cases of SCLC.[118] The high-molecular-weight cytokeratin cocktail (clone 34ßE12, recognizing types 1, 5, 10, and 14) is always negative in pure SCLC.[122] A panel of neuroendocrine markers is useful, including NCAM/CD56 (mostly decorating cell membrane),[101] chromogranin A, and synaptophysin (both with cytoplasmic labeling), which are regularly

expressed in SCLC.[118,123] NCAM/CD56 is the most sensitive marker, but it is also less specific and should be interpreted in the appropriate morphologic context. Although synaptophysin and NCAM/CD56 stain SCLC diffusely and strongly, chromogranin A staining can be more focal and weak. Less than 10% of SCLCs, however, are completely unreactive or only very focally stainable for neuroendocrine markers, probably because of a lack of overt neuroendocrine differentiation or artifacts of preservation.[124] SCLC is also positive for TTF-1 in up to 75% to 85% of cases,[111] especially when using the less specific clone SPT24,[125,126] whereas napsin A, a marker of adenocarcinoma differentiation, is consistently unreactive. Markers of squamous cell carcinoma such as p63 may be found in pure forms of SCLC, raising concerns about the differential diagnosis, whereas p40 is negative.[53] More than 60% of SCLCs express CD11 also in a phosphorylated form.[127] Whenever possible, particularly in small biopsy specimens, the proliferation activity of SCLC as assessed by Ki-67 antigen immunostaining can be useful to avoid misdiagnosing carcinoid tumors in the presence of crush artifact. In SCLC, Ki-67 ranges from 64.5% to 77.5% and may reach 100%.[105]

OTHER UNCLASSIFIED TUMORS

Lymphoepithelioma-Like Carcinoma

Lymphoepithelioma-like carcinoma (LELC) is a rare type of lung carcinoma characterized by a poorly differentiated morphology admixed with marked lymphocyte infiltration and expression of Epstein-Barr virus in the nuclei of the neoplastic cells.[5] The tumors are usually solitary, circumscribed, and round to ovoid. LELCs are usually located in the peripheral lung. On histologic examination, the tumor has anastomosing smooth-contoured borders with irregular islands or diffuse sheets of cells. Focal squamous differentiation can occur. The accompanying lymphoid infiltration contains a mixture of CD3-positive T cells and CD20-positive B cells. Sometimes, Epstein-Barr virus is detected in the tumor nuclei. The tumor cells are usually positive for cytokeratin cocktails (AE1/AE3), CK5/6, p40, p63 and the B-cell lymphoma-2 (Bcl-2) marker, which suggests that LELC has squamous differentiation. No specific genetic abnormalities of LELC have been reported.

NUT Carcinoma

This uncommon tumor is usually referred to as nuclear protein in testis (NUT) midline carcinoma. This tumor occurs mainly in the sinonasal region and the upper respiratory or digestive tract. The hallmark of this carcinoma is a specific translocation between the NUT gene (*NUT1*) on chromosome 15q14 (100%) and other genes, including *BRD4* on chromosome 19p13.1 (70%), *BRD3* on chromosome 9q34.2 (6%), or unknown partner genes (22%). Histologically, NUT carcinoma is an undifferentiated carcinoma and sometimes contains foci of squamous differentiation. On immunohistochemical analysis, NUT carcinoma shows speckled nuclear positivity for NUT protein in more than 50% of the tumor cells, as demonstrated using a highly specific monoclonal anti-NUT antibody.[5]

SALIVARY GLAND–TYPE TUMORS

Because the upper respiratory tract is related to the oral cavity, salivary gland–type tumors can sometimes occur in the lung. These tumors are divided into four subtypes: mucoepidermoid carcinoma, adenoid cystic carcinoma, epithelial–myoepithelial carcinoma, and pleomorphic adenoma. These tumors arise from, or differentiate to, bronchial glands. Their clinicopathologic and immunohistochemical characteristics are similar to those of tumors arising from the salivary gland.

USE OF IMMUNOHISTOCHEMISTRY FOR LUNG CANCER DIAGNOSIS

One of the major new proposals in the IASLC/ATS/ERS classification is the development of standardized criteria and terminology for the pathologic diagnosis of lung cancer in small biopsy and cytology specimens (Table 17.3).[7,128] In addition to the criteria and terminology, the new classification creates two paradigm shifts for pathologists in terms of tumor classification and management of specimens. The first is the need to perform immunohistochemistry to further classify tumors formerly diagnosed as NSCLC-NOS. Because the distinction between histologic types of lung cancer, particularly adenocarcinoma and squamous cell carcinoma, is so important, the new classification recommends that pathologists use special stains to try to further subtype carcinomas that are difficult to classify by light microscopic evaluation of hematoxylin and eosin (H&E) sections alone. These advances have now made it essential for pathologists to make every effort to identify a specific histologic type for tumors formerly classified as NSCLC.

With all the new therapeutic targets recognized during the past decade, an urgent need arose to create a classification for nonresection specimens, in particular small biopsy and cytology samples. Furthermore, therapeutic targets are increasingly being recognized outside of adenocarcinoma, so that a firm diagnosis of squamous cell carcinoma may become just as important. Accordingly, tissue samples are no longer used just for diagnosis, but also for immunohistochemical staining and molecular testing (Fig. 17.11). This methodology is particularly important for small biopsy and cytology specimens because approximately 70% of lung cancers are unresectable, with presentation at an advanced stage, and targeted therapies that require molecular testing are mostly applied to patients with advanced NSCLC. Therefore, strategic tissue management is crucial for ancillary analyses, as well as histologic diagnosis.[129] Although there are many different approaches to manage these small specimens that vary greatly depending between laboratories, a minimum consensus for good clinical practice of small biopsies and cytology preparations is provided, based on multidisciplinary consensus (Table 17.3).[7] However, the guidelines emphasize that ancillary techniques are not always necessary. Many studies have reported that adenocarcinoma or squamous cell carcinoma can be diagnosed with biopsy or cytology specimens in 50% to 70% of patients based on morphology alone. Nevertheless, the application of immunohistochemistry refines the diagnosis so that the designation of NSCLC-NOS can be avoided in up to 90% of cases.[54,130] Indeed, the guidelines strongly recommend that the term NSCLC-NOS be used as little as possible, and only when a more specific diagnosis is not possible by morphology and/or special stains.[7,9]

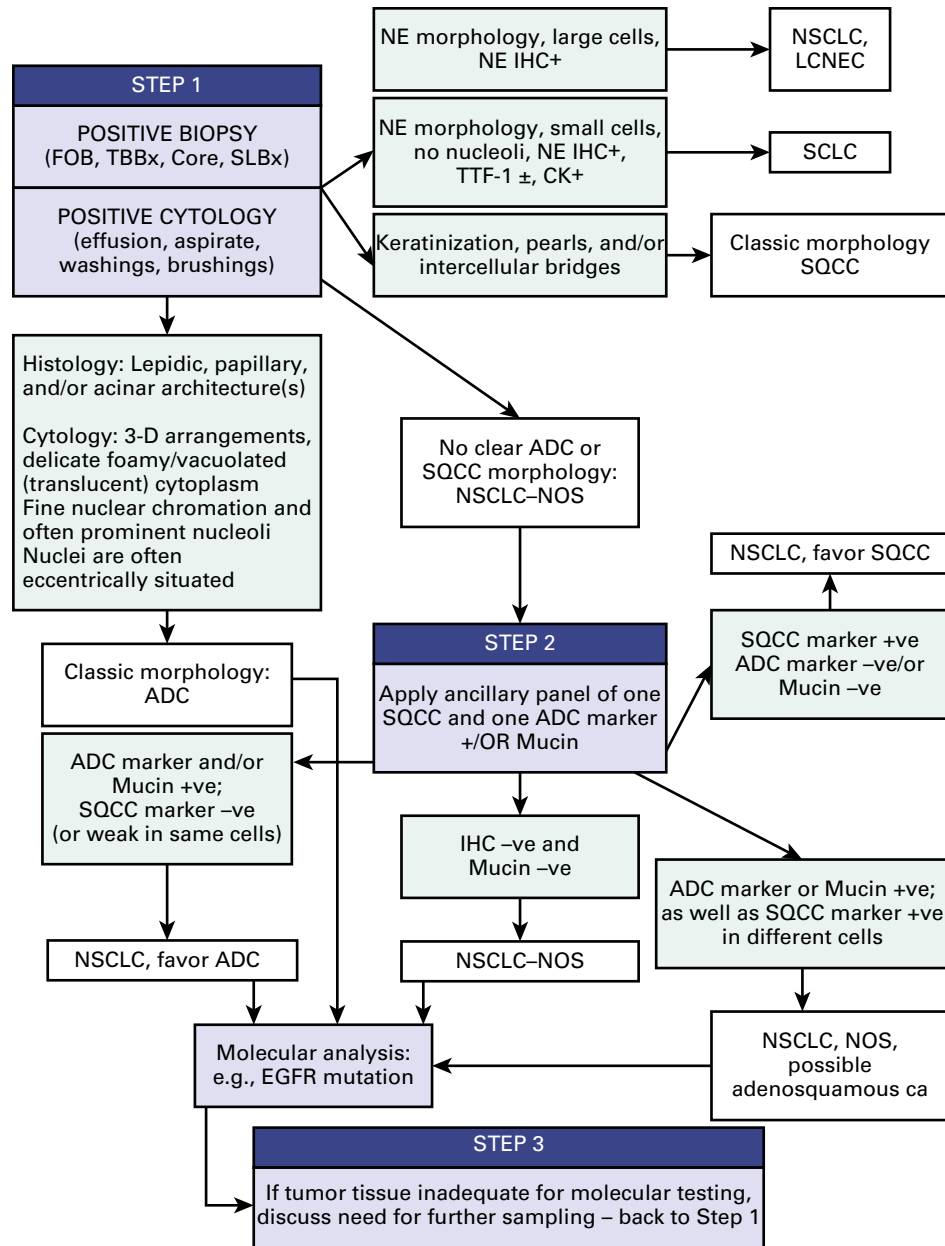
Not all laboratories worldwide will have access to immunohistochemistry, or even a mucin stain, but the current classification must encompass scientific advances wherever relevant. Accepted markers for identifying differentiation toward adenocarcinoma are TTF-1[53,74,130] and napsin A,[131,132] both of which are approximately 80% sensitive. In relation to squamous differentiation, the markers CK5/6 and p63 have been advocated as both sensitive and specific,[49,130,131] although data from 2012 have suggested that p63 is less specific than first thought and the p63 isoform p40 has been reported as a more specific antibody in this setting.[53,73,74,133] Expression of p63 can occur in up to one-third of adenocarcinomas.[49,130,134] Therefore, among tumors that lack squamous cell morphology, virtually all tumors that show coexpression of p63 and TTF-1 are preferably classified as adenocarcinomas. Some investigators have also used CK7 as a marker of adenocarcinoma differentiation although this marker is not universally accepted.[134] Less commonly used markers for squamous differentiation include desmocollin-3 and desmoglein.[135,136] A reasonable recommendation is that, when immunohistochemistry is deemed


Fig. 17.11. Algorithm for the diagnosis of adenocarcinoma in small biopsy and/or cytology specimens. Step 1: When positive biopsy specimens (fiberoptic bronchoscopy [*FOB*], transbronchial [*TBBx*], core, or surgical lung biopsy [*SLBx*]) or cytology specimens (effusion, aspirate, washings, and brushings) show clear adenocarcinoma (*ADC*) or squamous cell carcinoma (*SQCC*) morphology, the diagnosis can be firmly established. If neuroendocrine morphology is detected, the tumor may be classified as small cell lung cancer (*SCLC*) or nonsmall cell lung cancer (*NSCLC*), probably large cell neuroendocrine carcinoma (LCNEC), according to standard criteria (+ve = positive; –ve = negative). If ADC or SQCC morphology is not clear, the tumor is regarded as NSCLC-not otherwise specified (*NOS*). Step 2: NSCLC-NOS can be further classified based on immunohistochemical stains, mucin stains (diastase–periodic acid Schiff [*DPAS*] or mucicarmine), or molecular data. If the stains all favor ADC with positive ADC marker(s) (i.e., positive for thyroid transcription factor-1 [*TTF-1*] and/or mucin) with negative SQCC markers, then the tumor is classified as NSCLC, favor ADC. If SQCC markers (i.e., p63 and/or CK5/6) are positive with negative ADC markers, the tumor is classified as NSCLC, favor SQCC. If the ADC and SQCC markers are both strongly positive in different populations of tumor cells, the tumor is classified as NSCLC-NOS, with a comment that it may represent adenosquamous carcinoma. If all markers are negative, the tumor is classified as NSCLC-NOS. See text for recommendations on NSCLCs with marked pleomorphic and overlapping ADC/SQCC morphology. †Mutation testing for epidermal growth factor receptor (*EGFR*) should be performed in classic ADC; NSCLC, favor ADC; NSCLC-NOS; and NSCLC-NOS, possible adenosquamous carcinoma. Step 3: If clinical management requires a more specific diagnosis than NSCLC-NOS, additional biopsies may be indicated. *IHC,* immunohistochemistry; *NE,* neuroendocrine; *CD,* cluster designation; *CK,* cytokeratin. *(Reprinted with permission from: Travis WD, Brambilla E, Noguchi M, et al. International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society international multidisciplinary classification of lung adenocarcinoma.* J Thorac Oncol. *2011;6(2):244–285).*

necessary, at least one antibody for squamous and glandular differentiation, but no more than two antibodies, should be used in each case.[131,134] Thus, a simple panel of TTF-1 and p40 may be able to classify most cases of NSCLC-NOS.

In small biopsy specimens, tumors that are positive for an adenocarcinoma marker (e.g., TTF-1) and/or mucin and are negative for a squamous marker (e.g., p40 or p63) should be classified as NSCLC, favor adenocarcinoma. Those tumors that are positive for a squamous marker, with at least moderate, diffuse staining, and negative for an adenocarcinoma immunohistochemistry marker and/or mucin stain, should be classified as NSCLC, favor nonkeratinizing squamous cell carcinoma, with a comment in the pathology report specifying whether the differentiation was detected by light microscopy and/or by special stains. These two markers, TTF-1 and p40, are generally mutually exclusive. If an adenocarcinoma marker such as TTF-1 is positive, the tumor should be classified as NSCLC, favor adenocarcinoma, despite any expression of squamous markers. If one population of tumor cells is reactive for TTF-1 and another population is positive for squamous markers, this may raise the possibility of adenosquamous carcinoma, although this diagnosis can be made only on a resection specimen. If no clear staining is found for adenocarcinoma or squamous markers, the tumor should be classified as NSCLC-NOS.

PATHOLOGY SAMPLES FOR MOLECULAR TESTING

The recent advances in targeted therapy for NSCLC require the analysis of a panel of molecular abnormalities, including gene mutations, amplifications, and fusions, by applying various methodologies to tumor tissue specimens.[137] However, the tissue (biopsy) and cell (cytology) samples available for molecular testing in advanced metastatic tumors are likely to be small specimens, including those from core-needle biopsy and/or fine-needle aspiration, and small sample size may limit the molecular and genomic analysis with currently available methodologies and technologies. The current and the newly emerging technologies must be adapted and incorporated into the molecular analysis of small tissue specimens from core-needle biopsy and fine-needle aspiration obtained from patients with NSCLC.

In pathology laboratories, the diagnostic tumor tissue specimens (e.g., core-needle biopsy, bronchoscopy samples, surgical resections, etc.) are fixed in formalin and embedded in paraffin for histologic processing. Both formalin fixation and paraffin embedding compromise the integrity of proteins and nucleic acids (RNA, DNA) for molecular testing, particularly when non-buffered formalin is used and the specimens are fixed in formalin for more than 24 hours. The cytology specimens (e.g., sputum, bronchial brushes, bronchoalveolar lavages, pleural fluids, and fine-needle aspiration) are usually fixed in alcohol, which is optimal for preservation of nucleic acids. When the cytology specimen has abundant material, the sample can be fixed in formalin and processed as a tissue specimen (cell block) to obtain histologic sections.[68] Although tissue specimens are preferable for molecular testing, most cytology samples with abundant malignant cells can be successfully used for molecular testing.

The handling of the biopsy and cytology specimens for histologic analysis and subsequent molecular testing requires thoughtful prioritization of sample use to prevent the loss of tissue in less important analysis when molecular testing is required for selection of therapy. Also, the pathologist should determine whether the amount of malignant cells available in the specimen is adequate for extraction of DNA and also for molecular tests based on histologic sections (e.g., fluorescence in situ hybridization and immunohistochemistry) (Fig. 17.11).

On the other hand, our growing understanding of the biology of NSCLC, particularly the molecular evolution of tumors during local progression and metastasis, and the identification of molecular abnormalities developing after resistance to targeted therapies emphasize the importance of characterizing the molecular abnormalities of the disease at every stage of its evolution. Tumor sampling and molecular testing of advanced metastatic NSCLC are important at each time point of clinical decision making.[138,139] Therefore, it is recommended to obtain a new tissue specimen for molecular testing in lung tumors that acquired resistance to a given targeted therapy to better determine the molecular resistance mechanisms and next therapy options.

CYTOLOGIC ANALYSIS OF LUNG CANCER

Cytology is a useful tool for diagnosis of lung cancer. The use of cytologic sampling approaches in lung cancer includes: (1) screening for lung carcinoma using sputum specimens; (2) presumptive diagnosis of lung cancer by brushing or scraping cytology; (3) diagnosis of lung cancer by fine-needle aspiration cytology; and (4) intraoperative cytologic diagnosis using the resected end of a bronchus or the resection margin in lung parenchyma.[94,140,142] Materials for cytologic diagnosis include sputum smears; smears prepared by bronchial scraping, brushing, or washing; fine-needle aspiration via a bronchoscope or through the chest wall; and pleural fluid or washing samples.[143–145,146,147–149] Materials obtained by curettage or brushing are usually scanty and must be fixed immediately to avoid drying artifacts, which may result in a false-positive diagnosis. To evaluate the surgical margin of wedge-resected materials, immediate cytologic diagnosis is performed using touch smears.

Cytologic Methods

Sputum Smears

Sputum cytology is a routine examination and/or screening method for detection of central-type lung carcinomas (squamous cell carcinoma and small cell carcinoma).

Smears Prepared by Bronchial Scraping, Brushing, or Washing

These cytology smears are obtained using bronchoscopy. For washing cytology, the lesion is washed with 20–40 mL of saline.[150]

Fine-Needle Aspiration Samples

Transbronchial lung biopsy or transcutaneous fine-needle aspiration cytology are two basic methods for collecting cytology samples from a tumor located in the periphery of the lung. Transcutaneous needle aspiration cytology is usually supported by CT examination.[151]

Pleural Fluid or Washing Materials

Normally, the pleural space contains little fluid, but exudative fluid may accumulate when lung cancer irritates the visceral pleural membrane.[152] Malignant pleural fluid that contains lung cancer cells may be detected by chest x-ray when the amount exceeds 200–300 mL. Pleural fluid is usually collected by percutaneous thoracocentesis.

Liquid-Based Cytology

This is a thin-layer or monolayer technique for slide preparation that has been introduced as a potential solution for improving the sensitivity and specificity of cytologic assessment.[153,154] Liquid-based cytology has gained favor over conventional smear and cytospin techniques and has been shown to yield equivalent

or better diagnostic accuracy, particularly in specimens containing abundant mucus and/or blood. Liquid-based cytology is also more suitable for immunocytochemistry and for further investigations such as molecular analysis.

Special Staining and Immunocytochemistry of Cytology Specimens

After collection, the cytology slides should be fixed immediately in 95% ethyl alcohol for Papanicolaou staining, and the remaining slides should be air-dried and fixed in 100% methanol for May-Giemsa staining. For immunocytochemistry, the slides should be fixed in 15% formalin. The clinical applications of immunocytochemistry have been expanding because of the increasing need for differential diagnosis between squamous cell carcinoma and adenocarcinoma.[155] If the tumor is poorly differentiated, it is sometimes difficult to differentiate each histologic subtype by Papanicolaou staining. In those cases, staining for TTF-1 and p40 is very useful for establishing tumor differentiation and proper diagnosis.[156–158] However, cytologists should estimate antigenicity for TTF-1 carefully, because it is delicate and easily lost during long storage periods of the cytology smears. Cell blocks prepared from cytology specimens are useful tools for immunohistochemical analysis.

Molecular Analysis of Cytology Specimens

Cytologic specimens are very useful for DNA analysis, because they are fixed with alcohol or by dehydration.[159] Nucleic acids are well preserved in alcohol, in comparison with formalin. Therefore, pathologists should be encouraged to prepare a cell block for molecular testing.[160–162]

Cytologic Characteristics of Each Histologic Type of Lung Cancer

Because histologic heterogeneity is one of the characteristics of lung carcinoma, each specific histologic subtype shows specific cytologic features. The cytologic characteristics of several typical subtypes are introduced in the following text.

Adenocarcinoma

In addition to the histologic heterogeneity of lung adenocarcinoma, the cytologic features of these tumors are highly variable. The usual mixed type of adenocarcinoma shows an accumulated mass of tumor cells (Fig. 17.12A). The nuclei tend to be located in the periphery of the cytoplasm and to have vesicular chromatin with prominent nucleoli. The cytoplasm is usually finely vacuolated, and cytoplasmic mucin may be present. The glandular morphology may be detected as various arrangements of cells in organized units, including columnar cells lining up as so-called "pegshaped" cells arranged like a flat honeycomb, and cells organized as three-dimensional cell balls or branching groups with a smooth luminal border ("community border"). Poorly differentiated adenocarcinomas have nondescript overtly malignant cells, usually in cohesive groups, which may be impossible to distinguish from nonkeratinizing squamous cell carcinoma in the absence of ancillary studies such as immunocytochemistry.

AAH is unlikely to be sampled by cytologic techniques, but materials resected from stumps show cytomorphologic features similar to those of AIS with less nuclear atypia.[163] In nonmucinous AIS, the tumor cells are arranged in a flat monolayer. The nuclei include fine chromatin, inconspicuous pinpoint nucleoli, nuclear grooves, and nuclear pseudoinclusions. A specific diagnosis of AIS cannot be made from cytologic specimens because the possibility of an invasive component not present in the sample cannot be excluded.
Fig. 17.12. Cytology of lung cancer. (A) Adenocarcinoma showing tumor cell cluster with tubular formation and cells with conspicuous nucleoli; (B) squamous cell carcinoma with atypical keratotic cell clusters; and (C) SCLC showing carcinoma cells with very high nuclear-to-cytoplasmic ratio and finely stippled chromatin. (A–C, sputum, Papanicolaou stain, ×1000.)

It is not possible to differentiate MIA from AIS cytologically because invasive tumor cells may not be included in the sample. Although no studies are available on the cytologic features of MIA, one would expect a mixture of frankly invasive carcinoma and AIS. If the tumor is located in the periphery and shows pure

ground-glass opacity, and accumulated high-grade tumor cells are detected, then MIA may be included in the differential diagnosis.

Squamous Cell Carcinoma

The cytologic features of pulmonary squamous cell carcinoma are similar to those of squamous cell carcinoma at other sites and depend on the grade of the tumor. Well-differentiated squamous cell carcinomas show obvious keratinization, manifested as dense retractile cytoplasm showing red, orange, yellow, or light blue Papanicolaou staining (Fig. 17.12B). Unlike squamous cell carcinomas of the head and neck, pulmonary squamous tumors develop from metaplastic cells, and in most cases evidence of cytoplasmic keratinization is only focal. Typical nuclei of well-differentiated squamous cell carcinomas have dark nontransparent chromatin without obvious nuclear detail or prominent nucleoli. Spindle cell shapes are common. Necrosis and an inflammatory reaction are also common. Cells are usually present both singly and in large multilayered sheets. Poorly differentiated squamous cell carcinoma is difficult to differentiate from poorly differentiated adenocarcinoma because cytoplasmic keratinization is absent or unapparent, and the nuclei may have open chromatin with prominent nucleoli. In such cases, immunocytochemistry is sometimes effective for differentiating adenocarcinoma.

Cells derived from the precursor lesions of squamous cell carcinoma are much more likely to appear in exfoliative specimens than in aspiration biopsy samples.[169] The degree of dysplasia of cells in sputum specimens ranges from mild to severe according to the degree of cytocohesiveness, thickness of the cytoplasm, nucleus-to-cytoplasm ratio, roundness of the nucleus, and the pattern and distribution of chromatin. As the severity of dysplasia increases, the enlarged nuclei have more irregularities in the membrane contour, more darkly stained chromatin, and more coarsely granular and irregularly distributed chromatin granules or a homogeneous (pyknotic) appearance. Cytoplasmic keratinization may be present, especially in more severe lesions, and associated Papanicolaou staining has a brilliant, dense orange hue. The nuclear-to-cytoplasmic ratio also increases progressively. The dysplastic cells in scraped material are usually larger than those in sputum smears. The chromatin pattern is smoother and more finely granular than in sputum specimens because of the better degree of preservation.

Small Cell Lung Cancer

The cytologic characteristics of small cell carcinoma are very specific and pathognomonic. The individual tumor cells are small with round, oval, or spindle-shaped nuclei in which the chromatin is uniformly and finely divided and the nucleoli are not prominent, although chromocenters are sometimes visible (Fig. 17.12C). The accepted nuclear diameter is usually no greater than three lymphocytes. The nucleus-to-cytoplasm ratio is very high and the cytoplasm surrounding the nuclei is very scanty; nuclear molding is prominent. Chromatin streaking is a very specific feature of small cell carcinoma. Mitotic figures are not as common as might be expected.

CONCLUSION

A clinically relevant pathologic classification of lung cancer is essential for accurate diagnosis and for patients to receive appropriate therapy. Although classification of the vast majority of lung cancers is straightforward, areas of controversy and diagnostic challenges remain. Pathologists play a critical role in lung cancer therapy by providing a precise pathologic diagnosis and by properly handling tissue and cytology samples for molecular testing of lung cancer. The 2011 IASLC/ATS/ERS revised lung adenocarcinoma classification and the recently released 2015 WHO classification of lung cancers are applicable to surgically resected as well as small biopsy and cytologic specimens,[5] and they address the new therapeutic challenges in treating this disease. The recently developed classification and approaches for lung cancer diagnosis are aligned with current clinical practice and open new avenues for research.

18 Molecular Testing in Lung Cancer

Celine Mascaux, Ming-Sound Tsao, and Fred R. Hirsch

SUMMARY OF KEY POINTS

- Of key importance is whether a prognostic marker is also a predictive marker for therapeutic benefit.
- As predictive biomarkers become integral in the use of targeted therapies to treat lung cancer, multidisciplinary and evidence-based guidelines for molecular testing are needed; the College of American Pathologists, the International Association for the Study of Lung Cancer, and the Association of Molecular Pathologists have published a multidisciplinary and evidence-based guideline for molecular testing in lung cancer.
- Immunohistochemistry (IHC) is considered to be an easy and inexpensive clinically applicable assay.
- The method for detecting mutations needs to take into account the tumor content available, the possibility of detecting all mutations, the timing required for testing, and the urgency to start the patient's treatment.
- Mutation testing should be performed on formalin-fixed paraffin-embedded, frozen, or alcohol-fixed tissue specimens.
- The advantage of IHC and fluorescence in situ hybridization is that the evaluation of the protein expression level or genomic aberration can be analyzed more specifically on individual tumor cells.
- The choice of the biomarkers to be tested must be based on evidence of their clinical relevance for therapeutic decision.
- Epidermal growth factor receptor (EGFR) testing should be done for any mutation located in exons 18 to 21 with over 1% prevalence.
- Currently, EGFR mutation is detected by classic molecular tests.
- In addition to EGFR, the other approved targetable biomarker used in the treatment of patients with advanced lung cancer is anaplastic lymphoma kinase (ALK) gene rearrangement, which should be done on the same patient population as tested for EGFR mutations.
- Aside from EGFR mutations and ALK rearrangements, several other biomarkers have also been tested for their ability to predict lung cancer response to treatment, but none have shown sufficient evidence for current use in clinical practice.
- Tests for EGFR mutations, ALK, and ROS gene rearrangements to predict response to EGFR tyrosine kinase inhibitors (TKIs) and ALK/ROS1 TKIs, respectively, are currently the only biomarker tests recommended in clinical practice.

Biomarker research in lung cancer aims to characterize prognostic factors and to determine predictive markers of benefit, usually in terms of response rate or outcome from local treatment (e.g., radiation) or systemic treatment (e.g., chemotherapy, targeted therapy, and immunotherapy). These biomarkers can be used to select the patient groups who will most likely derive differential benefit from the treatments and can help to avoid the toxicities associated with ineffective therapies. It is important to distinguish between prognosis and prediction.[1] Prognostic factors are patient- and tumor-related factors that predict patient outcome (usually survival) and are independent of treatment administered. Predictive factors are clinical, cellular, and molecular markers that predict response of the tumor to treatment (either in terms of tumor shrinkage or a survival benefit from treatment). Therefore prognostic factors define the effects of tumor characteristics on the patient, whereas predictive factors define the effect of treatment on the tumor. Those measures are not always similar, as tumor response may not necessarily translate into greater survival benefit.[2]

Many candidate prognostic biomarkers have been reported to be associated with earlier stages of nonsmall cell lung cancer (NSCLC) in patients who are treated primarily by surgical resection. However, it should be emphasized that not all prognostic classifiers that may predict survival will be associated with the benefit of adjuvant chemotherapy. For this reason, it is important to demonstrate if a prognostic marker is also a predictive marker for therapeutic benefit. In this chapter, we mainly focus on clinical recommendations for the use of molecular testing as predictive biomarkers for response and outcome to systemic therapy, as there has been strong evidence for implementation of routine molecular testing in standard clinical practice. We also discuss the research data on prognostic biomarkers.

GENETIC ABNORMALITIES IN LUNG CANCER

The epidermal growth factor receptor (EGFR) mutation is the first molecular abnormality in lung cancer that has been associated with marked sensitivity to a tyrosine kinase inhibitor (TKI) with specificity for the EGFR.[3] This discovery revolutionized the diagnosis and treatment of lung cancer and established the paradigm for subsequent research to identify oncogenic driver mutations that could represent additional targets for the treatment of lung cancer. Shortly after the discovery of *EGFR* mutations, gene rearrangement involving the *anaplastic lymphoma kinase* (*ALK*) was identified as a potent oncogene in NSCLC and has become a predictor of very high rates of response and good outcomes with crizotinib, which inhibits hepatocyte growth factor receptor and ALK.[4] By direct and next-generation high-throughput sequencing, other mutations have subsequently been identified in different histologic types of lung cancers. First in lung adenocarcinoma, Ding et al.[5] reported on a set of 26 genes with significant mutations selected on the basis of statistic models, including known tumor suppressor genes (tumor protein 53 [P53], serine/threonine kinase 11 [STK11], neurofibromatosis 1 [NF1], ataxia telangiectasia mutated [ATM], adenomatous polyposis coli [APC], cyclin-dependent kinase inhibitor [CDKN2A], retinoblastoma 1 [RB1], inhibin beta A [INHBA]); known oncogenes (Kirsten rat sarcoma [KRAS], neuroblastoma RAS viral (v-ras) oncogene homolog [NRAS]); putative oncogenic tyrosine kinase receptors (EGFR, v-erb-b2 avian erythroblastic leukemia viral oncogene homolog [ERBB] 4, fibroblast growth factor receptor 4 [FGFR4], ephrin (EPH) receptor A3 [EPHA3], EPH receptor A5 [EPHA5], neurotrophic tyrosine kinase, receptor, type 1], kinase insert domain receptor [KDR], neurotrophic tyrosine kinase, receptor, type 3 [NTRK3], platelet-derived growth

factor receptor, alpha polypeptide [PDGFRA], leukocyte receptor tyrosine kinase [LTK], p21 protein [Cdc42/Rac]-activated kinase 3 [PAK3]); and other genes with undetermined roles (low-density lipoprotein receptor-related protein 1B [LRP1B], protein tyrosine phosphatase, receptor type, D [PTPRD], GNAS complex locus [GNAS], zinc finger, MYND-type containing 10 [ZMYND10/BLU], and solute carrier family 38, member 3 [SLC38A3]). Other studies using DNA and RNA next-generation sequencing (NGS) reported additional potentially actionable oncogene driver mutations, including ERBB2; v-akt murine thymoma viral oncogene homolog 1 (AKT1); met proto-oncogene (MET); lemur tyrosine kinase 2 (LMTK2); catenin (cadherin-associated protein), beta 1, 88 kDa (CTNNB1); neurogenic locus notch homolog protein 2 (NOTCH2); SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a, member 4 (SMARCA4); kelch-like epoxycyclohexanone (ECH)-associated protein 1 (KEAP1), AT-rich interactive domain 1A (SWI-like; ARID1A); U2 small nuclear RNA auxiliary factor 1 (U2AF1); and RNA binding motif protein 10 (RBM10), as well as gene fusions, including c-ROS oncogene 1, receptor tyrosine kinase (ROS1), ret proto-oncogene (RET), fibroblast growth factor receptor 2 (FGFR2), AXL receptor tyrosine kinase (AXL), microtubule-associated protein 4 (MAP4/3K3); and platelet-derived growth factor receptor, beta polypeptide (PDGFR1).[6–10] More recently, putative targetable mutations/amplifications were identified in lung squamous cell carcinoma, including phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (PI3KCA); phosphatase and tensin homolog (PTEN); AKT1–3; FGFR1–3; EGFR; ERBB2; v-raf murine sarcoma viral oncogene homolog B (BRAF); NOTCH; RAS; TP53; cyclin-dependent kinase inhibitor 2A (CDK2N2A [p16INK4A])/Rb; KEAP1; cullin 3 (CUL3); nuclear factor, erythroid 2-like 2 (NFE2L2); SRY (sex determining region Y)-box 2 (SOX2); tumor protein p63 (TP63); NOTCH1/2; achaete–scute family bHLH transcription factor 4 (ASCL4); and Forkhead box P1 (FOXP1).[11–14] Much less data are available in small cell lung cancer (SCLC) because of the rarity of resected specimens. However, gene amplification has been detected with the use of array-comparative genomic hybridization in Janus kinase 2 (JAK2), FGFR1; and SOX2; and cyclin E1 and MYC family members.[15] Gene mutations have also been reported in SCLC in TP53, RB, PTEN, slit homolog 2 (SLIT2), and EPH7, and in genes playing a role in epigenetic gene regulations as CREB-binding protein (CREBBP), E1A-binding protein p300 (EP300), and myeloid/lymphoid or mixed-lineage leukemia (MLL) genes.[16–18]

Because *EGFR* mutations and *ALK* rearrangement have been found to predict therapeutic benefit with their respective targeted drugs, biomarker testing has been implemented and integrated into therapeutic decision making for patients with advanced NSCLC. As predictive biomarkers are becoming integral in the use of targeted therapies to treat patients with lung cancer, there is a need to establish a multidisciplinary and evidence-based guideline for molecular testing. In 2013, the College of American Pathologists (CAP), the International Association for the Study of Lung Cancer (IASLC), and the Association of Molecular Pathologists (AMP) published such guidelines for molecular testing in lung cancer.[19] Following a systematic review of the literature and consensus meetings as well as public consultation, an expert panel developed 37 guideline items addressing 14 subjects and made 15 recommendations, ranging from tissue acquisition and processing to assay interpretations. Several other guidelines for biomarker testing have been published by other organizations, including the National Consensus of the Spanish Society of Medical Oncology, the Spanish Society of Pathology, and the European Society of Medical Oncology.[20,21] In addition, specific recommendations for EGFR testing have been published in the Canadian National Consensus Statement, and recommendations for ALK testing have been made by the Italian Association of Medical Oncology/Italian Society of Pathology and Cytopathology and other international groups of authors.[22–26]

ASSAY PLATFORMS IN MOLECULAR TESTING

Protein Expression

Immunohistochemistry (IHC) is most commonly used for protein expression assessment in the clinical context. IHC is a process that is easily performed by investigators because of the short time needed to complete testing and low cost, and due to its applicability to formalin-fixed paraffin-embedded (FFPE) rather than fresh frozen tissue. In addition, IHC may help investigators assess protein expression at the cellular level, thus allowing them to evaluate cellular localization (e.g., membranous, nuclear, or cytoplasmic), topography (e.g., tumor or stromal cells), and heterogeneity of expression and is also applicable to very small specimens, including cytologic samples. However, many preanalytic and analytic factors may influence IHC reactions, resulting in potentially variable staining that may affect the interpretation of the results. Therefore optimizing and standardizing the protocols and conditions are required for each marker tested. Interpreting the results is also observer dependent and may vary between observers, thus requiring standardization of protocols and conditions. Lastly, the scores for defining positive or negative IHC results for their prognostic or predictive value of specific biomarkers need to be well defined and validated in multiple independent cohorts/institutions and clinical trial samples. However, despite the mentioned limitations, IHC is considered to be an easy and inexpensive clinically applicable assay, which already is available in most pathology departments.

Gene Mutations

The technologies available for mutation analyses are associated with different sensitivity. Analytic sensitivity is defined as the lowest percentage of tumor cells or tumor cell DNA concentration in which a mutation is detectable with confidence within replicate assays.[19] The standard method for detecting mutations has been direct sequencing by the Sanger method. This method allows the detection of a minimum of 25% of mutated allele frequency from tissue containing 50% cancer cells cellularity, if the mutation is heterozygous and in the absence of gene amplification. However, mutated driver oncogenes, such as *EGFR* and *KRAS*, are commonly amplified implying that a lower number of tumor cellularity in the sample may yield 25% mutated alleles. Bidirectional sequencing and confirmation by repeat sequencing on independently amplified polymerase chain reaction (PCR) products should be performed especially on FFPE tissue (see later). The impact of the lower sensitivity of the Sanger sequencing method resulting in a substantial false-negative response rate (approximately 30%) in the detection of *EGFR* mutations has been documented.[27]

To overcome the generally lower sensitivity of the Sanger sequencing method, various technologies are available that allow mutation detection at significantly higher sensitivity with a tumor cellularity of as low as 1% to 5% or mutated allele. These more sensitive technologies involve a mutated allele-enriching strategy, including the peptide nucleic acid/locked nucleic acid amplification, the coamplification at lower denaturation temperature-PCR, or the enzymatic digestion of wild-type sequences.[19] The US Food and Drug Administration (FDA) has approved two assays for the detection of EGFR mutation analyses in advanced NSCLC: the Scorpion-amplification refractory mutation system (ARMS) and cobas technologies (Roche Molecular Diagnostics, Pleasanton, CA, USA). Several other methods may be used to detect *EGFR* mutations (Table 18.1). The Scorpion-ARMS technology is available as a commercial kit that allows investigators to test for 29 *EGFR* mutations and has a sensitivity of at least 5%. The cobas EGFR mutation test is a reverse transcription-PCR-based (RT-PCR) test for the qualitative detection of exon 19 deletion and exon 21 L858R mutations of *EGFR* in DNA

TABLE 18.1 Commonly Used Methods for EGFR Mutation Detection[30,31]

Method	Tumor DNA Required (%)	Targeted or Screening Method	EGFR Mutations Detected	Detection of Deletions and Insertions
Sanger direct sequencing	25	Screening	Known and new	Yes
Real time/TaqMan PCR	10	Targeted	Known only	No
High-resolution melting analysis	5–10	Screening	Known and new	Yes
Cobas	5–10	Targeted	Known only	Yes
Pyrosequencing	5–10	Screening	Known only	Yes
SNaPshot PCR	1–10	Targeted	Known only	Yes
MALDI-TOF MS-based genotyping	5	Targeted	Known only	No
Cycleave PCR	5	Targeted	Known only	Yes
Fragment length and RFLP analysis	5	Screening/targeted	Known only	Yes
Allelic-specific PCR/Scorpion ARMS	1	Targeted	Known only	No
MassARRAY	1	Targeted	Known only	Yes
PNA–LNA PCR clamp	1	Targeted	Known only	No
Denaturing HPLC	1	Screening	Known and new	Yes
Massively parallel/NGS	0.1	Screening	Known and new	Yes
Digital droplet PCR	0.01	Targeted	Known only	Yes

ARMS, amplification refractory mutation system; *EGFR,* epidermal growth factor receptor; *HPLC,* high-performance liquid chromatography; *MALDI-TOF,* matrix-assisted laser desorption/ionization time-of-flight; *MS,* mass spectrometry; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction; *PNA–LNA,* peptide nucleic acid-locked nucleic acid; *RFLP,* restriction fragment length polymorphism.

extracted from FFPE tissue and was used by the investigators in the European Randomized Trial of Tarceva versus Chemotherapy (EURTAC) and LUX-Lung 3 trials.[28,29]

Several other available assays are based on different technologies. Their sensitivities vary, and only certain techniques have the ability to detect new mutations and/or insertions and deletions. In contrast to the Sanger method that lacks sensitivity for samples with fewer tumor cells, the more sensitive methods might give rise to false-positive results and a lower specificity. Therefore it is crucial that the appropriate positive and negative controls always be included in the assay. Of note, the Sanger method detects any mutation including previously unidentified mutations in the sequenced exons, but other assays are designed for specific mutation testing, as in the case of the digital droplet PCR that has a very high sensitivity. Another option could be a two-step procedure, starting with a highly sensitive detection of the presence of a mutation and the subsequent characterization of the mutation. When finding a mutation that has not or has rarely been reported, the results should not be considered as errors until the replicate test confirms or denies it. However, testing all mutations can require more time and might not be suitable for the clinical situation when treatment must be initiated without delay. In such cases, another approach can be used that tests the most common mutations first and then completes the screening of less frequent mutation.

The recent and rapid development of NGS accomplishes massive parallel gene mutation analyses and discovery and requires a small amount of tissue, preferably fresh frozen. This technology uses miniaturized and parallelized platforms for sequencing of millions of short nucleotides (50–400 bases). The different platforms all have in common a technical paradigm of massively parallel sequencing via clonally amplified, spatially separated DNA templates or single DNA molecules in a flow cell. Currently, NGS is used for research purposes rather than to test specific biomarkers. However, with the expansion of the use of molecular biomarkers and the rapidly growing targeted therapies available, using NGS to have a full molecular profiling of the tumor or at least multiplex mutation testing of a panel of biomarkers of interest might become preferable in the future in order to spare time and tissue. In addition, in a recent study, even for individual gene mutation analyses, NGS has been shown to have better sensitivity, as it detected all relevant *EGFR* mutations for prediction of response to EGFR TKIs in 24 tumors, compared with the Sanger method and pyro-sequencing, which resulted in four and two false-negative results, respectively.[32]

Nevertheless, the clinician's chosen approach needs to take into account the tumor content available, the possibility of detecting all mutations, the timing required for testing, and the urgency to start the patient's treatment. Usually a laboratory investigator will decide to choose a specific method based on equipment availability and cost and will conduct an assay optimization and standardization exercise and test for assay sensitivity and specificity.[19,20]

Changes in Gene Structure and Copy Number

Fluorescence in situ hybridization (FISH) is the standard method for assessing changes in gene structure and copy number. Similar to IHC, FISH can be performed on FFPE tissue but requires standardized protocols (Fig. 18.1). Interpreting and reading FISH specimens is observer dependent and requires a dark room and a specific microscope, and the reader needs specific training and expertise in order to achieve reproducible results. Of note is that the tissue structure is not well visualized, and this factor necessitates the preselection of areas to assess in order to discriminate tumor cells from nonmalignant cells. Furthermore, the fluorescence probes are unstable and fade over a short period, which can limit the possibility of revisiting the specimens. Therefore imaging the specimens in a short time frame is important. By using probes against multiple targets labeled with different fluorescent dyes, it is possible to assess multiple markers on the same sections. In addition to detecting the gene copy number, FISH is used to assess structural changes including fusions between genes. The example of ALK fusion is detailed later in this chapter.

Several alternative techniques to FISH have been developed, including chromogenic in situ hybridization and silver in situ hybridization. These techniques are used primarily in research and give results comparable with FISH; however, they are not commonly used in routine clinical testing in lung cancer. Silver in situ hybridization is now FDA approved for human epidermal growth factor receptor-2 (HER2) determination in breast cancer and is widely used for that indication. Multicolor assays are in development. Finally, gene copy number can be assessed by array-comparative genomic hybridization technique. However, comparative genomic hybridization is used mainly to probe for a large number of markers in exploratory discovery research, rather than to assess specific markers for clinical applications.

Another assay that is used for assessing gene copy number is PCR, which is a very sensitive method that requires specific primers and probes as are used in gene rearrangement in the ALK gene.[33] More recently, computational algorithms have also been developed to derive gene copy number estimate using high coverage NGS data.
Fig. 18.1. Fluorescence in situ hybridization (FISH) to detect gene copy number changes. (A) FISH microscope. (B–D) Tumors that were hybridized to the EGFR (red signal) and chromosome 7 centromeric or CEP7 (green signal) probes, with cells showing two copies of each probe, consistent with disomy (B); high polysomy, as indicated by an increased number of green and red probes (C); or clusters of red probes, consistent with high amplification of the *epidermal growth factor receptor (EGFR)* gene.

TISSUE REQUIREMENTS FOR MOLECULAR TESTING

Preanalytic Factors

Based on expert consensus opinion mutation testing should be performed on FFPE, frozen, or alcohol-fixed tissue specimens.[19,20] The main advantage of using FFPE tissue is that it is the most commonly used method to process tissue for routine histology. FFPE also allows for a better evaluation of tumor cell content, which is also possible with fresh tissue, but is less convenient and requires cutting and staining of frozen sections adjacent to the section used for DNA extraction. The results of mutation testing with alcohol-fixed tissue specimens are also excellent. This fixation method is often used on cytologic specimens, which are then suitable for mutation testing. DNA isolated from fresh or frozen tissues may yield fragments of 1000 base pairs (bp) and longer. Fixation of tissue in formalin induces crosslinks between DNA, RNA and proteins, and DNA fragmentation that results in DNA fragments of 300 bp or less. Formalin fixation also creates random nucleotide base exchange, resulting in

false-positive results. This type of problem mostly occurs with low DNA yield and/or with ultrasensitive assays.[19] Tissue treated with acidic or heavy-metal fixatives, including lead, cobalt, chromium, silver, mercury, and sometimes even uranium and decalcifying solutions, may reduce the success rate of mutation testing and should be avoided when alternate FFPE specimens are available. In molecular biology, heavy-metal fixatives inhibit the DNA polymerases used in PCR testing. Acidic solutions, including the decalcifying solutions that are used to process samples obtained from bone metastasis, can induce a high rate of DNA fragmentation. For these types of specimens that are obtained specifically for molecular testing, nonacidic methods of decalcification, such as nonacidic chelating decalcifying solutions, should be used in the sample-processing step.

IHC and FISH should be performed on FFPE tissue, ideally on cut sections that have been stored for fewer than 6 weeks, to avoid the oxidation process that occurs over time. Whatever the method used, standardizing the fixation procedure and storage conditions is required. The fixation should be performed within hours after the sample has been obtained. Fixation duration

should be controlled and not exceed 12 hours for small biopsy specimens and 18 hours to 24 hours for resected specimens.[19,20]

Data have shown that molecular testing (i.e., mutation testing or FISH) can be performed on liquid biopsies (circulating DNA extracted from plasma or circulating tumor cells).[34–38] These assays are still experimental and need to be reproduced and standardized before any clinical application.

Sample Processing and Analysis

Tumor tissue is heterogeneously composed of a mixture of tumor cells and host cells. Host cells include inflammatory cells and vascular endothelial and stromal fibroblasts and their abundance is highly variable but may have a substantial impact on the sensitivity of mutation testing (Fig. 18.2). The proportion of tumor cells in the specimen, as compared with normal tissue and inflammatory cells, may affect the result of the mutation analyses, mainly with less sensitive methods for mutation detection, as a low copy number of the DNA template generates artifacts in the results. To avoid false-negative results, specimens with a minimum proportion of tumor cells ideally should be selected for mutation analyses.[19]

Routinely, DNA is extracted from five to ten scratched unstained sections, depending on the size of tissue sample. However, in some cases, a very low amount of DNA is obtained. To overcome the low amount of DNA extracted from small tissue specimens, different techniques can be used. Whole-genome amplification has been developed and is used in research; however, this technique has not been implemented in clinical testing yet, as it may introduce bias. Performing the assay in duplicate, and ideally in triplicate, may ensure the accurate interpretation of the results, but these methods may not be practical in a clinical laboratory because of the lack of tissue and the time and labor needed to duplicate (or triplicate) testing. Different methods of tissue enrichment can be used for tissue with heterogeneity in areas with tumor cells, including gross macrodissection, coring areas with tumor cells out of an FFPE block, microdissection from the glass, flow sorting, or laser capture microdissection (LCM).[19,20] Macrodissection is used for clinical testing, but LCM is not routinely used because it is labor intensive and because the effects of a laser on mutation testing are unknown and must be evaluated. In addition, even if LCM produces a very pure sample of tumor cells, it also provides a very low DNA yield.

The advantage of IHC and FISH is that the evaluation of the protein expression level or genomic aberration can be analyzed more specifically on individual tumor cells. In IHC and FISH,

cells are analyzed individually. Therefore the tumor cell's content is less crucial than for mutation testing. However, focusing the analysis on tumor-rich areas is important in FISH. Thus a corresponding hematoxylin and eosin (H&E)-stained section should be used to select areas for analysis. When using IHC, a larger sample size provides a better evaluation of the tumor heterogeneity and percentage of cells expressing the biomarker. However, obtaining larger samples is not easily controlled, as the sample size depends on the type of specimen that can be obtained from the tumor.[19]

SAMPLE AVAILABILITY AND PRIORITIZATION OF BIOMARKERS FOR TESTING

Three types of tissue samples can be used for molecular testing. A first approach is used for patients who originally presented with early-stage disease and had subsequent recurrence, a case in which large amounts of the initially resected archival primary tumor should be available for testing. A second approach is used for patients who presented with advanced-stage disease, for whom limited tissue in the form of bronchial, core-needle aspiration biopsy samples of the primary or metastatic tumor, or pleural effusion specimens are suitable for testing. In some instances, if the archival biopsy materials are no longer available or have been exhausted, a new biopsy for molecular testing purposes will be necessary. In all instances, histologic assessment of a freshly cut H&E-stained section of the tissue block should be performed, as part of the preanalytic quality control of the sample. However, in the case of repeat biopsy for testing purposes, there should be a clear indication to the pathologist about the purpose of the biopsy, such that unnecessary ancillary diagnostic IHC studies can be avoided to maximize samples for molecular testing.

Although biopsy tissue samples from patients with advanced-stage disease may be very limited, the tested biomarkers should be prioritized on the basis of their clinical relevance, and the methods used to test them should have a fast turnaround time for therapeutic decisions. In the initial diagnostic workup of biopsy materials, the biomarkers should be rationally and judiciously selected. Because each repeat facing of paraffin blocks results in tissue loss, cutting additional slides for molecular testing, when initially cutting the slides for histopathologic diagnosis, will help if further testing is necessary. However, this option is not always practical as it can increase the laboratory space needed for storing unstained sections, and more importantly, unstained sections stored at room air are no longer optimal for IHC or molecular studies beyond a few weeks or months. The more practical
Fig. 18.2. Tumor cellularity in biopsy specimen. (A) Sample with more than 80% high cellularity. (B) Sample with less than 10% low cellularity, with circled areas showing small clusters of tumor cells.

approach is to order and perform all necessary biomarker testing simultaneously or use multiplex techniques. A third approach that is gaining more acceptance is to perform reflex testing, which is automatically initiated by the pathologist at the time of initial diagnosis. This approach provides the most rapid turnaround time and greatest saving of tissue for future additional studies that may be required for new biomarkers or participation in clinical trials.

Although mutation testing is ideally reported in histology samples, in many cases for patients with advanced disease, the only diagnostic material is based on fine-needle aspiration or cytologic samples. Despite the fact that some molecular/protein analyses can be performed on cytology smear specimens, mutation testing has been better performed on cell blocks prepared from these cells. Therefore cell block preparation is recommended in processing cytologic specimens.

The choice of the biomarkers to be tested must be based on evidence of their clinical relevance for therapeutic decision. To obtain consistent and dependable results, molecular testing should be performed in laboratories that are certified by regional or national regulatory bodies and by well-trained personnel using well-maintained equipment. When determining the methodologic and technical strategy for molecular testing, the main concerns include the sensitivity and specificity of the test, the amount of materials required for successful testing, equipment availability, turnaround time, and cost of the test.[19]

CURRENTLY RECOMMENDED PREDICTIVE BIOMARKERS IN LUNG CANCER

EGFR Mutations for EGFR TKI Therapy

The *EGFR* gene is located on chromosome 7. EGFR TK domain mutations are more frequent in East Asian (40% to 50%) than in white (10% to 20%) patients.[18] EGFR mutations are also found more often in never-smokers than in smokers, and in more women than in men. The mutations are mostly found in adenocarcinomas (around 50% in Asian patients and 25% in non-Asian patients), including adenosquamous carcinomas, but they are uncommon in squamous cell carcinomas (5%; Tables 18.2 and 18.3).[19]

In patients with advanced NSCLCs that harbor an *EGFR* activating mutation, the response rate to EGFR TKIs is 68% and the progression-free survival is 12 months, whereas in patients with unselected advanced NSCLC, the response rate and progression-free survival are 8% to 9% and 2.2 months to 3.0 months, respectively.[28,29,39–42] The discovery of this difference prompted investigators to conduct studies comparing chemotherapy with EGFR TKIs in NSCLC patients with an activating mutation. The Iressa Pan-Asia Study (IPASS) was the first randomized trial in which results showed an advantage for EGFR TKIs as compared with chemotherapy for first-line treatment of stage IIIB/IV disease in never-smoker East Asian patients with a tumor harboring an *EGFR* mutation (hazard ratio for progression-free survival, 0.48; $p < 0.001$).[1,40] Subsequently, in several other randomized trials, results showed the superiority of treatment with EGFR TKIs for patients with *EGFR*-mutated NSCLC tumors (Table 18.4).[28,29,39–42]

EGFR Mutations to Be Tested

Ninety percent of the activating somatic *EGFR* mutations are short in-frame deletions in exon 19 (most frequently, delE746-A750) and a point mutation in exon 21 (L858R; see Fig. 18.1).[43,44] These two mutations have been largely associated with sensitivity to EGFR TKIs. However, the other 10% of *EGFR* mutations are of interest for therapeutic decisions as well. The most frequent in-frame deletions in exon 19 are 15-bp and 19-bp deletions, involving three to seven codons centered on the uniformly deleted codons 747 to 749 (Leu–Arg–Glu sequence). However, 9-bp, 12-bp, 24-bp, and 27-bp deletions are also found, as well as 15-bp and 18-bp insertions.[45] Other, less frequent, *EGFR* activating mutations that have been identified are in exon 18 (E709 and G719X) and in exon 21 (T854 and L861X).[44] All of these

mutations result in an EGFR that is constitutively active and may be sensitive to EGFR TKIs.[46]

Both primary and acquired resistance to EGFR TKIs have been reported. After initial response or disease stabilization for several months, a great majority of EGFR mutation-positive tumors eventually become resistant to EGFR TKIs. Another *EGFR* mutation, the T790M mutation of exon 20, was found to be a resistance mechanism that is acquired secondarily to treatment with EGFR TKIs in almost 50% of cases.[47] Although the T790M mutation is usually acquired, rare cases of NSCLC harbor T790M-mutated cells, with or without an activating mutation, before treatment with EGFR TKIs and, based on preliminary data, the T790M mutation seems to initially confirm resistance to EGFR TKIs.[48–50] Inherited T790M germline mutations have also been identified in some families with lung cancer.[51]

Some other mutations in exon 20 include S768 and insertions and are associated with initial resistance to EGFR TKIs.[52,53] As more sensitive mutation assays are available and as more rare mutations are detected, studies are needed to establish the clinical and therapeutic roles of these rare mutations. More recently, a germline point mutation in exon 21 at codon 843 (vv8431) has been reported as the cause of familial lung adenocarcinoma with resistance to EGFR TKIs.[54,55]

The *EGFR* in-frame truncated variant (EGFR vIII), resulting from a deletion of exons 2–7 and consequently of a truncation of 801 bp in the extracellular domain, has been rarely reported in NSCLC.[56] The response of a tumor with the *EGFR vIII* mutation to EGFR TKIs is not known.

In conclusion, EGFR testing should be performed for any mutation located in exons 18–21 with over 1% prevalence.

Assays Used for Testing

Currently, the *EGFR* mutation is detected by classic molecular tests. Based on expert consensus opinion,[19] as for any other molecular testing, *EGFR* mutation testing should be performed on FFPE, frozen, or alcohol-fixed tissue specimens. The largest and best available quality tumor specimen should be used, even if the techniques can be adapted, and include tissue enrichment steps for cases where a low amount of DNA is obtained. The different methods for mutation testing have been described earlier in this chapter. The Sanger sequencing method, ideally used by performing bidirectional sequencing and by confirming with additional sequencing, can be used. However, using Sanger sequencing can result in missing approximately 30% of sensitizing

mutation because of the relative low sensitivity of this technique.[57] Therefore when using Sanger sequencing, the cellularity limit needs to be higher, at least 20%, and/or it should be used in combination with a more sensitive mutated allele-enriching strategy or both methods (standard and high sensitivity). When choosing the test, the clinician should take into account the clinical situation and the available tumor content. As mentioned earlier, *EGFR* mutation testing should be performed in a certified laboratory. The method used should test any mutations in exons 18–21 and be highly sensitive to detect any mutation with a prevalence over 1%. Data have shown the feasibility of detecting *EGFR* mutations in circulating DNA as well as in circulating tumor cells in patients with NSCLC.[34,38] The sensitivity of EGFR detection in circulating DNA, with the *EGFR* mutation detected on a tumor considered as the standard, is approximately 70%.[34–36] Thus circulating DNA could be used for screening in the first-line treatment setting, but further mutation tumor testing would be required on specimens that test negatively. Besides first-line testing, an increased interest has been shown for using liquid biopsies for monitoring molecular abnormalities and, particularly, to detect *EGFR* T790M mutations at the time of acquired resistance to first-line EGFR TKIs. The third-generation EGFR TKIs have shown very high response rates in patients whose tumor harbors T790M mutation that is resistant to first-line EGFR TKIs.[58] Therefore molecular testing at resistance is required but rebiopsy in a clinical practice may be challenging and the success rate is limited in advanced NSCLC patients.[59] Therefore T790M detection in the circulating DNA has been performed and showed a sensitivity between 40% and 70% according to the technique that was used.[60] Hence, testing the *EGFR* mutation with blood samples is a promising and attractive alternative, particularly in second and later lines of treatment, because it does not require an invasive procedure (biopsy), but stronger evidence is needed before it can be recommended as first-line testing. Currently, circulating DNA may be used for EGFR testing for first-line treatment in specific clinical settings in which tissue is absent or limited for molecular testing. Circulating DNA may be used to detect EGFR T790M mutations in NSCLC patients with progression or acquired resistance to first-line EGFR TKIs. However, as the sensitivity is modest, any negative results in the blood should be followed by EGFR testing in the tumor sample.

Specific antibodies for the detection of EGFR mutations by IHC have been assessed, and the authors of several studies have consistently reported good sensitivity and specificity for the detection of the exon 21 L858R mutations as well as the EGFR

exon 19 15-bp deletions.[61–64] Unfortunately, the sensitivity is lower for the detection of EGFR exon 19 deletion of other sizes.[62,63,65,66] After validation and standardization, IHC using mutation-specific antibodies could be an option for initial screening for patients with samples with low cellularity that otherwise would not be adequate for mutation testing. Tumors that test negatively by IHC would still need mutation testing. However, this option needs stronger evidence to be recommended for the selection of patients for EGFR TKI therapy.[19]

Proteomic profile using mass spectrometry has also been shown to predict response to EGFR TKIs. From an analysis of serum samples taken from 139 patients with NSCLC before treatment with gefitinib, investigators developed a proteomic signature that was used retrospectively to classify patients according to response, both in the first- and second-line treatment settings.[67] A significant difference in overall survival was found according to the outcome predicted by the proteomic signatures in gefitinib and erlotinib validation cohorts. The proteomic classifier has since been commercialized as VeriStrat (Biodesix, CO, USA). Testing with VeriStrat predicted survival outcome in the Eastern Cooperative Oncology Group 3503 phase II trial of erlotinib as first-line therapy in NSCLC.[68] However, in a retrospective analysis of patients treated in the National Cancer Institute Canada (NCIC) BR-21 study, testing with VeriStrat was found to be prognostic for both overall survival and progression-free survival and was predictive for response but was not able to predict for differential survival benefit for erlotinib.[69] The proteomic classifier, which is unrelated to EGFR mutation status, is currently being validated in several prospective studies. In PROSE (Randomized Proteomic Stratified Phase III Study of Second Line Erlotinib versus Chemotherapy in Patients with Inoperable Non-Small Cell Lung Cancer), investigators prospectively validated the VeriStrat classifier for second-line therapy in patients with advanced NSCLC.[70] Patients were classified as poor or good according to VeriStrat analysis, and the analysis clearly distinguished patients who would benefit from chemotherapy versus EGFR TKI.

Other Potential Biomarkers for EGFR TKI Sensitivity

Other biomarkers have been assessed for their potential association with sensitivity to EGFR TKI, including EGFR gene copy number and EGFR expression.

Tumors that are EGFR positive on FISH (including high polysomy and gene amplification using the Colorado scoring system[71]) have been found in 22% to 76% of patients with NSCLC and are associated with a 30% rate of response to EGFR TKIs.[27,72–78] However, the EGFR gene copy number is not recommended for prediction of response to EGFR TKIs for several reasons. The response rate of 30% among patients with an increased EGFR gene copy number remains much lower than the response rate of 68% in patients with activating EGFR mutations. In addition, there is a strong association between EGFR mutations and gene amplification and the higher response rate with gene amplification is a consequence of the association with EGFR activating mutations.[79,80] Some studies, including IPASS, have involved both EGFR gene copy number and EGFR mutation analysis. The response rate for patients with tumors harboring the EGFR mutation but with no increase in gene copy number remains at 68%.[2,41,79,80] For patients with an EGFR mutation-negative tumor, the response rate was low, irrespective of whether the EGFR gene copy number was high or normal. Lastly, in IPASS, the outcome with EGFR TKIs was better for patients with NSCLC who were selected on the basis of the presence of an EGFR mutation than it was for patients who were selected on the basis of the EGFR copy number.[2,41] Therefore EGFR copy number should not be used to select patients for EGFR TKI treatment. It is not well established whether EGFR gene copy number has a predictive value for response to EGFR TKIs in selected patients with EGFR

wild-type tumors. FISH-determined EGFR is currently being evaluated as a predictive biomarker for EGFR TKI therapy (i.e., cetuximab, necitumumab) in prospective studies.

EGFR protein expression by IHC has been assessed to predict response and outcome to EGFR TKIs. Total EGFR expression has not been shown to be associated with a better outcome to EGFR TKIs or with EGFR mutation.[79–81] In a retrospective analysis, the use of a specific antibody targeting the intracellular domain of EGFR has been shown to improve the prediction of response to EGFR TKIs compared with antibodies targeting the external domain.[82] Still, this method needs to be validated and does not appear to provide a better prediction than EGFR mutations can provide. Therefore total EGFR expression cannot currently be recommended to select patients for EGFR TKI therapy. However, high EGFR protein expression has been shown to predict response to anti-EGFR monoclonal antibody therapy (cetuximab).[83,84] The American Society of Clinical Oncology guidelines include cetuximab plus chemotherapy as an option for first-line treatment of patients with tumors positive for EGFR expression by IHC based on the results of the First-Line ErbituX in lung cancer (FLEX) study.[85] In the FLEX study update, there was a survival benefit for patients who had tumors with higher EGFR expression, when the score used considered the percentage of cells stained and the intensity of the staining (H score).[86] Further evidence and validation in independent clinical trials are warranted to recommend the use of EGFR expression in select patients for therapy with an anti-EGFR monoclonal antibody.

Other Biomarkers of Resistance to EGFR TKIs

In addition to EGFR mutations, other biomarkers have been indicated as potentially associated with primary resistance to EGFR TKIs. KRAS mutations with constitutive activation of the downstream pathways are seen in 30% of people with lung adenocarcinomas and have been associated with poor prognosis.[87] Based on retrospective analyses in trials of patients receiving EGFR TKIs as second- and third-line treatment, the presence of KRAS mutation is associated with lower response rates in patients taking EGFR TKIs (0% to 3%);[27,42,49,79,80,88–93] however, there is no substantial effect on outcome. Because KRAS and EGFR mutations are considered mutually exclusive, KRAS testing is sometimes used as a screening assay and only KRAS wild-type tumors are tested for the EGFR mutation. This approach has not been validated and implies that enough material is available for successive testing of KRAS and EGFR mutations and would not delay the results. Therefore more data are required and KRAS mutation testing cannot be recommended to exclude patients for EGFR TKI therapy.[19] Furthermore, although subtyping of KRAS mutations has been shown to have clinical relevance in colorectal cancer, no studies in lung cancer have established a clinically relevant difference between subtypes of KRAS mutations.

Mesenchymal–epithelial transition is another potential mechanism for resistance to EGFR TKIs. MET gene amplification has been associated with 10% to 20% of acquired resistance to EGFR TKIs.[94–96] More recently, HER2 has been associated with acquired resistance to EGFR TKIs.[97] High expression of insulin-like growth factor receptor 1 (IGF1R) has also been shown to be associated with resistance to EGFR TKIs.[98–100] Recently, BCL2 interacting protein (BIM) polymorphism has been shown to potentially induce EGFR TKI resistance in patients with NSCLC harboring EGFR mutations.[101] Currently, none of these biomarkers (MET, HER2, or IGF1R amplification) can be used for negative selection of patients for EGFR TKI treatment.

Patients Who Should Have Testing

Based on currently available published data, the EGFR sensitizing mutation is the only biomarker recommended as the predictive biomarker for testing of patients to receive EGFR TKI

therapy. Although *EGFR* mutations are more frequent in tumors in patients who are Asian, female, or never-smokers, they also occur in other patients.[2,39,72,102] Therefore clinical characteristics are not recommended for selecting or excluding patients for EGFR mutation testing.

EGFR mutations are most frequently found in people with adenocarcinomas and are very uncommon in people with pure lung squamous cell carcinomas and in pure small cell carcinomas (such as SCLC).[103–107] However, mutations have been found in patients with other mixed carcinomas with an adenocarcinoma component, such as adenosquamous carcinomas or combined small cell carcinoma with an adenocarcinoma component. Consequently, in the absence of IHC evidence for the presence of an adenocarcinoma component, *EGFR* mutation testing is not recommended for patients with squamous cell carcinomas and SCLC carcinomas.[19] In patients with marginally sufficient lung cancer specimens, including samples from biopsy, fine-needle aspiration, and cytologic samples from pleural effusions, the diagnosis of adenosquamous or poorly differentiated adenocarcinoma may be challenging, and an adenocarcinoma component should not be entirely excluded.[19] This exclusion may explain why, in a few studies involving small specimens for EGFR mutation testing, *EGFR* mutations have been reported in rare cases of squamous cell carcinomas.[103] In addition, in order to alleviate misclassification of squamous cell carcinoma versus adenocarcinoma of the lung on small specimens, the optimal IHC diagnostic algorithm should be used.[108] The suitability of thoracic cytology for EGFR molecular testing has been confirmed, but IHC was used for histologic subtyping of the patients.[109] Thus in cases of limited lung cancer specimens that may not exclude definitively an adenocarcinoma component, *EGFR* mutation testing should be performed in all patients, including those with squamous cell and small cell carcinomas. However, *EGFR* mutations have been identified in patients with proven squamous cell carcinoma of the lung.[110,111] Therefore as recommended in the European Society for Medical Oncology guidelines and the CAP/IASLC/AMP guidelines, molecular testing could be performed in patients with squamous cell carcinoma of the lung who are never-smokers and former light-smokers (fewer than 15 pack-years).[19,112] *EGFR* mutation testing should also be performed for patients with tumors that are classified as NSCLC not otherwise specified (NOS), if possible.

When Testing Should Be Done

Evidence for the use of EGFR mutation testing in selecting patients for EGFR TKI therapy is available only for those with advanced NSCLC.[2,39,40,72] By contrast, evidence for its use to select patients for adjuvant TKI therapy in early-stage and surgically treated disease is currently not available.[113,114] The test is not useful for many of these patients who will have surgery with or without adjuvant chemotherapy. However, for 50% of patients who are expected to have relapse, no initial testing on the resected specimen may mean that the test must be done at the time of disease progression, with delayed availability of the result, lack of a readily available sample, and even the necessity of repeating biopsy. Thus clinicians must balance the cost of performing unnecessary tests in cured patients with delaying therapy in others because results are not readily available.[19] At the time of relapse, it is also relevant to consider the value of *EGFR* mutation on the diagnostic sample and the possibility of resistant mutations present in the metastatic relapse sites but not in the primary tumor.

Tumor Site to Be Used for Testing

The type of samples used for EGFR testing is largely determined by the convenience of sample availability. Currently, testing of the primary tumor or metastatic lesions is equally acceptable before initial EGFR TKI treatment. However, there is some debate with regard to sample choice for testing because of tumor heterogeneity. In some studies, *EGFR* mutation testing has been shown to be very consistent between the primary lung tumor and metastatic lesions.[69,115] However, other investigators have reported heterogeneity of the *EGFR* mutation status between the primary lung tumor and the metastasis.[116,117] Overall, the quality of the tissue should be the primary factor for choosing the sample for a patient with metastatic lung cancer. Nevertheless, as previously discussed, metastatic bone lesions might not be optimal for testing if the biopsy specimen has been processed in acidic decalcifying solutions. For patients with multiple primary sites, it seems rational to test each tumor separately, as the detection of different mutations in different primary tumors has been reported.[118]

Clinical Recommendations for EGFR Testing

The guideline by CAP/IASLC/AMP recommends that, at diagnosis, any patient with advanced NSCLC with an adenocarcinoma, a large cell carcinoma, or a carcinoma with an adenocarcinoma component should be tested for the *EGFR* mutation, using the most accessible tissue (primary tumor or metastasis). If the specimen is not large enough to exclude an adenocarcinoma component, other histologies, such as squamous cell carcinomas and small cell carcinoma, should be considered for EGFR mutation testing as well. For patients with early-stage NSCLC, *EGFR* mutation testing at the time of diagnosis is debatable, but seems reasonable and should be done if possible.[19]

ALK Rearrangement: A Predictor of Response to ALK Inhibitors

The other approved targetable biomarker used in the treatment of patients with advanced lung cancer is *ALK* gene rearrangement. The discovery in 2007 of the *ALK* gene rearrangement in lung cancer has been quickly translated into a therapeutic target.[4] The most frequent *ALK* rearrangement is an inversion on the short arm of chromosome 2 resulting in a fusion gene, *echinoderm microtubule-associated protein like 4 (EML4)–ALK*, of which the fusion protein product demonstrates a constitutive tyrosine kinase activity. In addition, other fusion partners of ALK have been reported in lung cancer, including kinesin family member 5B (KIF5B)–ALK and TRK-fused gene (TFG)–ALK, which are rare fusions involving a translocation with a chromosome segment other than 2p (Fig. 18.3). The prevalence of ALK fusion ranges from 2% to 7% of patients with NSCLC (Table 18.5). ALK rearrangements appear more frequently in never-smokers and, potentially, in younger people, and occur more often in adenocarcinomas than in other NSCLC histologic types. However, *ALK* rearrangements seem not to be associated with gender or ethnicity, in contrast to EGFR mutations.[119–131]

Crizotinib, a small-molecule inhibitor of the tyrosine kinase of ALK fusion protein, has been tested in patients with NSCLCs that harbor an *ALK* rearrangement. The response rate for this selected population was 57%.[123] In a more recent study, crizotinib was compared with chemotherapy in patients with advanced NSCLC with *ALK* rearrangements, and crizotinib was found to be associated with a significantly greater response rate (65% vs. 20%; $p < 0.001$) and progression-free survival (7.7 months vs. 3.0 months; hazard ratio, 0.49; $p < 0.001$).[131] Testing for *ALK* rearrangement to select patients for treatment with ALK inhibitors such as crizotinib is now generally recommended.

Despite reports of encouraging results from treatment with crizotinib, clinical resistance has emerged. Several secondary mutations occurring in *ALK* and conferring acquired resistance to crizotinib have been reported, including L1152R, C1156Y, F1174L, L1196M, L1198P, D1203N, and G1269A.[132–137] Several molecules have been developed to target these resistant ALK mutations and show high response rate.[138] However, there is
Fig. 18.3. ALK, anaplastic lymphoma kinase; *NSCLC,* nonsmall cell lung cancer.
Modified from Tsao MS, Hirsch FR, Yatabe Y. IASLC Atlas of ALK Testing in Lung Cancer. *2013. Copyright International Association for the Study of Lung Cancer.*

currently insufficient evidence for recommending testing of these mutations in clinical practice. Resistance to ALK inhibitors may also involve activations of other pathways and development of other mutations, such as *EGFR* and *KRAS* mutations.[118,136]

Assays Used for Testing

In the United States, the FDA approved crizotinib for the treatment of patients with NSCLC that harbors an *ALK* rearrangement that can be detected using a commercial ALK break-apart assay (Vysis LSI ALK Break Apart FISH Probe Kit; Abbott Molecular, Abbott Park, IL, USA). This assay was used to detect *ALK* rearrangements in the clinical trials showing a clinical benefit with crizotinib in patients with NSCLC.[121,123,131,139] The assay involves hybridizing a telomeric 3′ probe labeled with Spectrum Orange (orange/red signal) and a centromeric 5′ probe labeled with Spectrum Green (green signal) to FFPE tissue sections. In the absence of rearrangement, the probes are fused and the signal is yellow (Fig. 18.4). The inversion results typically in a separation of the probes that gives individual orange and green signals.

A tumor is considered positive for *ALK* rearrangement if at least 15% of 50 nuclei of tumor cells assessed harbor the typically described split signals of *ALK* rearrangement.[139] However, other FISH abnormalities may occur with an atypical FISH pattern.[33,112] Interpreting the results of the FISH assay require special training and expertise and need to be performed or supervised by a pathologist.

Because of cost and convenience, IHC as a first-line screening assay for *ALK* rearrangement has been considered and adopted worldwide. In several studies, the detection of the protein product of the ALK fusion gene has been reported to reach a sensitivity and specificity of nearly 100%.[33,140] A crucial consideration in the application of an ALK-IHC assay is the use of the signal amplification step.[33] Several antibodies have been tested. A special IHC assay (Ventana Medical Systems, Tucson, AZ, USA) using the D5F3 antibody has been studied for interobserver reproducibility and comparability to the ALK-FISH assay.[116] The assay was highly reproducible and the results were strongly correlated with those of the ALK-FISH assay. In the centers using IHC to screen for *ALK* rearrangement, FISH is still being performed subsequently to confirm the positivity of the tumor for *ALK* rearrangement.[19] Although positive findings on ALK-FISH are strongly associated with response and outcome with crizotinib, an increasing number of reports have noted that some NSCLCs that are ALK negative on FISH (using the FDA-approved criteria) are ALK positive on IHC.[141] More recently, an ALK-IHC companion diagnostics assay has received approval by the FDA and in several other countries for use as a stand-alone ALK assay to diagnose and treat ALK-rearranged lung cancer patients.

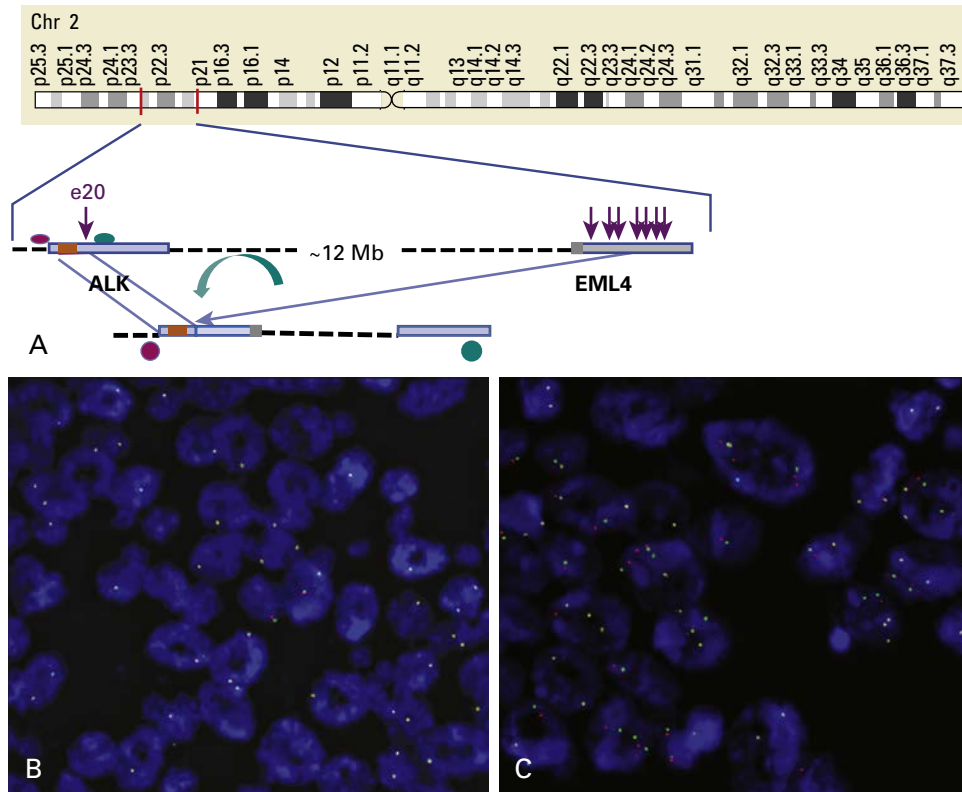
ALK testing with IHC and FISH are currently performed on FFPE tumor sections. FISH is a robust technique that might


Fig. 18.4. Anaplastic lymphoma kinase (ALK) break-apart fluorescent in situ hybridization (FISH) assays. (A) Schematic diagram showing the location of *ALK* and *echinoderm microtubule-associated protein like 4 (EML4)* genes on chromosome 2p, and the location of the break-apart probes in relation to the inversion breakpoint with *ALK* gene rearrangement. Tumors were probed by the break-apart ALK probes. (B) Tumor showing close approximation of the green and orange/red (artifically colored red) signals, indicating normal ALK gene structure. (C) Separation of the green and red signals indicates an inversion-type ALK gene rearrangement.

technically also be applicable to cytologic specimens, such as direct smears, cytospins, or liquid-based preparations.[33] However, the criteria for ALK-FISH analyses are the same as the criteria used for histology. Cell blocks or cytologic specimens may not contain enough tumor cells in many cases. Although FISH analysis on cytologic preparations is not recommended for predictive ALK testing, cell blocks might be acceptable.[33]

ALK rearrangements have been detected in circulating tumor cells with a sensitivity and specificity of 100% compared with testing of the primary tumor as the standard.[37] The circulating tumor cells were collected with a filter-based technology that does not eliminate the cells in epithelial–mesenchymal transition, while the FDA-approved epithelial cell adhesion molecule-based technology would not retain these cells. Interestingly, new ALK rearrangement patterns were found in circulating tumor cells. In one study, the 15% cutoff could not be used because of a low number of tumor cells. In the case of circulating tumor cells, a cutoff of four or more circulating tumor cells with ALK rearrangement per 1 mL of blood was chosen based on a receiver operating characteristic curve that resulted in the optimal prediction of *ALK* rearrangement in tumors.[37]

PCR methods can also be used to detect *ALK* rearrangement. The method is highly sensitive, but requires probes for identified fusion partners. Studies comparing the advantages and disadvantages of ALK testing with FISH, IHC, and RT-PCR are ongoing.[33]

Patients Who Should Have Testing

ALK testing should be done on the same patient population tested for EGFR mutations. As mentioned previously, although

ALK rearrangements are more frequent in never-smokers and younger people, they are also found in people with other clinical features. Therefore as with EGFR, clinical characteristics, except squamous cell carcinoma histology, should not be used to exclude patients with NSCLC from ALK testing.[119–130] *ALK* rearrangements are most common in adenocarcinomas and have been described in other lung cancers with adenocarcinoma components, but they are extremely uncommon in pure lung squamous cell carcinomas.[126,142–144] Because of this, as with EGFR testing, ALK testing should be done if IHC indicates that there is an adenocarcinoma component in a lung cancer specimen.[19] However, if a young never-smoker has a tumor with squamous cell histology, ALK testing should be recommended.

When Testing Should Be Done

The clinical results from different trials with crizotinib and preliminary results from studies of other ALK inhibitors have established the crucial role for *ALK* rearrangement testing in patients with advanced NSCLC.[123,131] For patients with curable early-stage disease, there are no data to support reflex testing at the time of diagnosis,[19] but the same argument can be made as for EGFR mutation testing, as previously discussed.

Tumor Site to Be Tested

For *ALK* rearrangements, no data are available regarding whether to test the primary tumor or metastatic lesions. However, because *ALK* rearrangements are driver oncogenes similar to *EGFR* mutations, consistency of results is expected between the

primary lung tumor and metastatic lesions. Thus the quality of the tissue and the feasibility for obtaining it should be the primary factors for choosing the sample to be tested. Similar to the case with EGFR mutations, there are no data on patients with several primary tumors, but it seems rational to test every tumor separately.[19]

Clinical Recommendations for ALK Testing

The CAP/IASLC/AMP guidelines recommend that testing for *ALK* rearrangement should be performed at the time of diagnosis for any patient with an advanced NSCLC that is an adenocarcinoma or has an adenocarcinoma component, with testing done on the most accessible tissue (primary tumor or metastasis).[19] If the specimen is not large enough to exclude an adenocarcinoma component, tumors with other histologies, such as squamous cell carcinomas and small cell carcinoma, as well as NSCLC NOS, should also be considered for *ALK* mutation testing. Testing of early-stage tumors is debatable, but appears reasonable and should be done, if possible.

POTENTIAL NEW MOLECULAR MARKERS FOR THE FUTURE

Prognostic Markers

A very large number of individual biomarkers have been studied for their prognostic role in NSCLC, but to date, there is no evidence to recommend any of them in clinical practice. Most of the markers are IHC markers that have been studied by many investigators, but the results of different studies are discordant.[145] Some biomarkers have been studied in meta-analyses (KRAS, EGFR, P53, HER2, cyclooxygenase-2 [COX-2], Ki-67, and Bcl2), and several had a significant, but weak, impact on overall survival.[87,146–151] Six markers (overexpression of cyclin E and vascular endothelial growth factor A, and loss of p16INK4A, p27kip1, B-catenin, and E-cadherin) showed a consistent prognostic impact in more than half of the studies.[145] The absence of clinically relevant prognostic biomarkers and the discordant results are partially due to the lack of homogeneity of study cohorts and of standardization of the techniques used in different laboratories for each marker. A more pragmatic approach to biomarker study and validation is needed and could be achieved through a multiphase approach similar to that used in clinical trials.[145] Translational researchers from the NCIC Clinical Trials Group, the International Adjuvant Lung Cancer Trial Biologic Program (IALT-Bio), and the Lung Adjuvant Cisplatin Evaluation Biologic Program (LACE-Bio) have investigated the prognostic value of several biomarkers in large phase III randomized trials, which offer the advantage of more uniform and better defined patient populations and allow testing if the markers predict benefit from adjuvant chemotherapy. The studies performed by these groups might then provide more clinically relevant biomarkers. The LACE-Bio group pooled the analysis of the prognostic and predictive effects of *KRAS* mutation in patients with early-stage resected NSCLC in four trials of adjuvant chemotherapy. Among 1543 patients, of which 300 had *KRAS* mutations, the presence of *KRAS* mutation, either at codon 12 or 13, was not found to be a prognostic factor for overall survival.[150] In addition, the LACE-Bio group has reported that *TP53* mutation is also not a prognostic factor but is marginally predictive of poorer survival in patients who received adjuvant chemotherapy.[152] More recently, the investigators have also reported that intratumoral lymphocytic infiltrate and histologic subtype of lung adenocarcinoma are significant prognostic markers.[153,154]

Panels of biomarkers or signatures may be used to predict prognoses and could have greater power than individual biomarkers to discriminate patients with different prognoses. Many studies of prognostic gene signatures in patients with NSCLC have been published. Since 2005, the studies include validation in independent cohorts, in most cases based on publicly available gene expression data sets. However, the prospective validation of these signatures has been missing and very difficult to conduct, thus the clinical applicability of signatures with a large number of genes has been challenging. Zhu et al.[155] identified a 15-gene signature derived from patients participating in the JBR.10 study that discriminated patients at high- and low-risk in the observation arm. In addition, high-risk patients derived significant benefit from chemotherapy, but low-risk patients did not. Tang et al.[156] reported on another signature of 12 genes that predicted for survival benefit with adjuvant chemotherapy, identified in a cohort of 442 stage I–III NSCLC specimens and further validated in two independent data sets of 90 (University of Texas cohort) and 176 patients (JBR.10), respectively. In both cohorts, the groups that were predicted to benefit from adjuvant chemotherapy had an improved survival rate with adjuvant chemotherapy, and the groups that were predicted not to benefit from adjuvant chemotherapy did not have any survival benefit after adjuvant chemotherapy.[155] Kratz et al.[157] reported on a 14-gene signature, based on quantitative PCR assays of FFPE tissue samples in a testing cohort of 361 patients and two validation cohorts of 433 and 1006 patients, respectively. This signature identified patients at high risk of mortality after surgical resection of an early-stage NSCLC. To date, however, all signatures lack sufficient validation to be implemented in clinical practice.

Other Predictive Biomarkers

Aside from *EGFR* mutations and *ALK* rearrangements, several other biomarkers have also been tested for their ability to predict lung cancer response to treatment, but none have shown sufficient evidence for current use in clinical practice. Part of the reason is that predictive biomarkers are relevant only for therapies that show clinical efficacy, and to date, few targeted therapies have been approved for patients with NSCLC. Initial biomarker research has focused on prediction of outcome with systemic therapy in advanced NSCLC. More recently, however, the predictive biomarker research has focused on the adjuvant setting.

Biomarkers are commonly investigated for both prognostic value and for prediction of response to chemotherapy. To date, preliminary evidence from studies in NSCLC suggests that DNA repair markers may be prognostic and predictive for treatment with cisplatin (excision repair cross-complementing rodent repair deficiency, complementation group 1 [ERCC1] and MutS homolog 2 [MSH2]), gemcitabine (ribonucleotide reductase M1 [RRM1]), taxanes (breast cancer 1 [BRCA1]), and pemetrexed (thymidylate synthetase).[158–163] Class III beta-tubulin (TUBB3), a block for microtubules, is potentially predictive for outcome to agents targeting the microtubules, such as taxanes and vinca alkaloids.[164] The roles of other genes or proteins involved in the cell cycle (p27) or apoptosis (Bax) or multiple critical cell functions (P53, KRAS) have also been studied as potential predictive biomarkers.[165–167] Controversial results have been published on the prognostic role of p27 by the IALT-Bio and LACE-Bio programs.[165,168] In a pooled analysis of data from IALT-Bio and JBR.10, IHC protein expression of Bax significantly predicted survival benefit with adjuvant chemotherapy.[166] In the LACE-Bio study of *KRAS* mutation, no significant benefit of adjuvant chemotherapy was found in patients with wild-type or *KRAS* mutations in codon 12, but a deleterious effect with adjuvant chemotherapy was noted in patients with *KRAS* mutations in codon 13 (interaction p = 0.002).[169] This finding requires further validation. The LACE-Bio group assessed the role of *KRAS* in 426 patients with *EGFR* wild-type adenocarcinomas and found that the double *P53/KRAS* mutation status was not of prognostic value. However, compared with patients with double *P53/KRAS*

wild-type tumors, patients with the double *P53/KRAS* mutations in the tumor had a detrimental effect of chemotherapy (compared with observation), with a comparative hazard ratio of 3.03 (*p* = 0.01).[170]

There has been a resurgence of interest in immunotherapy in lung cancer, with several drugs currently being evaluated in clinical trials. Immunotherapy covers three categories of treatments: (1) vaccines such as the antigen-specific melanoma-associated antigen 3 (MAGE-A3) vaccine (MAGE-A3 ASCI)[171] and the liposomal BLP25 vaccine (L-BLP25) targeting MUC1[136]; (2) checkpoint targets, including T-cell-modulating agents such as the monoclonal antibodies against program death-1 (PD1) and MPDL3280A against the ligand of PD1 (PDL1); and (3) T-cell antigens such as ipilimumab against the cytotoxic T lymphocyte-associated antigen-4.[172] Investigators are searching for biomarkers for prediction of response to these therapies and some biomarkers have been studied, but none is currently validated or recommended for clinical practice. For the vaccines, the MAGE-A3 messenger RNA level of expression is assessed for the prediction of response to the MAGE-A3 immune vaccine. As an example of gene expression signature, an 84-gene signature has been recently reported to be associated with clinical response to MAGE-A3 immunotherapy in metastatic melanoma, and this association has been confirmed in resected NSCLC.[173] Different biomarkers are also currently assessed for the checkpoint therapy; the PD1 and PDL1 expression are assessed by IHC as potential predictors of response to nivolumab and other checkpoint targeting agents. Variable and discordant results have been published for the predictive value of PDL1 expression with various PD1 and PDL1 inhibitors.[174,175] In nonsquamous carcinomas, a greater benefit of nivolumab was seen when PDL1 was chosen as the cutoff value and the amplitude of the benefit increased when a higher level of PDL1 expression was present,[176] but PDL1 expression was not predictive for the benefit of the same drug, nivolumab, in lung squamous carcinoma.[177] In addition, different methodologies, including different antibodies, variable cutoff values, and assessment of the staining in different cells' compartment, that is, tumor versus inflammatory cells, have been used in the different trials assessing the checkpoint inhibitors.[178] A coordinative study, the BLUEPRINT project, is currently comparing the different testing methods for PDL1 expression. Many other biomarkers are currently tested for their predictive value with checkpoint inhibitors including the high mutation load that seems to predict a better sensitivity.[179] Thus no biomarker can be currently recommended to predict sensitivity to checkpoint inhibitors. The PDL1 expression showed some positive results but the tested methods must be defined and standardized and a panel of other biomarkers may be useful alone or in combination.

Other targetable oncogenic drivers that have been identified more recently include RET[5] and ROS fusions,[1,5,180] phosphatidylinositol 3-kinase subunits (PIK3C),[181,182] BRAF,[183] HER2,[184] and exon 14 Met splice junction mutations.[185–191] Several new gene fusions have been discovered with use of NGS, including metabolic enzymes.[9,192] As new therapies are being developed and tested to target these new oncogenic drivers as well as drivers that have been difficult to target (e.g., *KRAS* mutant tumors), corresponding predictive biomarkers are being investigated as possible companion diagnostics in parallel with the clinical development of these drugs. The presence of the oncogenic drivers is expected to predict response to the targeted therapy, but it might not always be the case, thus requiring extensive preclinical as well as clinical validation studies. A consistent benefit has been shown when treating patients whose tumor harbors *ROS1* rearrangement with treatment by crizotinib in several trials, and crizotinib was approved by the FDA in *ROS1*-rearranged NSCLC patients.[193,194] Therefore ROS1 testing should be conducted for all patients with negative results for EGFR and ALK testing, and possibly in parallel when there is no concern about tissue availability. BRAF, RET, HER2, KRAS, and MET testing are not indicated in routine testing in first-line treatment yet. They may be tested in first-line treatment in the context of clinical trials or they may be part of a panel testing when routing EGFR, ALK, and ROS1 testing are negative. More recently, accumulating evidence suggests that lung cancer patients with *MET* exon 14 skipping mutation may experience dramatic clinical response to MET TKIs such as crizotinib.[195–197] This splice-site mutation results in the loss of exon 14 and Cbl-binding site on the MET receptor protein, resulting in its decreased degradation and high receptor expression level.[198,199]

Worldwide efforts are ongoing for extensive molecular testing on large cohorts of patients. In France, routine testing of *EGFR*, *KRAS*, *HER2*, *BRAF*, and *PIK3CA* mutations as well as *ALK* gene rearrangement is being performed in 28 centers. The results of testing in a very large cohort of more than 18,000 patients with NSCLC were published.[200,201] A known target was identified in around 50% of the samples, 51% of the patients received biomarker-guided treatment, and the presence of a genetic alteration was associated with an improved prognosis. In the United States, the Lung Cancer Mutation Consortium assessed the frequency of 10 oncogenic drivers in advanced lung adenocarcinomas and provided results to clinicians to select treatments or clinical trials based on testing results. Among 1007 patients, 64% had a known oncogenic driver and 28% of patients received targeted therapy.[202] Patients with oncogenic drivers in the tumor who received targeted therapy had a better outcome than patients who did not have targeted therapy.[202]

Strong clinical evidence of the predictive value of the biomarker and standardizing the assay are mandatory for clinical use. The publication of a report on a technical issue regarding ERCC1 testing highlights the importance of standardizing and validating the assays.[203] In this study, ERCC1 immunostaining was reassessed in a validation cohort (494 samples) from two independent phase III trials (JBR.10 and CALGB-9633) using 16 commercial ERCC1 antibodies. In addition, 589 samples of the IALT-Bio cohort were restained. The results of the previously studied IALT-Bio samples with the 8F1 antibody could not be validated, indicating a batch-to-batch variation of the antibodies. More important, however, none of the 16 antibodies could distinguish the four ERCC1 protein isoforms, although only one isoform was functional in terms of nucleotide excision repair and resistance to treatment with cisplatin.[203]

CONCLUSION

Many biomarkers have been or are being assessed for prediction of prognosis and of benefit from different types of systemic therapies. Tests for *EGFR* mutations, *ALK* and *ROS1* rearrangements to predict response to EGFR TKIs and ALK/ROS1 TKIs, respectively, are currently the only biomarker tests recommended in clinical practice. Both tests should be performed at the time of diagnosis, especially for patients who have advanced NSCLC adenocarcinoma or a carcinoma with an adenocarcinoma component, and the most accessible tissue (primary tumor or metastasis) should be used. EGFR and ALK testing at the time of diagnosis is debatable for patients with early-stage NSCLC, but seems reasonable and should be done if possible. Standardized methods proven to be associated with clinical benefit must be used to test these biomarkers in certified laboratories.

19 Management of Small Histologic and Cytologic Specimens in the Molecular Era

Anjali Saqi and David F. Yankelevitz

SUMMARY OF KEY POINTS

- Techniques for the optimal triage and preparation of small specimens for diagnosis and ancillary studies are provided.
- For optimal results, a standardized protocol and algorithm should be implemented in the laboratory.
- Various factors determine the decision to perform a core-needle biopsy or fine-needle aspiration, including operator and pathologist preference, availability of rapid onsite evaluation, risk of complications such as pneumothorax or hemorrhage, the possibility of tumor cell seeding, the type of lesion (epithelial or spindle cell), and the lesion's location and size.
- Optimal use of a specimen requires appropriate handling and triage, with attention to both the quantity and quality of the specimen.
- Several measures can ensure that there is sufficient material in cores and cell blocks and that the tissue is not exhausted; the interventionalist should perform a gross examination of the specimen.
- In 2011, changes were made to the classification of adenocarcinoma to emphasize the interrelation of the tumor's clinical, radiographic, and molecular characteristics.
- Cytologic preparations are important; each preparation is unique, and taken together, they offer complementary information that can be valuable in rendering a diagnosis.
- Smearing requires technical skill that is not always available or optimal.
- Cell blocks have been recommended instead of smears for use in ancillary tests by the College of American Pathologists/International Association for the Study of Lung Cancer/Association for Molecular Pathology (CAAP/IASLC/AMP) guidelines; yet despite the usefulness of cell blocks, there is no standardized procedure for processing them.
- Methods for the management of small biopsy samples in patients with lung cancer will improve in the future in order to maximize the use of material for diagnosis.

Lung cancer is the leading cause of cancer-related deaths worldwide, despite knowledge of the primary etiologic factor (tobacco use) and advances in identifying underlying mechanisms, detecting mutations, and developing new treatments.[1] At one time, treatment selection depended on distinguishing small cell lung cancer (SCLC) from nonsmall cell lung cancer (NSCLC), but histologic subtyping of NSCLC has become increasingly important for selecting therapy. The addition of targeted therapies to the armamentarium for lung cancer necessitates testing for the presence of particular key driver mutations in lung adenocarcinomas to determine if a patient is eligible for a targeted therapy.

Small histologic and cytologic specimens obtained by core-needle biopsy and fine-needle aspiration are increasingly common.[2,3] Use of computed tomography (CT), endobronchial ultrasound (EBUS), endoscopic ultrasound, and electromagnetic navigational bronchoscopy has enabled the collection of small specimens for more patients through minimally invasive procedures, replacing traditional methods for obtaining specimens, such as mediastinoscopy, video-assisted thoracoscopic surgery, and thoracotomy. Less invasive small specimen collection is especially useful for patients with advanced-stage cancer, nonsurgical diseases such as granuloma, or fibrosis after previous surgery, as well as for patients who are poor surgical candidates or who are undergoing restaging.[4] In some cases, only small specimens are obtainable.

Small samples present a challenge: although the quantity of sample tissue being obtained is much smaller, the information required from the sample has increased substantially. In the past, little importance was placed on triaging small biopsy or cytologic specimens; however, now that treatment decisions are based on the histologic subtype and molecular profile of NSCLC, triaging the small specimens that comprise most or all of the diagnostic tissue has become crucial.[5] A poorly managed specimen may preclude an accurate diagnosis. For patients with NSCLC, it is necessary to have sufficient tissue for ancillary studies, such as immunohistochemistry (IHC) and/or molecular tests, to determine treatment. Appropriate management is also necessary for cases that are not NSCLC.

The shift to using small specimens for diagnosis has created a practice gap, because limited guidance is available for the management of small specimens (Fig. 19.1).[6,7] An optimal algorithm would define the steps for appropriate triage and processing of tissue to select a course of treatment. It would provide for a tissue reserve for identifying novel predictive biomarkers and suggest personalized therapies. Testing for mutations is likely to increase, and access to sufficient tissue will be crucial.

Specimens obtained by surgical biopsy are typically placed in formalin at the time of acquisition and then processed in the laboratory; this procedure rarely varies, and formalin fixation and hematoxylin and eosin staining are standard. The handling of cytologic specimens, especially fine-needle aspirates, is much less standardized. A number of methods are available to prepare and fix fine-needle aspirates after the collection procedure and in the laboratory. Several stains (Diff-Quik, Papanicolaou, hematoxylin and eosin, and ultra-fast Papanicolaou stains), slide preparations (smear, cytospin, ThinPrep, and SurePath), cell block processing methods (at least 10 homebrews and automated processing), and fixatives (saline, alcohol-based, formalin, Roswell Park Memorial Institute [RPMI] culture medium, and CytoRich) are used.[8] Furthermore, specimens are not triaged uniformly according to a protocol. Together, these factors produce inconsistent results across laboratories.

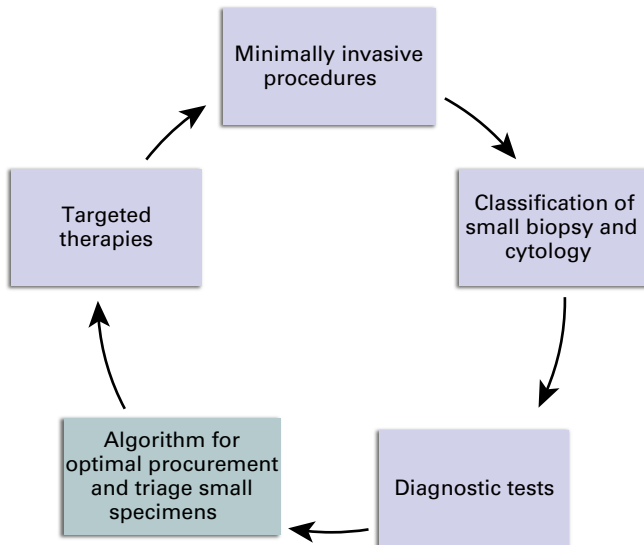
For optimal results, a standardized protocol and algorithm should be implemented in the laboratory. Along with improvements in tissue preservation, triaging the sample at the time of the procedure is increasingly important. In an ideal scenario, an interventionalist would collect a specimen according to a well-defined protocol. A cytologist—preferably someone onsite—would immediately assess the specimen's adequacy, confirming the presence of diagnostic material and determining if there is enough material for any necessary ancillary studies. The interventionalist


Fig. 19.1. The absence of a standardized algorithm for optimal procurement, processing, and triaging of small specimens has created a practice gap.

and the cytologist should communicate with each other at the time of the procedure, and the objectives of the sampling procedure should be specified to the extent possible. For example, if the initial small sample is needed only to confirm a diagnosis of malignant disease before definitive removal of the tumor, it is unnecessary to obtain additional samples because samples needed for advanced diagnostic studies could be obtained later during the surgical resection.

Techniques for the optimal triage and preparation of small specimens for diagnosis and ancillary studies are outlined in this chapter.

CORE-NEEDLE BIOPSY VERSUS FINE-NEEDLE ASPIRATION

The decision to perform a core-needle biopsy or fine-needle aspiration depends on various factors, including operator and pathologist preference, availability of rapid onsite evaluation (ROSE), risk of complications such as pneumothorax or hemorrhage, the possibility of tumor cell seeding, the type of lesion (epithelial or spindle cell), and the lesion's location and size.[9] To date, there has been no consensus on the preferred method. Critics of fine-needle aspiration question whether it is possible to obtain sufficient material for molecular diagnosis with this technique.[10,11] In contrast, proponents of cytologic specimens cite evidence that sampling different areas of a neoplasm with fine-needle aspiration is superior to using core-needle biopsy to obtain a specimen from a single area.[12,13] In a study published in 2012, it was reported that fine-needle aspiration and core-needle biopsy performed with ROSE provide equivalent results in terms of diagnosing a specific malignancy and obtaining sufficient material for ancillary studies (e.g., IHC and molecular testing) to guide tumor-specific treatment.[14] Lastly, molecular testing results showed 100% concordance between cytologic samples obtained by fine-needle aspiration and histologic resections obtained by core-needle biopsy.[15]

Some pathologists advocate a sequential approach to obtaining small specimens, namely, initial use of fine-needle aspiration followed by core-needle biopsy, if additional tissue is necessary.[13] Improved results have been demonstrated in studies in which fine-needle aspiration and core-needle biopsy are used together compared with either procedure alone.[16–18] A combined approach may be feasible for transthoracic CT-guided biopsy with use of a

coaxial needle, which permits acquisition of either type of specimen while minimizing the number of punctures.[3]

The two methods of obtaining small specimens may provide complementary information. For this reason, reviewing cases with paired cytologic and histologic specimens can be useful in rendering a specific and concordant diagnosis and minimizing the number of diagnoses of NSCLC not otherwise specified that can result from having samples with poor differentiation or scant cellularity.[12,19,20]

Navigational Bronchoscopy for Sample Collection

With navigational bronchoscopy, a sample can be collected with either aspiration or core-needle biopsy forceps. Little has been published comparing the cellular yield of each method. In one study, it was reported that catheter aspiration was associated with a higher diagnostic yield than biopsy.[21] The authors hypothesized that the back-and-forth motion of the catheter and the aspiration enabled access to target cells that may not be accessible by forceps biopsy. When both sampling procedures are going to be performed, experience has shown that it is better to conduct the aspiration first because doing so produces a less bloody sample without diluting the cells of interest.

RAPID ONSITE EVALUATION

Advantages

One of the most effective ways to ensure appropriate management of fine-needle aspiration is with ROSE, which involves working with an experienced cytopathologist or cytotechnologist in an adjacent room at the time of the procedure.[3] Several studies have demonstrated the usefulness of ROSE in optimizing the yield and efficiency of fine-needle aspiration and increasing its diagnostic accuracy.[22–27]

Onsite assessment has many advantages. First, it is an integrated approach to diagnosis. The cytologist obtains the pertinent history and can correlate the morphologic features with clinical findings and imaging study results. A preliminary evaluation and diagnosis is valuable in patient management. For instance, when treatment is urgent or patients have travelled far for care, processing can be initiated when the sample arrives in the laboratory.[7] Appointments with clinicians involved in treatment can be scheduled, and additional imaging studies or laboratory tests can be performed without delay.

By providing real-time feedback, ROSE decreases the number of false-negative diagnoses, which usually result from sampling error by the interventionalist.[3,19] Well-defined sampling protocols for obtaining specimens may minimize false-negative results; an example is requiring documentation of the needle tip in the lesion. Sparse cellularity obscured by blood, inflammation, or foreign material in a cytologic specimen can contribute to false-negative results.[19] When an onsite cytologist determines that the specimen is inadequate, a second sample can be obtained during the same session rather than having the patient return for another procedure.

Although imaging provides guidance and confirmation of the needle's placement in the target, the needle may inadvertently catch nonneoplastic cells or elements as it traverses through other tissues. Many times a specimen obtained by EBUS biopsy appears grossly diagnostic but consists of bronchial cells, macrophages, mucus, cartilage, or blood clot.[7] With CT-guided sampling of pleural-based lesions, mesothelial cells may be the main cellular component. A core may consist mostly of necrotic tissue or clotted blood. In the absence of ROSE, these samples may be misinterpreted as diagnostic specimens.

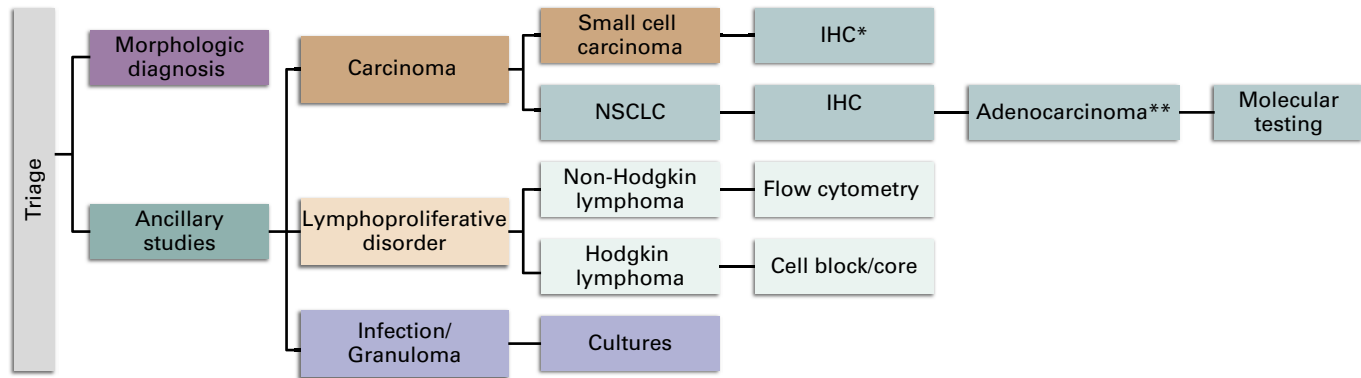
ROSE confirms the presence of adequate viable, nonnecrotic tissue. In a setting without ROSE, additional dedicated passes are


Fig. 19.2. Small specimens can be triaged for ancillary studies using this algorithm. *Perform IHC to confirm diagnosis, if necessary. **Perform molecular testing on carcinomas with adenocarcinoma or when a component of adenocarcinoma cannot entirely be excluded. *IHC,* immunohisto-chemistry; *NSCLC,* nonsmall cell lung cancer.

needed to increase the likelihood of a definitive diagnosis. Relative to a protocol that requires a fixed number of passes, immediate assessment with ROSE may mean fewer passes are necessary. Avoiding unnecessary passes decreases the duration of anesthesia or sedation and reduces potential morbidity. Benefits of shorter biopsy time include rapid turnover of the procedure room and imaging facilities and fewer repeat procedures, resulting in cost savings.[28–30]

With ROSE, the cytologist also is involved in the adequate preparation and triage of specimens. Based on the preliminary assessment, the specimen can be allocated for IHC or molecular testing for carcinomas, microbiologic cultures in cases of inflammation or granulomas, or flow cytometry for lymphoma assessment (Fig. 19.2).[31]

A biopsy or aspiration may be performed to determine whether a lymph node is negative for carcinoma, infection, or lymphoma; this scenario is common during EBUS staging procedures. With ROSE, a cytologist is able to assess whether the specimen is representative of a lymph node and whether a sufficient number of lymphocytes have been included to prevent a false-negative diagnosis and increase the negative predictive value.[24,32,33]

A well-prepared specimen expedites final examination by limiting the number of intradepartmental second opinions, consults, and deliberation necessitated by sparse cellularity, poor preparation, or artifacts; instead, cytologists can focus their attention on diagnostic dilemmas. When ROSE and the final interpretation are performed by the same cytologist, less time is required overall because a portion of the specimen has already been previewed.[7]

Disadvantages

Experience and training are necessary to prepare smears, assess a sample, and triage the specimen, and not all institutions have the resources or personnel to provide ROSE. ROSE can be time consuming: in addition to the procedure time, travel time to and from the procedure site can be substantial for large institutions or offsite practices. Given the time required for ROSE, reimbursement is low, and a pathologist can generate greater revenue and relative value units by examining slides under a microscope in his or her office.

Algorithm for Processing Small Samples

No standardized algorithm exists for processing small specimens, and few methods have been outlined.[6,34] The goal of processing small specimens is to preserve as much material as possible for molecular testing, especially for patients with advanced lung adeno cancer.[19,35] Ideally, each institution should engage a

multidisciplinary team and determine best practices for managing small specimens.[19] An algorithm and ROSE were used together to obtain sufficient cytologic material by EBUS-guided trans-bronchial needle aspiration for reflex molecular testing in 93% of patients with adenocarcinoma (Fig. 19.3 and Box 19.1).[6,36]

MANAGING SMALL SAMPLES WITHOUT RAPID ONSITE EVALUATION

When ROSE is not possible, there are some strategies to facilitate good management of samples obtained with fine-needle aspiration, although no standardized protocols exist. Interventionalists can prepare slides for the pathologist's review, either at the time of the procedure or afterward.[3] Telepathology, in which a pathologist views prepared slides from a remote location, may be an alternative to ROSE.[37] As technology improves, the role of telepathology is likely to increase, although additional studies are needed to determine best practices. Neither of these approaches ensures that an adequate specimen has been procured for ancillary testing or that the specimen will be triaged appropriately, however.

Performing a fixed number of aspirates per site (e.g., three) and a dedicated pass for cell block preparation or ancillary studies can enhance the cellular yield.[38,39] However, additional samples cannot always be obtained, especially when doing so poses an increased risk to the patient. To minimize suboptimal smearing and specimen use, the specimen can be placed directly into a fixative for liquid-based cytologic examination, or a cell block can be prepared; the usefulness of this technique has not been formally studied, though. Above all, it is essential to define a process for handling specimens in coordination with the cytopathology laboratory.

OPTIMIZATION AND TRIAGE

Optimal use of a specimen requires appropriate handling and triage, with attention to both the quantity and quality of the specimen.[3] Even in the presence of abundant tissue, poor preparation and allocation can preclude definitive diagnosis and ancillary studies.

Optimization

Slide Preparation for Fine-Needle Aspirate

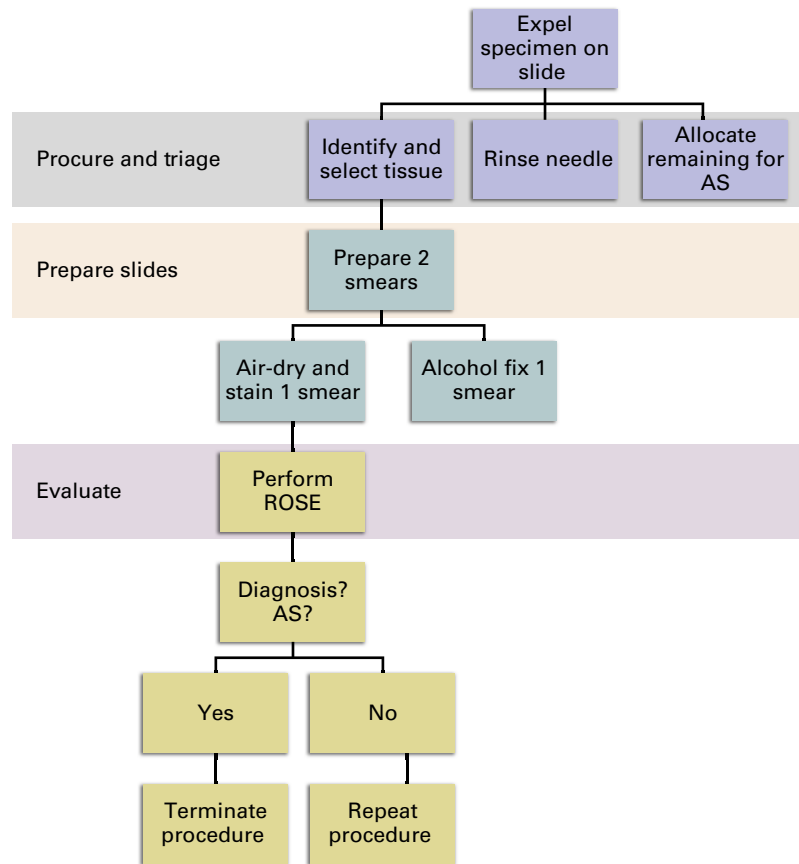
It is necessary to prepare only enough smears to make a diagnosis; the preparation of excessive smears can leave insufficient tissue for ancillary studies.[36] Ideally for ROSE, only two smears should be prepared per pass: one air-dried for Diff-Quik staining and the


Fig. 19.3. The algorithm for optimizing samples obtained using fine-needle aspiration with rapid onsite evaluation is divided into three stages: (1) specimen procurement and triage, (2) slide preparation, and (3) tissue evaluation for diagnosis and assessment of sample adequacy for ancillary studies, if necessary. *AS,* ancillary studies; *ROSE,* rapid onsite evaluation.

BOX 19.1 Steps for Processing Fine-Needle Aspirate

1. For each pass of the needle, expel the specimen onto a single slide with a syringe. (Fig. 19.3).
   a. If clotting prevents the material from being expelled, use a stylet to dislodge the specimen.
2. Identify diagnostic tissue particles, often tan or white specks but may vary depending on the nature of the lesion (e.g., mucoid material in cases of a mucinous carcinoma), and select them with the corner of a second slide (Fig. 19.5).
   a. When there is significant clot formation, gently press the specimen in between two slides to identify tissue particles.
   b. A scant sample may allow for preparation of only one or two smears.
3. For each pass, prepare two smears from the selected tissue particles (Fig. 19.5).
   a. Air-dry one smear and stain with Diff-Quik, or similar method, for ROSE.
   b. Fix one smear in alcohol for Papanicolaou staining in the laboratory.
4. Flush the needle and/or syringe to remove any remaining cells.
   a. For CT-guided aspirations, rinse the needle and syringe in CytoLyt (or another preservative used by the laboratory).

b. For EBUS and/or EUS fine-needle aspiration, pass approximately 0.5 cc to 1 cc of saline through the needle into CytoLyt (or other preservative used by the laboratory).
5. Place the remaining specimen in media appropriate for ancillary studies and/or cell block preparation.
   a. Cell blocks can be made by allowing the specimen to clot on the expelled slide for a few minutes and then placing it into formalin. (Partial) clotting simplifies cell block processing.
   b. Separate diagnostic material or more cellular elements from nondiagnostic ones (e.g., passes containing mostly blood) to prevent specimen dilution and improve the cellular yield of cell blocks.
6. Perform ROSE.
   a. Is there sufficient material for diagnosis?
      i. If not, repeat steps 1–5.
      ii. If yes, and ancillary studies are needed, determine whether the specimen includes sufficient material.
      iii. If no, perform dedicated passes for ancillary studies.
      iv. If yes, end the procedure.

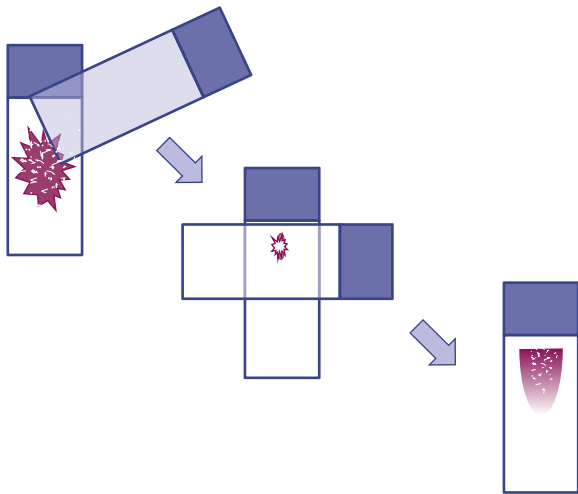
CT, computed tomography; *EBUS,* endobronchial ultrasound; *EUS,* endoscopic ultrasound; *ROSE,* rapid onsite evaluation.
Fig. 19.4. Optimal tissue use involves preparing smears of selected tissue particles, which are stained with Diff-Quik and Papanicolaou stains, and then placing excess material in media for ancillary studies, if needed. With suboptimal preparation, slides are thick and bloody and contain clots, and the specimen is spread across almost the entire slide surface. Suboptimal preparation obscures cellular detail, hinders accurate interpretation of slides, and may leave inadequate material for ancillary studies.


Fig. 19.5. To prepare a smear, select a tissue particle with the corner of a slide. Place the tissue on a clean slide and smear, holding the second slide perpendicularly.

Fig. 19.6. For optimal touch preparation, gently touch the core to the slide once or twice. If the core adheres to the slide, lift it with a needle and place it in the appropriate medium for fixation or transport. A smear can be prepared from a touch preparation with excessive tissue or liquid. In suboptimal touch preparations, the core is smeared or rubbed onto a slide, which can result in crush artifact and the transfer of a significant portion of lesional cells onto the slide, hindering final interpretation and compromising the core.

second fixed in alcohol for Papanicolaou staining. Any remaining material can be allocated for cell block preparation or other ancillary studies (Fig. 19.4). It is preferable to avoid thick smears. Not only do thin, even smears minimize tissue expenditure, they also allow for better visualization of diagnostic cells. Excess material and clots can be placed in a fixative or medium, which may obviate the need for additional passes for ancillary studies.

Use of excessive pressure when making the smears can create artifacts that hinder interpretation and lead to misdiagnosis. Slides should be placed perpendicular, rather than parallel, to each other to create smears with a concentration of specimen at the top and thin distribution below for easy visualization (Fig. 19.5).

Touch Preparation for Core-Needle Biopsy Specimens

The value of touch preparation for specimens obtained by core-needle biopsy is the subject of ongoing debate. Proponents argue that onsite touch preparation of CT-guided core biopsy specimens has been associated with greater diagnostic accuracy, because it guides the radiologist in obtaining additional cores needed for diagnosis and, possibly, molecular testing.[3,31] Critics note that the lesional cells may be transferred to the touch preparation, leaving only normal tissue on the histologic sections of the core.[31]

Gentle handling of the core can prevent cellular loss.[31] Typically, cores are thin and delicate. They dry rapidly and substantial

manipulation can cause them to fragment. Touching the core on a slide once or twice while it is still in the sheath yields the best results (Fig. 19.6). If excessive material is transferred to the slide, it can be smeared with a second slide to distribute the cells thinly.

Preparing a touch preparation for Papanicolaou stain can be challenging. Even if the slide is touched rapidly and immediately placed in alcohol, the slide may have air-drying artifacts. Artifacts can be minimized by hydrating the slide with a few drops of normal saline, which is available in syringes, for a few minutes. Placing a slide hydrated in this manner in alcohol salvages the nuclear features. This technique can also be applied to fine-needle aspirate smears when there is a delay in alcohol fixation.

Processing Core-Needle Biopsy Specimens and Cell Blocks

Several measures can ensure that there is sufficient material in cores and cell blocks and that the tissue is not exhausted. For example, the interventionalist should perform a gross examination of the specimen. It is important to determine whether the core represents a solid piece of tan-white tissue, which is typical of neoplasms. Sometimes the specimen consists mainly of red blood cell clot, mucus, liquefied necrotic inflammatory tissue, or bronchial cell contamination.[36] In this case, additional tissue is likely necessary.

Obtaining more cores increases the likelihood of having sufficient tissue for ancillary testing. At the time of publication, no guidelines are available to suggest a minimum number of cores. However, if feasible and accessible without substantial risk to the patient, one to four cores from 18- to 20-gauge core needles can yield sufficient tissue for mutational analysis.[40–42] Placing no more than three fragments or a single core in a single histology cassette hedges against inadvertent trimming of one block by leaving others available for ancillary testing if necessary (Fig. 19.7).[19] The consequences of excessive facing of the block should also be communicated to the histotechnologists cutting the blocks.

Tissue is lost during routine trimming processes in histology laboratories. To minimize this loss, 10 to 20 blank slides can be cut for core biopsy specimens and cell blocks at the onset.[19] Although this practice may reduce the risk of having insufficient tissue, some of the cut slides may go unused.[35]

Immunohistochemistry

When using IHC to distinguish between adenocarcinoma and squamous cell carcinoma, a limited panel should be performed in a stepwise fashion. For example, in case of a suspected primary

- Create >1 block when possible
  - Core biopsies
    - Divide cores/fragments into multiple cassettes
  - Cell blocks
    - Exfoliative and FNA specimens
      - Divide excess tissue into multiple cassettes
    - FNAs with ROSE
      - Separate passes with scant diagnostic tissue from those with abundant blood lacking lesional tissue
- Minimize loss of tissue while trimming/facing paraffin block
  - ROSE
    - Order blank slides for ancillary studies up front
  - No ROSE
    - Cut blanks and/or save intervening levels up front
    - Following H&E evaluation and at time of IHC order, request blanks
- Limit one section per slide*

Fig. 19.7. Core biopsy and cell block management in the laboratory. Whenever possible, create more than one tissue block for core biopsies and cells blocks. If one tissue block is exhausted, an additional one(s) is available for ancillary studies. In cases of FNAs, separating passes with scant diagnostic tissue or mostly blood from those with diagnostic tissue can prevent dilution of the cell block. Limit trimming and facing of the paraffin blocks to avoid inadvertent loss of tissue. In cases with ROSE, blank slides can be ordered up front. By limiting one section to a slide, greater numbers of slides are available, as when a broader immunohistochemical panel is required in case of an unknown primary or metastasis. *FNAs*, Fine needle aspirations; *H&E*, hematoxylin and eosin; *IHC*, immunohistochemical; *ROSE*, rapid onsite evaluation.

lung carcinoma, a combination of p40 and thyroid transcription factor-1 may be sufficient to distinguish between squamous cell carcinoma and lung adenocarcinoma, respectively. This approach helps to ensure that tissue remains for molecular diagnosis in cases of lung adenocarcinoma.[43,44]

Molecular Testing

For patients with stage IV adenocarcinomas for whom therapy is suitable, testing for mutation of the epidermal growth factor receptor (*EGFR*) gene or rearrangement of the anaplastic lymphoma kinase (*ALK*) gene is the standard of care and should be ordered at the time of diagnosis.[35] More recently, the US Food and Drug Administration approved Ventana anti-ALK(D5F3) IHC, which is 90.9% and 99.8% sensitive and specific, respectively.[45] Even in the presence of an *EGFR* mutation or *ALK* rearrangement—for which targeted therapies are available—life expectancy is relatively short, and it is important to obtain sufficient tissue during the initial collection procedure and triage it appropriately to avoid repeat procedures.[35] Similarly, when EBUS is performed to stage and diagnose NSCLC simultaneously, the sample should be managed especially carefully. Dedicated passes improve the yield of the specimen.[46] Making an additional pass can be difficult for a number of reasons, including the inability of the patient to tolerate the procedure, risk of a pneumothorax, difficulty reaching the target, or lack of time or willingness.[46]

The number of cells necessary for *EGFR* molecular testing depends on a few factors, including the absolute number of cells, the proportion of tumor cells to nonneoplastic cells, the sensitivity of the methodology, and sample enrichment with microdissection. Per published guidelines, the method should be sufficiently sensitive to detect *EGFR* mutation in a sample with 50% tumor content; however, a method that can identify a mutation in a sample with 10% neoplastic cells is ideal.[35] The minimum number of cells needed for EGFR molecular testing ranges from 50 to 400, with variation due to the sensitivity of the method and usage of microdissection to isolate neoplastic cells from others.[47,48]

Guidelines published in 2013 recommend that results of molecular testing be available within 10 days after the specimen is received in the molecular pathology laboratory.[35] Reflex testing is one way to expedite molecular testing results, but there are disadvantages. The drawbacks include performing additional fine-needle aspirations or core-needle biopsies, testing patients who have earlier stage localized cancer at the time of diagnosis, testing patients who may not be candidates for tyrosine kinase inhibitors (for example, because the cancer is advanced and the patient desires only palliative care), and conducting molecular testing when a larger resection is expected.[35]

In staging procedures for adenocarcinomas that have been previously diagnosed with IHC and molecular testing, the presence of tumor cells in a single sample is sufficient for molecular testing, especially if a patient cannot tolerate additional procedures to obtain biopsy specimens or aspirations.[7]

Adding Radiography for Evaluation of Adenocarcinomas

In 2011, changes were made to the classification of adenocarcinoma to emphasize the interrelation of the tumor's clinical, radiographic, and molecular characteristics. Given this evolution in adenocarcinoma classification, information from imaging studies often is used in conjunction with histologic evidence for the most accurate diagnosis.

Two of the new classifications are adenocarcinoma in situ (AIS; defined as localized adenocarcinoma 3 cm or less, with a pure lepidic pattern and without stromal, vascular, or pleural invasion) and minimally invasive carcinoma (MIA; defined as adenocarcinoma 3 cm or less, with a predominant lepidic pattern and invasion that is 5 mm or less, and without necrosis or lymph node, blood vessel, or pleural invasion).[2] Nonsolid and solid areas on a CT image correlate with lepidic and invasive (e.g., acinar) patterns, respectively, on histologic examination. Correlating a lepidic growth pattern on specimens collected using core-needle biopsy with the CT images may facilitate better assessment of the tumor. Aspirates taken from adenocarcinomas with a predominantly lepidic pattern have sheets of relatively bland-appearing cells, which may be accompanied by intranuclear grooves and invaginations.

When it is not possible to determine whether the cytologic sample shows hyperplasia or early cancer in a lepidic pattern, cross-referencing the image can be helpful. Larger lesion size and the presence of a solid component in the lesion outside of the area that may have been sampled virtually rule out hyperplasia.[49] A lepidic pattern may be recognized more easily on cell block sections, in which bland-appearing cells are seen as strips of cells.[22] The evaluation of the cell block is helpful because cells from MIA or AIS can be misinterpreted as benign.[14]

Triage

Carcinomas

In the case of carcinomas, smears should have enough material to render a diagnosis of SCLC or NSCLC. Any remaining material should be allocated for cell block preparation to be used in subclassification. A limited number of IHC stains can establish histologic subtype, especially in cases of poorly differentiated NSCLC.[12,49] For NSCLC, particularly in advanced stages, if adenocarcinoma is present or cannot entirely be excluded, an effort should be made to preserve as much tissue as possible for molecular analysis.[5]

Lymphoproliferative Disorders

Use of fine-needle aspirates to diagnose lymphoma is controversial.[7] Arguably, it can be difficult to obtain tissue from patients with nodular sclerosing Hodgkin lymphoma.[50] Although it is not possible to assess cell architecture in specimens obtained by fine-needle aspiration, aspirates can confirm recurrence in patients with a history of lymphoma.[50] They can also provide tissue to determine the cause of the underlying lymphadenopathy, obviating the need for an invasive procedure in the absence of a neoplastic process.

If clinical or morphologic evidence leads to suspicion of non-Hodgkin lymphoma, material should be obtained for flow cytometry. The sample should be placed into RPMI culture medium or saline. Some institutions routinely place samples in these media, especially in the absence of ROSE, so that flow cytometry can be performed, if necessary. Flow cytometry cannot be performed on alcohol- or formalin-fixed tissues.

Two or three dedicated passes for flow cytometry are recommended when lymphoma is suspected or ROSE is not available.[50] Adequacy of the sample can be ascertained by examining the saline or RPMI culture medium for clarity or cloudiness. In the absence of a bloody specimen, cloudiness indicates cellularity. Specimens obtained by core-needle biopsy and placed in RPMI culture medium or saline can be assessed the same way. A sample placed in RPMI culture medium can be sent for culture if further review of the slides leads the pathologist to suspect infection.

Infectious Processes and Granulomas

Small histologic specimens and aspirates play an important role in diagnosing nonneoplastic processes, including granulomas and infections. In fact, EBUS biopsy is used frequently for diagnosing sarcoidosis.[49] For patients with a disease of confirmed or suspected infectious etiology or a granuloma, a sample should be sent for microbiologic cultures to exclude the presence of organisms[51,52]. Material also should be reserved to perform special stains in the laboratory. Depending on the amount of material available, the syringe can be capped and sent directly to the lab, or the material can be expelled into sterile saline and then transported. Within each institution, a standardized approach to managing these samples should be developed jointly by pathologists and microbiologists.

CYTOLOGIC PREPARATIONS

Familiarity with the various cytologic preparations is important. Each preparation is unique; taken together they offer complementary information that can be valuable in rendering a diagnosis.

Diff-Quik Stain

The Diff-Quik stain is ideal for ROSE because it can be performed rapidly on smears and uses only three solutions. For diagnostic tissue, it enables assessment of the origin of cells—lymphoid (mostly single cells) or epithelial (mostly cohesive clusters)—and subtyping of the epithelial cells as either squamous or glandular based on cytoplasmic characteristics. Keratinizing squamous cells typically have dense, blue, and homogeneous cytoplasm, whereas the cytoplasm of glandular cells is often vacuolated or foamy. In addition, Diff-Quik stain highlights mucus and metachromatic stroma, which are key features associated with certain neoplasms, such as mucinous or colloid carcinomas and hamartomas, respectively.[53]

Allowing the tissue to dry completely is a crucial step in preparing a Diff-Quik smear. Staining a partially dried slide masks

cellular detail, limits the evaluation of sample adequacy, and possibly leads to misinterpretation.

Papanicolaou Stain

A Papanicolaou stain is typically performed in the laboratory on alcohol-fixed slides. This stain reveals nuclear details—membrane irregularities, chromatin pattern, and intranuclear invaginations—important for establishing a diagnosis of malignancy, especially well-differentiated neoplasms that lack significant pleomorphism. The stain also shows the speckled—or so-called salt and pepper—chromatin pattern associated with neuroendocrine differentiation. Most important, the Papanicolaou stain highlights keratinizing squamous cells, which have orange or pink cytoplasm. This finding is specific for squamous cells and precludes the need for immunostaining to distinguish between cells of squamous and glandular origin.[20]

Unlike a Diff-Quik slide that has to be dried completely before staining, a slide for Papanicolaou staining must be placed in alcohol immediately. Any delay in fixation results in air-drying artifacts (e.g., cellular enlargement and loss of nuclear detail) that create challenges in interpretation and possibly prevent a definitive diagnosis. Air-drying artifacts can also lead to misdiagnosis because the cells may take on an orange hue, mimicking squamous differentiation. Spray fixation is an alternative to placing the slide in a jar of alcohol, although the spray has a tendency to aggregate cells in distinct colonies rather than maintain the even distribution of the smear.

Liquid-Based Preparations

A combination of well-prepared and properly fixed Diff-Quik–stained and Papanicolaou-stained smears are used most commonly to evaluate cytologic specimens. However, smearing requires technical skill that is not always available or optimal. For these reasons—and to limit obstruction from blood, inflammation, and debris—liquid-based preparations are a standardized alternative for slide preparation.

The two most frequently used methods are ThinPrep (Hologic, Inc., Bedford, MA, USA) and SurePath (BD [Becton, Dickinson and Company] Diagnostics, Franklin Lakes, NJ, USA). At the time of collection, the specimen is placed in an alcohol-based solution (e.g., CytoLyt [Hologic] or SurePath vial), which serves as a fixative and transport medium. This fixative can be used for fine-needle aspirates and other exfoliative specimens, including fluids, brushings, and lavages. In the laboratory, an automated processor homogenizes the specimen and prepares a slide with uniform cell distribution and no cell loss, while minimizing background blood, inflammation, mucus, and debris that could obscure the cells of interest. The slides are then stained with Papanicolaou stain. Provided that the sample is sufficient, additional slides with similar content can be prepared for ancillary studies.

Liquid-based preparations have several drawbacks. The equipment and supplies needed to use liquid-based preparations are additional costs. Because these specimens are fixed in alcohol rather than formalin—the preservative typically used for histologic specimens—a laboratory may need to conduct tests to validate the results of ancillary studies, particularly IHC. The automated processing of liquid-based preparations precludes their use for ROSE. Because the slide preparation technique differs from the preparation of conventional smears, there is a learning curve for interpreting liquid-based cytologic specimens. In particular, SCLC and granulomas often pose diagnostic challenges when liquid-based preparation is used. SCLC appears as dyshesive cells with subtle nuclear molding. Granulomas may also have disassociated cells.

Fixation and Considerations for Ancillary Testing

Several fixatives and transport media are available for cytology specimens, including saline, RPMI culture medium, CytoLyt, SurePath medium, and formalin, each of which has benefits and drawbacks. For instance, flow cytometry analysis only can be conducted on a specimen placed in saline or RPMI culture medium. Formalin is the standard fixative for histologic specimens, and it is the medium on which most laboratory tests are validated.

In their joint guidelines, the College of American Pathologists, International Association for the Study of Lung Cancer, and the Association for Molecular Pathology (CAP/IASLC/AMP) recommend using formalin-fixed (10% neutral buffered), alcohol-fixed (70% ethanol), fresh, or frozen specimens after validation for *EGFR* mutation testing.[35] The advantage of using formalin- or alcohol-fixed tissues embedded in paraffin is that the tumor content and proportion can be assessed. Alcohol fixation may be problematic for fluorescence in situ hybridization testing.[35] Cytologic specimens initially placed in other solutions (i.e., saline or RPMI culture medium) can subsequently be placed in formalin or alcohol. Fixation for 6 to 12 hours is recommended for small specimens.[35]

Other media, such as heavy metal fixatives (e.g., B5, acid zinc formalin, Zenker, B plus) and acidic solutions (e.g., decalcifying solution, Bouin solution), interfere with testing and should be avoided.[35] When sampling bone, performing a fine-needle aspiration instead of a core-needle biopsy is advantageous: fine-needle aspiration extracts the neoplastic cells without collecting bone, which typically would require decalcification that interferes with molecular testing.

Cell Blocks

Cell blocks serve as adjuncts to smears and liquid-based preparations. A cell block is a cohesive pellet formed from dyshesive cells or small tissue fragments that are present in a cytologic specimen. These particles are centrifuged and congealed together into a pellet with agents such as agar, plasma-thrombin, or gelatin.[7] This process requires technical expertise and can be challenging. Following coalescence, the cell blocks are embedded in paraffin and processed like a specimen obtained by biopsy.

Although they do not provide the cytomorphologic details of Papanicolaou-stained slides,[46] cell blocks complement smears and liquid-based preparations. For instance, they show architectural detail of the tissue fragments similar to what is seen in histologic specimens. Most important, they provide material for IHC stains and molecular testing. Cell blocks have been recommended instead of smears for use in ancillary tests by the CAP/IASLC/AMP guidelines. Recent studies have shown that smears provide an alternative source of cells for molecular testing; this is especially useful to minimize repeat procedures.[58,59]

Yet despite the usefulness of cell blocks, there is no standardized procedure for processing them. In a survey, 95 respondents named more than 10 different methods for preparing cell blocks.[8] Forty-four percent of respondents were either unsatisfied or sometimes satisfied with the quality of their cell blocks. Low cellular yield was the leading cause of dissatisfaction. Scant cellularity leads to inconclusive or nondiagnostic results, and a repeat sampling procedure may be necessary.[54] Although no protocols specify the optimal cell block processing technique, some preparations result in greater yield than others.[55,56]

When tissue is abundant, the technique used to prepare the cell block may not play a substantial role in optimizing the sample. However, when tissue is scant, it is crucial to minimize cellular loss during cell block preparation, retaining as much cellular content as possible for ancillary studies. As use of minimally invasive procedures expands in the future and testing for multiple biomarkers in small specimens becomes the standard of care, optimizing cell block preparation will become increasingly relevant.[7,57]

Cell blocks also should be prepared for nonaspirate cytology specimens from patients with suspected lung adenocarcinoma, including pleural effusions, bronchoalveolar lavages, and bronchial brushings.[19]

CONCLUSION

There is no doubt that our methods for the management of small biopsy samples in patients with lung cancer will improve in the future in order to maximize the use of material for diagnosis. In the meantime, all pulmonologists, thoracic surgeons, pathologists, and medical oncologists should be familiar with the limitations of processing at this time and should be able to triage for maximum benefit to their patients. Consensus reports, as described in this chapter, as well as the information provided, will at least establish a standardized method that international community-based as well as academic institutions can follow.

20 Clinical Presentation and Prognostic Factors in Lung Cancer

Kristiaan Nackaerts, Keunchil Park, Jong-Mu Sun, and Kwun Fong

SUMMARY OF KEY POINTS

- Most people with lung cancer are symptomatic at the time of initial presentation; however, between 5% and 15% of people may be asymptomatic.
- Alarming symptoms for lung cancer like cough, hemoptysis, dyspnea, chest pain and weight loss should be timely recognized.
- No specific clinical manifestations exist to guide and help the physician distinguish between specific histologic subtypes.
- Increased awareness of cough, one of the most common lung cancer symptoms, may help in the earlier detection of lung cancer.
- Hemoptysis is the only symptom that typically causes people to be prompt in reporting to their primary care physician.
- Lung cancer is one of the most common etiologies for a malignant pleural effusion.
- Lung cancer is the cause of superior vena cava syndrome in about 50% of cases.
- Lung cancer is the most common cause of brain metastases.
- Paraneoplastic syndromes are not uncommon in lung cancer and may be the first clinical manifestation of the disease.
- Certain clinical as well as molecular factors may have a potential prognostic and/or predictive role for guiding lung cancer patients' personalized care.

Most people with lung cancer are symptomatic at the time of initial presentation; however, between 5% and 15% of people will be asymptomatic at the time of diagnosis.[1,2] Patients who do have symptoms at the time of diagnosis often have advanced disease and therefore have a poorer prognosis, with an overall 5-year survival rate of 15% or less.[3] In order to improve lung cancer survival, early detection with a screening method should be considered for asymptomatic people at highest risk.[4] Indeed, screening of asymptomatic high-risk individuals (defined as current or former smokers who are aged 55 to 74 years old, with a smoking history of a minimum of 30 pack-years) with use of low-dose computed tomography (CT) has been shown to be efficient not only for diagnosing lung cancer at an early stage but also for substantially reducing lung cancer–specific mortality.[6]

In contrast, people in whom lung cancer is detected during screening trials will usually be asymptomatic because these tumors are usually very small and peripherally located. Outside of screening programs, lung cancer in most asymptomatic people will be diagnosed coincidentally (e.g., on a chest x-ray for other indications or for a preoperative examination). It is of utmost importance for every clinician to be aware of all possible lung cancer symptoms at the time of initial presentation, and not just the so-called alarming symptoms. These alarming symptoms—cough, hemoptysis, dyspnea, chest pain, and weight loss—are mostly a result of local intrathoracic tumor growth, but may be further triggered by local–regional intrathoracic invasive growth and also by the development of extrathoracic metastases (Table 20.1). Timely recognition of alarming symptoms can be difficult because they often develop in older patients (aged 60 years or older) who are current or former smokers and who may also have comorbidities such as chronic obstructive pulmonary disease (COPD) or cardiac disease (e.g., heart failure, angina pectoris).[5] In certain cases of lung cancer, symptoms at presentation may be linked to specific paraneoplastic manifestations that, if unrecognized, may cause diagnostic dilemmas and further delay the diagnosis of lung cancer. The more common symptoms that occur at initial presentation of a person with lung cancer will be further described later in the chapter. Unfortunately, there are no specific clinical manifestations to guide and help the physician distinguish between specific histologic subtypes of lung cancer.[7] Physicians should also consider that as a result of a lung cancer diagnosis, other symptoms may arise that are not addressed in this chapter, including those caused by iatrogenic complications of surgery, systemic treatment or radiotherapy, or other symptoms that may only occur specifically during the end-of-life care of patients with lung cancer. Also addressed are a variety of clinical and molecular factors with potential use for early diagnosis and management of lung cancer, as well as for prognostication.

SYMPTOMS AND SIGNS OF LOCAL TUMOR GROWTH

Cough

One of the most common symptoms related to lung cancer is cough, which is reported in up to 60% to 70% of people at the time of diagnosis.[1,5,8] Increased awareness of cough may help in the earlier detection of lung cancer, resulting in better outcomes, as was demonstrated in a recent United Kingdom Cough Awareness Campaign.[9] Cough is most often caused by larger, centrally located bronchial mucosa invading lung tumors, but may also be present in smaller, peripheral lung tumors. A copious production of thin, colorless sputum (bronchorrhea) may be found in some patients with lung adenocarcinoma with a predominant lepidic growth pattern, but this is rare. Smaller but predominantly endobronchially located lung tumors may also cause cough. This cough may be either dry or nonproductive, but may be productive if respiratory infections occur as a consequence of the obstruction. Because cough is also a predominant symptom in other lung diseases such as COPD, it is sometimes difficult to recognize cough as a presenting symptom of lung cancer. When recording the medical history of the patient, special attention should be given to the changing cough pattern that may occur

TABLE 20.1 Clinical Presenting Symptoms and Signs in Lung Cancer

Asymptomatic
Symptoms caused by local tumor growth
  Cough
  Hemoptysis
  Chest pain
  Dyspnea/stridor
Symptoms caused by local–regional (intrathoracic) invasive growth
  Pleural effusion
  Pericardial effusion
  Hoarseness
  Superior vena cava syndrome
  Dysphagia
  Shoulder pain (Pancoast syndrome)
  Diaphragmatic paralysis
Symptoms due to extrathoracic or metastatic spread
  Metastatic sites in bone, brain, spinal cord, liver, adrenal gland, and
   others
Paraneoplastic symptoms
  Musculoskeletal
  Hematologic
  Vascular
  Endocrinologic
  Neurologic
  Cutaneous
  Miscellaneous

in patients with COPD or active smokers in whom lung cancer develops. The failure of an acute COPD exacerbation to resolve with adequate therapy should raise suspicion of an underlying respiratory malignancy.[10]

Hemoptysis

Hemoptysis is not only a common symptom in up to one-third of people at the time of lung cancer diagnosis, but is also the only symptom that typically causes people to be prompt in reporting to their primary care physician.[1,8,11,12] Approximately 20% of all cases of hemoptysis are associated with lung cancer; therefore, the occurrence of hemoptysis in a patient presenting to a primary care physician should always lead to further investigation, starting with chest x-rays.[7,11] Hemoptysis usually results from tumor necrosis, growth of new blood vessels in and around the tumor (neovascularization), and bronchial mucosa ulceration with erosion and invasion of bronchopulmonary vessels. It may also be caused by an obstructive pneumonia or by paraneoplastic pulmonary embolism. At presentation, hemoptysis may vary from mild (blood-streaked sputum) to moderate and severe blood loss. Fortunately, severe or massive hemoptysis (more than 200 mL of blood expectorated at once or over the course of 24 hours or 5–10 mL/h of blood expectorated over 24 hours) occurs rarely at initial presentation, but it may become an increasingly life-threatening problem during the palliative treatment phase of an advanced lung cancer. Treatment of massive hemoptysis at the time of diagnosis of lung cancer of an unknown stage or of a potentially curable, newly diagnosed lung cancer will require prompt securing of the airways by endotracheal intubation and maintaining of optimal oxygenation before more definitive alleviation of the hemoptysis by either endobronchial therapy or by urgent surgical intervention can be offered.[13] Moderate hemoptysis caused by tumors that cannot be reached by bronchoscope can be treated with bronchial artery embolization. For all other cases of endobronchial tumors causing hemoptysis, several endobronchial therapeutic modalities exist, ranging from photocoagulation with neodymium:yttrium aluminum garnet (Nd:YAG) laser to electrocautery to argon plasma coagulation. For distal or parenchymal-situated unresectable lung tumors, external-beam radiotherapy may be recommended.[14] Endobronchial brachytherapy has been used for the palliative treatment of hemoptysis

caused by endobronchially visible tumors, and the combination of high-dose-rate brachytherapy with external-beam radiotherapy demonstrated better symptom control than with external-beam radiotherapy alone.[15] In a recent Cochrane meta-analysis, external-beam radiotherapy alone was found to be more efficient for palliation compared with endobronchial brachytherapy alone, although there was insufficient evidence to support the superiority of the two modalities combined for palliative symptom relief compared with external-beam radiotherapy alone.[16]

Chest Pain

People with early-stage lung cancer may note vague, persistent chest pain or chest discomfort, even though no invasion of the chest wall, mediastinum, or pleura can be found.[7] The true origin of this pain sensation is not completely understood, as no pain fibers are present in the lung parenchyma. Peribronchial autonomic nerves are able to transmit sensations of discomfort via the vagus nerve, which may also cause rare craniofacial pain sensations in nonmetastatic lung cancers.[17] When further tumor growth occurs with local-regional invasion, such as in the pleura, mediastinum, or chest wall, more severe local pain symptoms may occur, requiring adequate analgesic treatment in combination with tumor-directed therapy.

Dyspnea, Stridor, Wheezing

Dyspnea is a common presenting symptom of lung cancer, occurring in up to 60% of people.[5] The causes of dyspnea are often multifactorial, related to the increasing tumor volume, endobronchial tumor obstruction causing parenchymal atelectasis, lymphangitic tumor spread in a lobe or the entire lung, or pulmonary artery embolism. When lung cancer starts its local–regional invasion into the trachea, pericardium, and pleura, dyspnea may become more severe. Besides the tumor-related causes of dyspnea, there may be other potential aggravating causes, particularly in people with lung cancer who have COPD or cardiac conditions. When a tumor occludes the lower trachea or a major central airway, an acute feeling of breathlessness can occur along with the typical sound of stridor (in cases of severe occlusion of the airway or trachea) or unilateral monophonic wheeze (in cases of left- or right-sided main airway subocclusion).[8,10] Standard treatment of the underlying cancer in people with early-stage or locally or regionally advanced disease will treat the dyspnea as well. For people with more advanced and symptomatic lung cancer, early palliative treatment of dyspnea (home oxygen therapy for hypoxemia, opioids, or inhaled furosemide) should be considered.[18]

SYMPTOMS AND SIGNS OF INVASIVE LOCAL–REGIONAL OR INTRATHORACIC SPREAD

Hoarseness

The left vocal cord is stimulated by the left recurrent laryngeal nerve, which passes deep into the left thoracic cavity and under the aortic arch before again climbing up to the left vocal cord. Enlarged lymph nodes in the aortic pulmonary window or a large, invasive tumor to the left of the aortic branch may cause left recurrent nerve entrapment, resulting in nerve palsy and vocal cord paralysis. This vocal cord paralysis—occurring in fewer than 10% of people with lung cancer—results in hoarseness and sometimes also cough and aspiration.[5] On a combination ^{18}F-2-deoxy-D-glucose (FDG)-positron emission tomography (PET)-CT, the internal laryngeal muscles on the opposite side of the entrapped recurrent laryngeal nerve (usually the left one) may present with false-positive increased FDG uptake because of the compensatory laryngeal muscle activation caused by the contralateral paralyzed vocal cord.[19] Entrapment of the right
Fig. 20.1. Chest radiography (A) and chest computed tomography image (B) of a nonsmall cell lung cancer, showing a left-sided pleural effusion as well as a pericardial effusion *(white arrows)* in the same patient, caused by a lung adenocarcinoma of the left upper lobe.

recurrent laryngeal nerve by lung tumor tissue occurs much less frequently because this nerve does not extensively run through the right side of the chest.

Pleural Effusion

Lung cancer is one of the most common etiologies for a malignant pleural effusion.[20] Malignant pleural fluid accumulation will eventually develop in 7% to 23% of people with lung cancer, but not all of them will be symptomatic at the time of diagnosis.[21] Patients with a pleural fluid accumulation will generally report dyspnea, cough, chest pain, fatigue, and weight loss. The accumulation of malignant pleural fluid may be by direct invasion of the tumor into the pleura or by metastasis into the pleura (Fig. 20.1). Pleural fluid accumulation may also have other causes in people with lung cancer, and these causes should be excluded: chylothorax by lymphatic obstruction or nonmalignant causes such as heart failure, pleuropulmonary infection, pulmonary infarction, and cirrhosis.[22] Diagnostic thoracocentesis is therefore necessary to document the presence of malignant cells. In 40% to 50% of cases, the results of cytology examination will be false-negative and diagnostic medical thoracoscopy should be done to obtain a new sampling of pleural fluid combined with pleural biopsy to be examined.[23,24] When the pleural effusion is confirmed as malignant, the lung cancer should be classified as stage IV (M1a), which is associated with a poor prognosis.[25] Besides systemic therapy (chemotherapy, targeted therapy), treatment of malignant pleural effusion consists of fluid drainage and pleurodesis. Optimal treatment depends on an individual patient's symptoms, performance status, and prognosis.[26–28] For patients with a very poor prognosis (less than 3 months), repeated thoracenteses may be performed to alleviate dyspnea and pain. However, for most patients with lung cancer, a more definitive therapy for the malignant pleural effusion should be planned, either by talc slurry instillation via chest tube, thoracoscopy, or by insertion of an indwelling pleural catheter. The latter procedure is necessary in the event of lung entrapment by widespread pleural involvement.

Pericardial Effusion

Pericardial effusion occurs in 5% to 10% of people with lung cancer (Fig. 20.1). Pericardial invasion by malignant cells occurs either by direct tumor invasion or by hematogenous or lymphatic spread of cancer cells.[5] Patients who have pericardial effusion at presentation will either be asymptomatic (with only radiographic documentation of the presence of pericardial fluid) or they will report symptoms such as increasing dyspnea (up to grade 3/4), orthopnea, anxiety, palpitations, and retrosternal pain. On physical examination, specific signs of right-sided heart failure, arrhythmias (atrial fibrillation), and pericardial tamponade (pulsus paradoxus) may be found. Cardiac tamponade should be regarded as a life-threatening condition requiring immediate intervention.[13,29] A suspected diagnosis of severe pericardial effusion should prompt investigation by echocardiography to document this effusion. When a right-sided ventricular collapse is found, urgent pericardiocentesis should be performed to provide relief. Following initial puncture, a pericardial catheter may be inserted for further fluid drainage. Recurrence of fluid accumulation after pericardial drainage has been performed may occur in one-third of patients.[30] After recurrence, a new pericardial puncture may be performed together with the instillation of a sclerosing agent (e.g., cisplatin, mitoxantrone).[29,31] Another treatment approach for patients with a better prognosis and a refractory pericardial effusion may be video-assisted surgical thoracoscopy with a pericardiotomy (pericardial window).[29]

Superior Vena Cava Syndrome

Obstruction or compression of the venous return from the head via the superior vena cava is a common complication of lung cancer. However, superior vena cava syndrome (SVCS) is rarely present (fewer than 5% of cases) at the time of initial lung cancer diagnosis. Lung cancer is the cause of SVCS in about 50% of cases, but other intrathoracic malignancies such as lymphoma, primary mediastinal tumors, and metastatic tumor in the mediastinum should be excluded as the cause.[32–34] SVCS results from a growing right upper lobe lung tumor that extends centrally to the superior vena cava or by growing, malignant right paratracheal lymph nodes. An intraluminal thrombus may also form.[7] Nonsmall cell lung cancer (NSCLC) causes SVCS more frequently than small cell lung cancer (SCLC).[32–34] The clinical presentation of SVCS typically involves swelling of the head and neck, edema of the eyelids, distention of the veins in the neck and on the chest wall, cough, breast swelling, dizziness, headache, blurred vision, dyspnea, dysphagia, and chest pain. When tumor growth is aggressive, symptoms may appear more rapidly because of lack of time for collateral circulation to develop proximal to the venous obstruction, particularly when the obstruction is situated above the level of the junction with the azygos vein.[5,7,8,10] Diagnosis of SVCS can be easily documented by chest CT
Fig. 20.2. (A) Subocclusion of the superior vena cava by a centrally located invasive lung cancer, resulting in clinical superior vena cava syndrome. (B–C) Reconstituted superior vena cava after percutaneous balloon dilatation and placement of endovascular stent. *(Figure courtesy of Hearns Charles MD, NYU Interventional Radiology Department).*

(Fig. 20.2), but a histologic diagnosis of the underlying cancer is mandatory before treatment can be initiated. Treatment of SVCS consists of alleviating symptoms as well as treating the underlying lung cancer.[35] In the case of a local–regionally advanced lung cancer, chemoradiation therapy can be initiated. For an advanced lung cancer (especially for a SCLC), chemotherapy may begin immediately.[34,35] When the patient is highly symptomatic, more rapid symptom relief can be achieved by placement of an endovascular stent than by chemoradiation therapy. Patients who present with stridor as a result of central airway obstruction or severe laryngeal edema, as well as patients who are in a coma caused by cerebral edema, should be immediately treated with endovascular stenting.[35] This procedure can be performed with use of different types of stents (e.g., stainless steel stents such as Gianturco, Wallstent, or Palmaz); however, nitinol stents currently appear to be more suitable for the safe and efficient endovascular management of SVCS.[36–38] Success rates associated with first stenting have ranged from 80% to 95%. Although the average risk of SVCS recurrence after stenting is 10% to 14%, recurrence can almost always be resolved by a new stenting procedure.

Pancoast Syndrome

A lung cancer that grows in the apex of the upper lobe toward the superior sulcus, ribs, and vertebrae will cause pain in the shoulder, scapula, and chest wall. Invasion of the brachial plexus (specifically the lower nerve roots of the ulnar nerve) will result in radiating pain and muscle wasting in the arm and hand. Horner syndrome, by invasion of the sympathetic chain and stellate ganglion, results in ptosis, miosis, and hemifacial anhidrosis, and may be part of the so-called Pancoast syndrome.[39] Typically, patients with Pancoast syndrome will have consulted other specialists before a final diagnosis of lung cancer is made, sometimes with a delay as long as 1 year from the time pain first occurred. Most people with lung cancer who present with Pancoast syndrome have NSCLC. Pancoast syndrome as an initial clinical presentation of lung cancer occurs in about 4% of cases.[7]

Dysphagia

Dysphagia may occur when the esophagus becomes obstructed by enlarged mediastinal lymph nodes or by a lung tumor invading the esophagus. Recurrent laryngeal nerve palsy may also cause dysphagia because of dysfunction of the laryngeal swallowing mechanism. Patients will typically note increasing difficulty swallowing and may subsequently become incapable of swallowing.[40] Therapy consists of treatment of the underlying local–regionally invasive lung cancer and temporary parenteral feeding, if necessary. Occasionally, palliative esophageal stenting is needed.

Diaphragmatic Paralysis

When the phrenic nerve gets trapped by a growing primary tumor or by bulky lymph nodes (typically originating from the aortic–pulmonary window lymph nodes), the diaphragm may become paralyzed, resulting in an increase in dyspnea.[7] Lung cancer invading the phrenic nerve is therefore an indication of locally advanced disease and should be staged as a cT3 tumor according to the International Association for the Study of Lung Cancer (IASLC) tumor, node, metastasis (TNM) classification eighth edition.[25]

SYMPTOMS AND SIGNS OF METASTATIC SPREAD

Bone Metastases

Bone metastases develop in approximately 30% to 40% of people with advanced NSCLC, with metastases either present at the time of diagnosis or developing during the course of the neoplastic disease.[41] Compared with bone scans, PET has similar sensitivity (at least 90%), but a higher specificity (at least 98%) and accuracy (at least 96%), and is therefore considered superior for detecting bone metastases.[42–44] Therefore, if no abnormality in bones is found on a PET scan of a patient who has no signs or symptoms suggestive of bone metastases, a bone scan is not needed.[45] Lung cancer metastases to bone are predominantly lytic.

Bone metastases cause significant pain and morbidity and are characterized by various skeletal-related events, including pathologic fractures, spinal cord compression, the need for radiation or surgery of the bone, and hypercalcemia of malignancy. Periosteal inflammation and elevation is the mechanism that most frequently causes pain from bone metastases. Pain that cannot be controlled with nonsteroidal anti-inflammatory drugs should be managed with narcotic analgesics. Most patients with symptomatic bone metastases achieve some pain relief with a low-dose, brief course of radiation therapy, as demonstrated in a trial from the Radiation Therapy Oncology Group (RTOG 97-14), which included patients with breast cancer or prostate cancer. In this trial, the efficacy of 8 Gy in a single fraction was comparable to that of the standard treatment course of 30 Gy delivered in 10 treatment fractions over 2 weeks in terms of response rates and the incidence of subsequent pathologic fractures. However, the retreatment rate was significantly higher in the 8-Gy arm (18% vs. 9%; $p <$ 0.001).[46] Stereotactic ablative radiotherapy (SABR) has emerged as a new treatment for bone metastases, and several randomized trials have shown promising results.[47–49] In particular, the focal nature of SABR provides an otherwise unavailable noninvasive treatment option for previously radiated spinal metastases. For select patients with weight-bearing bone metastases at special risk of pathologic fracture, surgical operation may be considered. Vertebral augmentation procedures (kyphoplasty and vertebroplasty) are also important modalities when treating symptomatic vertebral compression fractures. In addition to the immediate pain relief, these procedures have several advantages, including applicability in previously radiated sites, the possibility of outpatient care, and obtaining of tissue biopsy specimens.[13] Bisphosphonates (pamidronate and zoledronic acid) play an important role by preventing bone resorption at sites of bone remodeling. In one study, zoledronic acid was associated with a significantly lower incidence of skeletal-related events among patients with NSCLC with bone metastasis.[50] Denosumab, another drug in a novel class of bone-targeting agents, is designed to inhibit receptor activator of nuclear factor kappa-B ligand. Compared with zoledronic acid, denosumab prolonged overall survival of patients with NSCLC with bone metastases.[51]

Brain Metastases

Lung cancer is the most common cause of brain metastases.[52] Metastases to the brain are usually symptomatic, and more than two-thirds of patients with brain metastases have some neurologic symptoms during the course of their illness.[53] The clinical manifestations of brain metastases are variable depending on the location of the lesion and the degree of associated edema. Headache is a common presenting symptom and occurs more often with multiple metastases. Focal or generalized seizures have occurred in approximately 10% of patients by the time of presentation.[53] Other symptoms of brain metastases include nausea and vomiting, focal weakness, confusion, ataxia, or visual disturbance. The signs and symptoms of brain metastases are often subtle; therefore, brain metastases should be suspected in all patients with lung cancer in whom neurologic symptoms develop. Magnetic resonance imaging (MRI) is currently the criterion standard for the diagnosis of brain metastases.

Corticosteroids can rapidly decrease the symptoms associated with brain metastases by decreasing peritumoral edema.[54] Patients with seizures should be treated with antiepileptic medication. Subsequent treatment should be used according to size, number, and location of lesions as well as the extracranial disease status and performance status of the patient. Treatment modalities for brain metastases include whole-brain radiotherapy, stereotactic radiosurgery, and surgical resection. Stereotactic radiosurgery should be considered before whole-brain radiotherapy for patients with one to three brain metastases.[55]

Leptomeningeal carcinomatosis is not rare in NSCLC[56–58] and continues to be a devastating end-stage complication of the disease. Further improvements in systemic treatment may lead to prolonged survival for more patients with stage IV disease; therefore, when all existing therapies have failed in these patients, leptomeningeal carcinomatosis may be more likely to develop. The most common ways for malignant cells to gain access to the subarachnoid space are by direct extension from preexisting tumors or by hematogenous dissemination. A high index of suspicion is required to make an early diagnosis of leptomeningeal carcinomatosis as there is a variety of neurologic manifestations. Headache, changes in mental status, cranial nerve palsies, back or radicular pain, incontinence, lower motor neuron weakness, and sensory abnormalities are typical symptoms.[59] The most informative diagnostic tool in the evaluation of leptomeningeal carcinomatosis is lumbar puncture. The opening pressure should be measured and cerebrospinal fluid sent for cytologic examination, cell count, and measurement of protein and glucose.[60] Positive findings on cerebrospinal fluid cytology examination are found on initial lumbar puncture in 50% of patients with leptomeningeal carcinomatosis and in approximately 85% of patients who have three high-volume lumbar punctures.[61,62] Therefore, patients with clinical symptoms and signs suggestive of leptomeningeal carcinomatosis should have repeated lumbar puncture if the first cytology evaluation yields negative results.

Leptomeningeal carcinomatosis is a particularly difficult challenge in the treatment of cancer. Intrathecal chemotherapy has been the mainstay of treatment, even though the extent of its benefit has not been proven in randomized clinical trials.[63] A ventriculoperitoneal shunt is also an effective palliative tool to decrease intracranial pressure.[58] Given the dismal treatment outcome and prognosis of patients with leptomeningeal carcinomatosis, new therapeutic agents or strategies are urgently needed.[64]

Spinal Cord Metastases or Spinal Compression

Spinal cord metastases or compression can be classified anatomically as intramedullary, leptomeningeal, and extradural. Extradural compression includes several mechanisms, such as continued growth of bone metastases into epidural space, blockage of neural foramina by a paraspinal mass, and destruction of vertebral bone. At the time of presentation, 90% of patients have local or radicular pain, and up to 50% of patients may have paralysis, sensory loss, and sphincter dysfunction.[65,66] If the clinical suspicion of spinal cord compression is high, immediate high-dose dexamethasone should be administered before compression is confirmed radiographically.[67] Radiotherapy is the mainstay of treatment for spinal cord metastases and should be started immediately after MRI confirmation of spinal cord compression. For patients with lung cancer who have symptomatic epidural spinal cord compression and good performance status, a neurosurgical consultation is recommended and, if appropriate, surgery should be performed immediately, followed by radiotherapy.[13]

Liver and Adrenal Gland Metastases

Liver involvement occurs frequently with lung cancer. Patients may have upper quadrant or epigastric discomfort as a result of large metastases. Most liver metastases are asymptomatic, and some patients experience vague symptoms such as fatigue, weight loss, and nausea. Liver dysfunction occurs only in the presence of extensive metastases.

The type of cancer most often associated with adrenal metastases is lung cancer, followed by gastric cancer.[68] Adrenal metastases are usually detected on CT scans, and bilateral metastases

appear in approximately half of patients with lung cancer.[68,69] In most cases, these lesions are asymptomatic, although large metastatic masses may cause pain. Adrenal insufficiency is rare even in bilateral metastases because functional adrenal cortical loss occurs only when more than 90% of the adrenal gland has been destroyed.[68] However, adrenal insufficiency should be suspected in patients who present with appropriate clinical symptoms and bilateral adrenal metastases. Anecdotal reports have suggested that long-term survival can occur after resection of isolated adrenal metastasis from NSCLC,[70,71] but this has not been confirmed by randomized clinical trials and the chance of selection bias should be considered.

Other Metastatic Sites

Lung cancer metastases may occur at other sites, such as skin, soft tissue, pancreas, intraabdominal lymph nodes, bowel, ovaries, and thyroid. Management of these metastatic sites is primarily based on the patient's symptoms.

PARANEOPLASTIC SYNDROMES

Paraneoplastic symptoms are not uncommon in lung and other cancers, and can sometimes be the first clinical manifestation of the disease. Paraneoplastic symptoms are generally referred to as effects from the cancer that are not directly caused by invasion into vital organs, obstruction, or space-occupying effects from the primary cancer or remote metastasis.[72] Lung cancers have long been associated with paraneoplastic effects, which encompass a large spectrum of anatomic phenomena. They include a variety of endocrine, neurologic, dermatologic, and other body function disturbances that are indirect results of the cancer and not a result of the direct presence of cancer cells. Paraneoplastic phenomena are not specific to lung cancer, although the frequency of involvement is variable among tumor types. For instance, hypertrophic pulmonary osteoarthropathy and clubbing occur more often with lung and thoracic cancers than with other primary cancers. In addition, certain lung cancer subtypes may be more related to paraneoplastic phenomena than others, in particular SCLC, carcinoid tumors, and other neuroendocrine cancers. Paraneoplastic syndromes may be classified in several ways (Table 20.2) and in

TABLE 20.2 Classification of Different Paraneoplastic Syndromes of Lung Cancer

Classification	Paraneoplastic Phenomena
Dermatologic or musculoskeletal	Hypertrophic pulmonary osteoarthropathy Digital clubbing Dermatomyositis/polymyositis
Endocrine or metabolic	Syndrome of inappropriate antidiuretic hormone secretion (SIADH) Hypercalcemia Cushing syndrome Carcinoid syndrome
Neurologic	Lambert-Eaton myasthenic syndrome Cerebellar ataxia Sensory neuropathy Limbic encephalitis Encephalomyelitis Autonomic neuropathy Retinopathy Opsomyoclonus
Hematologic	Anemia Leukocytosis Thrombocytosis Eosinophilia
Constitutional	Anorexia Weight loss Asthenia

some cases reflect common or similar pathogenic mechanisms as well as organ of involvement.

Dermatologic or Musculoskeletal Disorders

Hypertrophic Pulmonary Osteoarthropathy and Digital Clubbing

Digital clubbing, which manifests early with the loss of angle between nail and nail fold, has long been acknowledged as a possible sign of lung cancer. In a review published in 2009, authors reported that digital clubbing was found in up to 10% of patients with lung cancer and in patients with tumors metastatic to the lung.[73] Digital clubbing is associated with hypertrophic pulmonary osteoarthropathy, a condition characterized by periosteal and subperiosteal new bone formation along the shaft of long bones and the phalanges.[72] Clinically, patients often report symmetrical, painful arthropathy of the wrists, ankles, knees, and elbows. Simple radiographic examination of the long bones may show typical periosteal new bone formation, and a bone scan usually confirms bilateral diffuse uptake by the long bones. Symptoms of hypertrophic pulmonary osteoarthropathy may respond completely to surgical resection; however, for patients who are not surgical candidates, symptomatic treatment includes specific systemic treatment of the cancer in addition to bisphosphonates; analgesics, including opiates and nonsteroidal antiinflammatory agents; and, occasionally, palliative radiation therapy.[73]

Rare Skin Disorders

Tripe palm is a rare paraneoplastic syndrome associated with lung cancer, presenting with symptoms of thickened velvety palms and pronounced dermatoglyphics.[74] It can occasionally occur with acanthosis nigricans, another paraneoplastic skin condition that manifests as gray-brown hyperpigmented skin plaques. Another rare paraneoplastic syndrome linked to lung cancer is erythema gyratum repens, which is usually associated with substantial disease burden and is a cutaneous eruption with a unique wood-grain pattern morphology.[75]

Dermatomyositis

Dermatomyositis is an inflammatory myopathy associated with skin changes.[72] A typical sign of dermatomyositis is a heliotrope rash (blue-purple discoloration named after the heliotrope plant) of the upper eyelids and an erythematous rash on the face, neck, and anterior chest (V sign) or back and shoulders (shawl sign), knees, elbows, and malleoli.[76] The rash can be pruritic and may worsen after sun exposure. Another characteristic is Gottron papules, a raised violaceous rash or papules at the knuckles, prominent in metacarpophalangeal and interphalangeal joints. This chronic rash can become scaly with a shiny appearance. Dilated fingernail base capillary loops with irregular, thickened, and distorted cuticles can also be seen, and the fingers may appear like so-called mechanic hands, with cracked, horizontal lines that look dirty. Associated proximal muscle weakness can range from mild to severe and may develop before or at the time of the skin changes.

Polymyositis

Polymyositis is another paraneoplastic syndrome associated with lung cancer and presents clinically as a subacute myopathy that evolves over weeks to months, along with weakness of the proximal muscles.[77] Dermatomyositis and polymyositis can develop in different subtypes of lung cancer.[77] It is important to note that these specific paraneoplastic phenomena may be the initial symptoms of lung cancer or may develop during the course of disease progression. Anticancer therapy may help to reduce the

symptoms of polymyositis and dermatomyositis; otherwise, corticosteroids are the standard treatment, with immunomodulators offered as an additional therapeutic option.[73]

Endocrine and Metabolic Phenomena

Most endocrine paraneoplastic syndromes result from tumor secretion of peptides or hormones that result in metabolic or homeostatic derangements. Well-known endocrine syndromes associated with lung cancer include syndrome of inappropriate antidiuretic hormone secretion (SIADH), Cushing syndrome, and carcinoid syndrome, as well as metabolic sequelae such as hypercalcemia. Other hormones known to be secreted by lung cancers include interleukin-1α, tumor necrosis factor, human chorionic gonadotropin, transforming growth factor-β, atrial natriuretic peptide, and others.[78] The paraneoplastic endocrine phenomena are typically discovered during initial evaluation of the patient or after diagnosis of lung cancer. These endocrine syndromes may not always correlate with stage or prognosis of the cancer. Anticancer treatments may improve the clinical condition.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Hyponatremia is a condition associated with many lung diseases, including lung cancer.[78] A study from the 1950s recognized SIADH as a cause of hyponatremia.[79] SIADH is more common in SCLC, affecting 10% to 45% of patients, compared with approximately 1% of patients with other types of cancer.[79] SIADH can cause anorexia, cognition change, confusion, lethargy, and seizures, because antidiuretic hormone secretion leads to persistent renal tubule overexpression of aquaporins and subsequent water resorption.[79] The duration of development and severity of the hyponatremia will influence the clinical symptoms. Life-threatening complications can occur when sodium levels fall to 120 mmol/L or lower, at which point organ failure can occur. The hallmarks of SIADH are euvolemic hyponatremia, plasma hypoosmolality, abnormally high urinary osmolality, and abnormally high urinary sodium concentration in the absence of confounders, such as volume depletion, adrenal insufficiency or hypothyroidism, and medication effects.

The diagnosis of SIADH requires exclusion of other causes, specifically volume depletion, which can confound the diagnostic algorithm and interpretation of laboratory results. The mainstay of SIADH treatment is therapy for the lung cancer, and hyponatremia may resolve within weeks from initiation of chemotherapy for SCLC. In the interval of time before response, the hyponatremia can be managed with fluid restriction, with or without demeclocycline or a vasopressin receptor antagonist (e.g., conivaptan or tolvaptan).[79] Acute severe hyponatremia may be carefully treated with hypertonic saline infusion, but the correction should be gradual so as to avoid overcorrection, thereby minimizing the risk of osmotic demyelination (central pontine demyelination).

Cushing Syndrome

Cushing syndrome has long been recognized as a paraneoplastic phenomenon in cancer, including lung cancer. Between 5% and 10% of Cushing syndrome cases are thought to be paraneoplastic in etiology, and most of these are a result of ectopic adrenocorticotropic hormone (ACTH) secretion rather than corticotropin-releasing hormone. Many cases of Cushing syndrome are related to lung cancer, especially those of neuroendocrine lineage such as SCLCs and carcinoid tumors, which are the lung cancer subtypes most likely to produce ectopic ACTH.[72,80] The symptoms of ectopic ACTH secretion in lung cancer can vary, and patients may not have all the typical features of Cushing syndrome, given the natural history of lung cancers, especially considering the aggressiveness of SCLC. In SCLC-related Cushing syndrome, there

may be aberrant processing of proopiomelanocortin, a precursor of pro-ACTH and ACTH.[81] The precursor levels are elevated more than the ACTH level and correlate with cortisol levels. Conversely, it is thought that bronchial carcinoid tumors process proopiomelanocortin normally and produce more ACTH, reminiscent of pituitary gland overproduction of ACTH.[82] Common symptoms include moon facies and proximal myopathy, as well as hypokalemia and hyperglycemia. Classic features of Cushing syndrome are more likely to occur in bronchial carcinoid tumors.

The diagnosis of Cushing syndrome is confirmed by an elevated cortisol level in a 24-hour urine sample, and an elevated serum ACTH. Failure of suppression by high-dose dexamethasone helps distinguish ectopic paraneoplastic ACTH secretion from pituitary ACTH oversecretion.[72] Imaging studies, including MRI of the pituitary, may be helpful in the differential diagnosis. Treatment should be directed at the cause of the syndrome. When surgical resection of the tumor (i.e., carcinoid) is possible, the syndrome may be resolved. In unresectable lung cancers, medical management includes the use of metyrapone, ketoconazole, somatostatin analogs, aminogluthetimide, tomidate, and mifepristone.[72,80] If medical management fails, bilateral adrenalectomy may be considered. Cushing syndrome often presents in patients with metastatic disease and portends a poor prognosis.[83]

Carcinoid Syndrome

Carcinoid syndrome, recognized by symptoms of flushing and diarrhea, is the result of secretion of serotonin and other vasoactive substances released into the circulatory system from neuroendocrine tumors. Carcinoid syndrome is mainly associated with metastatic tumors in the midgut, whereas hindgut (distal colorectal) and foregut (gastroduodenal, bronchial) carcinoid tumors are rarely a cause. Nonetheless, approximately 1% to 5% of bronchial neuroendocrine tumors may secrete ectopic serotonin and produce the syndrome.[79,84] Typical carcinoid syndrome symptoms include flushing of the chest, secretory diarrhea, bronchoconstriction, and, if the syndrome is chronic, it may lead to cardiac valvular fibrosis. Acute episodes may cause cardiovascular collapse and shock. The diagnosis of carcinoid syndrome requires evidence of an abnormal 5-hydroxy-indoleacetic acid level in a 24-hour urine collection, as this is the main metabolite of serotonin (although it may not be of as much value in bronchial carcinoids). In some cases, elevation of the serum chromogranin A levels may also have diagnostic utility, although with low specificity.[85] In terms of imaging, many neuroendocrine tumors express somatostatin receptors, so nuclear octreotide scintigraphy may be considered in addition to conventional imaging.[86] In the future, novel PET isotopes may prove useful for the localization of these tumors. Carcinoid crises, indicated by hypotension, arrhythmias, and bronchospasm, may be precipitated by surgery, anesthesia, biopsy, and drugs such as adrenergic agents or chemotherapy.[79] Acute cases may require early stabilization with octreotide treatment, and, for patients with carcinoid heart disease and severe valvular dysfunction, cardiac surgery may be necessary to improve quality of life and provide survival benefit.

Hypercalcemia

Hypercalcemia often occurs in lung cancer and is usually a result of humoral hypercalcemia of malignancy (HHM) or osteolytic bone metastases.[78,87,88] HHM is most commonly associated with squamous cell carcinoma and is caused by the production and secretion of parathyroid hormone (PTH)-related peptide by tumor cells.[80] Its discovery was the culmination of careful research, and most cases of hypercalcemia in lung cancer are now recognized as the result of HHM. The degree of hypercalcemia and the rapidity of biochemical changes influence the presentation. The symptoms of hypercalcemia include cognitive

changes, fatigue, polyuria, and abdominal symptoms in conjunction with dehydration. Laboratory tests show hypercalcemia and hypophosphatemia, and electrocardiogram changes may include a prolonged PR or QRS interval, a short QT interval, bradycardia, or heart block. HHM is associated with large tumor burden, male gender, advanced disease, elevated creatinine levels, and poor prognosis.[89] Greater degrees of HHM are associated with the presence of bone metastases, and severe hypercalcemia can lead to coma and death. Diagnosis requires exclusion of other causes, such as metastatic bone involvement, and may be verified by a normal PTH level, low serum phosphorus level, and elevated PTH-related protein level. Management of hypercalcemia involves addressing the calcium levels and associated complications, especially dehydration. Therapeutic strategies include correcting the fluid balance, increasing renal excretion of calcium, and, when possible, reducing bone resorption concurrently with anticancer treatments. Substantial hypercalcemia should be promptly treated; fluid restoration with isotonic saline is beneficial in the renal clearance of calcium, which may be further enhanced by a loop diuretic once adequate hydration has been achieved. Overaggressive rehydration should be avoided because patients with lung cancer may also have coexisting cardiac disease. Bisphosphonates, and particularly other novel agents such as denosumab, are indicated to inhibit calcium release and osteoclast function. Other agents that are effective in treating hypercalcemia include mithramycin, plicamycin, and calcitonin; gallium nitrate treatment has also been used.[79,80]

Blood Disorders

Anemia

Anemia is often found in patients presenting with lung cancer, and the disorder contributes to symptoms of fatigue and dyspnea. It can be considered a form of anemia of chronic disease if the ferritin levels are either normal or elevated. Other, less common hematologic disorders such as microangiopathic hemolytic anemia, characterized by Coombs-negative, hemolytic anemia with schistocytes and thrombocytopenia, have been reported.[90]

Leukocytosis

Mild leukocytosis is relatively common in lung cancer; however, extreme elevations are rare.[91] Autonomous production of cytokines (granulocyte colony-stimulating factor and granulocyte macrophage colony-stimulating factor) has been noted in some patients with lung cancer, and leukocytosis appears to have a negative prognostic effect.[92] Conversely, hypereosinophilia is not often found in patients with lung cancer, potentially because of tumor overexpression of granulocyte macrophage colony-stimulating factor leading to a leukemoid reaction.[93]

Thrombocytosis

Reactive thrombocytosis is relatively common in cancers, including lung cancer.[94] The prevalence of thrombocytosis in lung cancer is variable, and it is thought to be an independent prognostic factor of survival in patients with primary lung cancer, including operable NSCLC.[95,96]

Hypercoagulation States

The relationship between cancer and coagulopathy was suggested by Trousseau nearly 150 years ago, and it is now definitively known that patients with lung cancer are at a higher risk of thromboembolic events compared with people who have other types of cancer or who do not have cancer. Several hypercoagulative disorders have been associated with lung cancer, and they vary in severity. These disorders may either be present before the diagnosis of lung cancer or may occur during the course of treatment for the disease. The classic Trousseau syndrome (migratory superficial thrombophlebitis and occasionally arterial emboli) has been noted in patients with lung cancer.[97] Multiple aspects in lung cancer are associated with a higher risk of thrombosis because of patient-related, cancer-related, and treatment-related factors that combined can contribute to the risk of developing a thrombotic event.[98] Tissue factor overexpression is considered by some to be a major contributor to cancer-related thrombosis.[99]

Deep Venous Thrombosis and Thromboembolism

The authors of a large study published in 2008 reported that venous thromboembolism (VTE) developed in approximately 3% of patients with lung cancer within 2 years, and that the incidence of VTE was associated with a higher risk of death within 2 years after the diagnosis of NSCLC or SCLC.[100] Conventional anticoagulation may not be as effective for patients with lung cancer because VTE is more likely to recur in these patients compared with patients without cancer.[101] In a 2011 Cochrane review of randomized clinical trials comparing low-molecular-weight heparin, unfractionated heparin, and fondaparinux (a selective inhibitor of factor Xa) in patients with cancer and objectively confirmed VTE, low-molecular-weight heparin was potentially superior to unfractionated heparin in the initial treatment of VTE in patients with cancer.[102] A paucity of data are available on the ideal duration of anticoagulation therapy for this paraneoplastic cancer syndrome. A systematic review published in 2011 concluded that metastatic malignancy, adenocarcinoma, or lung cancer confers a higher risk of VTE recurrence than localized malignancy or some other cancers.[103] The development of VTE during lung cancer treatment is also not uncommon, and clinicians should be aware of the increased risk and introduce effective preventive measures when indicated.[104] Early data also suggest a possible link between KRAS gene mutations and an increased risk of VTE in NSCLC.[105]

Disseminated Intravascular Coagulopathy

Lung cancer may also be accompanied by disseminated intravascular coagulation, with bone marrow involvement and reduced platelet counts.[106] In addition, idiopathic thrombocytopenic purpura-like syndrome has been reported in patients with NSCLC.[107,108]

Thrombotic Microangiopathy

Thrombotic thrombocytopenic purpura, a disseminated form of thrombotic microangiopathy, has been found in patients with lung cancer.[109] Immunohistochemical (IHC) staining of lung tumor cells from patients with thrombotic thrombocytopenic purpura has demonstrated endothelial proliferative factors such as vascular endothelial growth factor and osteopontin.[110]

Paraneoplastic Neurologic Syndromes

Paraneoplastic neurologic syndromes (PNSs) are rare, affecting approximately 0.01% of patients with cancer overall, but they are more frequently found in patients with SCLC (3–5%).[111] In some cases, PNS may result from immune crossreactivity between cancer cells and antigens of the nervous system. Antibodies to neuronal surface antigens and intracellular antigens have been reported, and T cells are implicated.[112–114] Because the tumor cells do not directly produce the syndrome, treatment of the primary cancer may not always abolish the syndrome and additional immunosuppressive therapy is often required. PNS may often be identified before the cancer is diagnosed, and thus evaluation by CT and

PET imaging may be necessary. Repeated diagnostic evaluations for cancer may be needed when initial cancer screening does not identify an obvious tumor. The symptoms of PNS depend on the type of neuronal cells affected, ranging from the central nervous system to the peripheral nerves, as well as involvement of neuromuscular junctions.

Central Nervous System

Limbic Encephalitis. As a result of limbic system involvement, manifestations of limbic encephalitis include subacute seizures, memory loss, confusion, and psychiatric symptoms. SCLC is most often associated with limbic encephalitis, but NSCLC has also been linked with the syndrome.[111,115] A number of neuronal antibodies have been reported in limbic encephalitis, including voltage-gated potassium channel antibodies, GABAb, and others.[116,117]

Subacute Cerebellar Degeneration. Subacute cerebellar degeneration presents with rapidly developing cerebellar symptoms such as ataxia, nystagmus, and dysarthria. The prognosis for patients with subacute cerebellar degeneration is often poor, because the syndrome is associated with severe disability and impairment.[111] Selective loss of Purkinje fibers is causative, and cerebellar atrophy should be excluded. Associated antibodies in SCLC include anti-Hu (also called anti-neuronal nuclear antibody, type 1 or ANNA-1), anti-Ri, and anti-P/Q voltage-gated calcium channels (VGCCs).[111,118–120]

Encephalomyelitis. Encephalomyelitis is characterized by simultaneous dysfunction at various levels of the central nervous system such as the hippocampus, spinal cord, and dorsal root ganglia of myenteric plexus.[111] This condition is mostly found in patients with SCLC. The antibodies implicated include anti-Hu and anti-CV2.[121]

Peripheral Nervous System

Sensory Neuropathy. Sensory neuropathy from damage to the cells of the dorsal root ganglia manifests as subacute onset of asymmetrical numbness, pain, and involvement of the arms and lower limbs as well as proprioceptive loss.[79,111] Loss of deep tendon reflexes and panmodality sensory loss will be noted on physical examination. The diagnosis is supported by electrophysiologic demonstration of involvement of the sensory fibers. The commonly implicated antibodies in sensory neuronopathy include anti-Hu and anti-CV2, and SCLC is most often associated with this condition.[122]

Autonomic Neuropathy. Autonomic neuropathy may be subacute over weeks and involves the sympathetic, parasympathetic, and enteric systems, resulting in orthostatic hypotension, gastrointestinal tract dysfunction, sicca, bladder and bowel dysfunction, altered pupillary reflexes, loss of sinus arrhythmia, and weight loss.[72] Anti-Hu, anti-CV2, anti-nAchR, and anti-amphiphysin antibodies may be involved.

Neuromuscular Group of Peripheral Nervous System

Lambert-Eaton Myasthenic Syndrome. Lambert-Eaton myasthenic syndrome (LEMS) occurs with proximal muscle weakness, especially at the hip, with progression in cranio-caudal direction. Patients may also have an associated loss of deep tendon reflexes and autonomic dysfunction. The muscle weakness is thought to be caused by damage to VGCCs present on the presynaptic nerve terminal.[123] These same VGCCs are expressed by SCLC, and LEMS may affect up to 3% of patients with SCLC.[79] It is interesting to note that in SCLC LEMS may

precede the clinical or radiographic diagnosis of the cancer. Electromyography is helpful and shows low-voltage muscle action potential amplitude and decremental response with low-rate stimulation, but incremental response to high-rate stimulation.[72] LEMS should respond to treatment of the underlying lung cancer, and resistant LEMS may respond to plasma exchange, gamma globulin, and immunosuppression with azathioprine and corticosteroids.[124]

Less Common Peripheral Nervous Systems

Opsoclonus–Myoclonus. Opsoclonus–myoclonus is associated with anti-Ri antibodies in SCLC. Clinical features of the syndrome include myoclonus, involuntary eye movements, and truncal ataxia. Cerebrospinal fluid examination shows increased protein and mild pleocytosis. Partial or complete resolution may occur with treatment of the underlying SCLC.[79,124,125]

Cancer-Associated Retinopathy. Cancer-associated retinopathy in SCLC is thought to be caused by damage to the retinal photoreceptors, resulting in scotomas, photosensitivity, and reduced retinal arteriole caliber.[79,124,125] Leaks from retinal vessels can be seen with angiography. Spectral-domain optical coherence tomography has also been reported to be useful in the diagnosis of cancer-associated retinopathy. Progression to blindness is common and is caused by an autoantibody to the 23 kDa photoreceptor protein, recoverin. The condition may improve with corticosteroids and anticancer therapy.[126]

CLINICAL AND MOLECULAR PROGNOSTICATION OF LUNG CANCER

Lung cancer is the most common cause of cancer death in both men and women, accounting for 27% of cancer-related mortality every year.[127] At present, tumor staging is the most important prognostic factor for survival.[25] Unfortunately, patients with early-stage NSCLC are at substantial risk for recurrence and death, even after potentially curative surgical resection, with 5-year survival rates ranging from 30% to 60%. Recurrence and death will occur in as many as 40% of patients with stage I, 66% with stage II, and 75% with stage IIIA disease.[128,129] Given that some patients die of lung cancer whereas others survive without disease recurrence after surgery for an identically staged lung cancer, more factors must be considered to explain the variability of survival within each staging group. Although the TNM staging system has been the standard for determining outcome for patients with NSCLC, the stage classification may be imprecise for an individual patient. Therefore, efforts have been made to identify other prognostic factors for patients with lung cancer, including several molecular factors (Table 20.3).

Prognostic markers are patient or tumor-related factors that may provide information on the likely outcome for untreated patients; predictive markers influence and predict the outcome of a specific treatment in terms of either response or survival benefit.

Clinical Factors

Age

Many studies have shown that chemotherapy is feasible and safe in the older population of patients with NSCLC. Age on its own is not a negative predictive factor and treatment should not be withheld solely on the basis of a patient's age.[130,131] Functional impairment or comorbidity, rather than chronologic age, affects treatment tolerance and effectiveness in patients with NSCLC.[132] Many retrospective analyses have demonstrated similar efficacy outcomes between older and younger patients.[133–135] In a prospective study that enrolled

TABLE 20.3 Clinical and Molecular Prognostic Factors of Lung Cancer

Clinical Factors	Molecular Factors
Age	Nucleotide excision repair system

ALK, anaplastic lymphoma kinase; *EGFR,* epidermal growth factor receptor; *ERCC1,* excision repair cross-complementation group 1; *FGFR1,* fibroblast growth factor receptor 1; *KRAS,* Kirsten rat sarcoma; *PET,* positron emission tomography; *RRM1,* ribonucleotide reductase messenger 1.

451 older patients with NSCLC (median age, 77 years), combination therapy of carboplatin plus paclitaxel was compared with either vinorelbine or gemcitabine monotherapy.[136] The median survival was 10.3 months for the combination compared with 6.2 months for single-agent chemotherapy, which was comparable with the level reported based on an unselected NSCLC population. However, it should also be noted that toxicity is greater among older patients, leading to high morbidity and mortality rates.[137,138] Additionally, published data are highly likely to be affected by selection bias in favor of good prognosis, since only the fittest older patients would have been enrolled in these trials.

Performance Status

When the IASLC International Staging Committee proposed a revised tumor staging system based on details in a very large database, performance status was found to be an important prognostic factor in NSCLC.[139–141] An independent comprehensive analysis of a separate population of approximately 27,000 patients demonstrated that good performance status is an independent predictor of prolonged survival.[142]

Smoking Status

In addition to being the major risk factor in the development of lung cancer, smoking status is known to affect the clinical outcome of patients with the disease. In a retrospective analysis of patients with NSCLC, the median overall survival was 30.0 months for never-smokers and 10.0 months for ever-smokers ($p < 0.001$).

Although smoking status was associated with histology and performance status, a never-smoking status was demonstrated to be a favorable prognostic factor.[142,143]

Gender

Lung cancer in women has a different intrinsic biologic behavior and natural history compared with men.[144] The 5-year survival rate for women with lung cancer is 15.6% compared with 12.4% for men. Women have longer survival after surgical resection of early-stage lung cancer.[145–147] However, the prognostic implication of gender should be considered along with smoking status and histology, because female patients are more likely to

be never-smokers and to have histology of adenocarcinoma.[144,148] Although it seemed there was a sex-related difference in survival in prospectively enrolled Chinese patients with NSCLC, the difference disappeared in the subgroup analysis of never-smokers with adenocarcinoma.[149] (Gender and lung cancer is addressed fully in Chapter 5.)

Histology

The identification of specific histologic type has become important in the treatment of patients with NSCLC, particularly when studies showed greater efficacy of pemetrexed for patients with a nonsquamous cell carcinoma type than for patients with squamous cell carcinoma.[150] Targetable oncogenes, such as the epidermal growth factor receptor (*EGFR*) mutation or the anaplastic lymphoma kinase (ALK) translocation, are more commonly found in adenocarcinomas.[151,152] Unlike the predictive role of histologic type, the prognostic relevance has not been fully evaluated, although several studies recently showed the favorable prognostic feature of squamous cell carcinoma.[140,141]

PET Imaging

Recent advances in FDG-PET have enabled not only a better diagnosis and staging of lung cancer but also the prediction of its malignancy grade and prognosis.[153,154] (Further explanation about the prognostic role of PET is described in Chapter 22).

Molecular Factors

Nucleotide Excision Repair System

Excision Repair Cross-Complementation Group 1. Excision repair cross-complementation group 1 (ERCC1) is the primary DNA repair mechanism that removes platinum-DNA adducts, which are the basis for platinum cytotoxicity. In a study by Simon et al.[155] the authors initially reported that high ERCC1 expression, which was measured by real-time quantitative polymerase chain reaction (qRT-PCR), is an independent predictor of longer survival for patients with surgically resected NSCLC. The International Adjuvant Lung Cancer Trial evaluated ERCC1 expression using IHC in 761 tumors from a randomized trial of adjuvant cisplatin-based chemotherapy in completely resected NSCLC.[156] Adjuvant chemotherapy significantly prolonged survival among patients with ERCC1-negative tumors ($p = 0.002$) but not among patients with ERCC1-positive tumors ($p = 0.40$). Among patients with NSCLC who did not receive adjuvant chemotherapy, patients with ERCC1-positive tumors survived longer than patients with ERCC1-negative tumors. Since then, many studies have evaluated the predictive and prognostic roles of ERCC1 in early- or advanced-stage NSCLC.[157–163] Most recently, however, the level of expression of ERCC1 protein was determined by IHC in a validation set of samples obtained from 494 patients in two independent phase III trials (the National Cancer Institute of Canada Clinical Trials Group JBR.10 and the Cancer and Leukemia Group B 9633 trial from the Lung Adjuvant Cisplatin Evaluation Biology project). This study was unable to validate the predictive effect of IHC staining for the ERCC1 protein, and none of the 16 antibodies could distinguish the four ERCC1 protein isoforms.[164]

Ribonucleotide Reductase Messenger 1. Ribonucleotide reductase messenger 1 (RRM1) is a component of ribonucleotide reductase and the molecular target of gemcitabine. Although an initial prospective trial showed an inverse correlation between RRM1 expression and disease response rates in patients treated with gemcitabine-based chemotherapy, a subsequent trial failed to demonstrate RRM1 as a predictive factor for gemcitabine-based chemotherapy.[165,166] Data about its prognostic implication are rare.

Oncogenes and Tumor Suppressor Genes

KRAS. *KRAS* is a member of the RAS family of oncogenes and encodes a protein that binds guanine nucleotides. *KRAS* mutations occur frequently in NSCLC, found in 15% to 30% of NSCLC among Western patients, although the rate is lower among Asian patients.[167–173] Most of these mutations are found in adenocarcinomas and are associated with a history of smoking. The mutation in *KRAS* results in constitutive activation and continuous transmission of growth signals to the nucleus. A meta-analysis identified *KRAS* mutations as a negative prognostic factor.[174] In addition, among patients with completely resected or advanced NSCLC, the median survival of patients with *KRAS* mutation was shorter than that for patients with *KRAS* wild-type or *EGFR* mutation.[169,173] However, in a later study, which included 1543 patients who had been enrolled in four randomized trials of adjuvant chemotherapy for completely resected NSCLC, the authors reported that *KRAS* mutation had no prognostic role in patients with completely resected NSCLC.[175]

Unlike in colorectal cancer, where *KRAS* mutation has been demonstrated as a predictive factor for poor response to an EGFR-targeting agent such as cetuximab, the predictive role of *KRAS* mutation in NSCLC has been questionable.[176,177] Although many studies have demonstrated poorer clinical outcomes after therapy with EGFR-tyrosine kinase inhibitors (TKIs) among patients with *KRAS* mutation compared with patients with *KRAS* wild-type, this result was refuted by findings that *KRAS* mutation status had no effect on clinical outcomes with EGFR-TKIs in patients with EGFR wild-type.[168,169,173,178–180]

P53. The *p53* tumor suppressor gene is the most commonly mutated gene in all human malignancies, and alterations in the *p53* gene are the most frequently found genetic mutations in human cancer. Inactivation of p53 results in diminished efficiency of DNA repair, derangements of cell cycle regulation, and overall increased genomic instability. Prognostic significance of p53 has been investigated extensively in NSCLC. A prospective study demonstrated that p53 mutations were independently predictive of decreased survival for patients with stage I tumors but not for patients with stage II or III tumors.[181] The relationship between p53 mutational status and adverse survival outcomes has been supported by the results of several other studies in which NSCLC samples of all tumor stages were analyzed.[182–186] Meta-analyses generally have indicated that *p53* gene mutations or p53 protein over-expression were associated with decreased overall survival of patients with NSCLC.[187,188]

Protein Kinases

EGFR. The EGFR pathway is a regulator of cellular proliferation, angiogenesis, apoptosis, and migration. The mutations of genes in the EGFR signaling pathway are thought to be important for the pathogenesis of lung adenocarcinoma.[189] *EGFR* mutations in lung cancer are associated with never-smoking status, female gender, East Asian ethnicity, and histology of adenocarcinoma.[190,191] Typically, *EGFR* mutations are mutually exclusive with *KRAS* mutations or ALK rearrangements.[173,180,192,193] In 2004, EGFR mutation was described to be predictive for response to EGFR-TKIs in NSCLC.[194] Since then, many prospective trials have also demonstrated that *EGFR* mutations act as strong predictors for the efficacy of EGFR-TKIs.[152,195–199] The Iressa Pan Asia Study showed that the response rate to gefitinib was 71.2% in the EGFR mutation-positive subgroup, compared with 1.1% in the mutation-negative subgroup.[152] Other prospective studies have also demonstrated that *EGFR* mutation is a powerful predictive factor for clinical outcomes in patients treated with erlotinib or afatinib. Higher objective response rates and longer progression-free survival have been reported for EGFR-TKIs compared with cytotoxic

chemotherapy for EGFR-positive tumors.[197–199] Based on these data, *EGFR* mutation testing is strongly recommended for advanced NSCLC. The prognostic role of *EGFR* mutation, however, is still controversial, particularly in surgically resected early-stage NSCLC. Although initial studies showed that *EGFR* mutation correlated with worse survival in NSCLC, other studies have shown no significant association.[191,200,201] The clinical observation that patients with *EGFR* mutation survive longer may be because EGFR mutation is more frequently associated with other good prognostic factors.

Anaplastic Lymphoma Kinase. In 2007, Soda et al.[202] identified the echinoderm microtubule-associated protein like 4 (EML4)-ALK fusion gene as a driving oncogene in a subset of NSCLC. ALK-rearranged lung cancer is a unique NSCLC subset that is characterized by ALK gene inversion or translocation. Several selective ALK inhibitors have demonstrated their effectiveness in patients with NSCLC harboring ALK rearrangement.[203–206] Although the subset of patients with ALK-rearranged lung cancer mostly benefit from ALK inhibitors, the prognosis of patients with ALK-rearranged tumors who were not treated with ALK inhibitors was comparable to patients with tumors lacking ALK rearrangement.[207,208]

Fibroblast Growth Factor Receptor 1. Fibroblast growth factor receptor (FGFR) belongs to the super-family of receptor tyrosine kinases and is encoded by four genes (*FGFR1*, *FGFR2*, *FGFR3*, and *FGFR4*). *FGFR1* has been identified as one of the emerging molecular targets for the treatment of lung cancer.[209] *FGFR1* amplification is detected in about 15% of squamous cell lung carcinomas, and it is regarded as a druggable target.[210–212] However, the data about its prognostic relevance are contradictory, and further research is warranted.[210–212]

Tumor Cell Proliferation

Ki-67. Ki-67, a nonhistone protein, is a DNA-binding nuclear protein expressed throughout the cell cycle in proliferating cells, but not in quiescent (G0) cells. Although its exact function remains unclear, Ki-67 has been used as a proliferative marker in malignant tumors.[213] The prognostic relevance of Ki-67 has been extensively investigated in NSCLC. A recent meta-analysis, which included 28 studies conducted between 2000 and 2012, indicated that the expression of Ki-67 seems to have prognostic influence in NSCLC, with a high labeling index pointing toward poor prognosis.[214] However, it is difficult to reach consensus on the prognostic value of Ki-67 expression because various cut-off levels and methods have been used across studies.[214]

Gene Expression Arrays

Molecular profiling of tumors has led to the identification of gene expression patterns that are associated with specific phenotypes and prognosis. The development of genomic techniques, particularly DNA microarray and qRT-PCR, provides an opportunity to discover groups of genes whose coordinated expression could have greater power than individual genes to predict disease outcome. Despite the diversity in the approaches used, three main steps are needed in the model of genomic prognostication.[215] First, the expression levels of several hundred to tens of thousands of genes are quantified by microarray or qRT-PCR, and the data are then processed. Second, expression data are combined and grouped by clustering and risk score generation to produce a gene signature that correlates with a clinical outcome. Third, the signature is validated in datasets of independent cohorts.

It is well accepted that alterations in the expression levels of certain genes are strongly associated with carcinogenesis. These changes in gene expression are represented by the quantitative changes in mRNA levels. In 1995, Schena et al.[216] demonstrated

a gene expression profiling technique—adapted from Southern blotting that used strands of complementary DNA spotted onto a piece of glass to examine multiple mRNA expression levels at once—known as a microarray. Since then, this technology was quickly developed and many investigators found differences in gene expression profiles between lung cancer and normal lung tissue.[217,218] Bhattacharjee et al.[217] examined 186 snap-frozen lung tumors using 12,600 unique transcript-containing oligonucleotide microarrays and classified the group of lung adenocarcinomas into four distinct subgroups according to the genetic profiles. The median survival rates among the four subgroups were significantly different. Beer et al.[219] examined 86 resected lung adenocarcinomas using 6800 transcript-containing oligonucleotide microarrays. They defined a risk index based on the top 50 genes to identify low-risk and high-risk stage I lung adenocarcinomas, which differed significantly with respect to survival, showing that gene-expression profiles based on microarray analysis can be used to predict survival in early-stage lung adenocarcinoma. The first report of a qRT-PCR–based molecular signature with prognostic implications was published in 2007.[220] In this study, investigators identified 16 genes that correlated with survival among patients with NSCLC by analyzing microarray data and risk scores, and then, five genes (*DUSP6*, *MMD*, *STAT1*, *ERBB3*, and *LCK*) were selected for qRT-PCR and decision-tree analysis. The five-gene signature was demonstrated as an independent predictor of survival.[220]

Epigenetics

Epigenetic modifications are now known to significantly contribute to lung cancer carcinogenesis. For example, the aberrant promoter methylation of the tumor suppressor gene p16 leads to gene silencing, which is an early event in carcinogenesis.[221,222] Epigenetic changes are being tested as a noninvasive biomarker for the prognosis of lung cancer. Brock et al.[223] evaluated the prognostic value of methylation patterns for seven genes (*p16*, *MGMT*, *DAPK*, *RASSF1A*, *CDH13*, *ASC*, and *APC*) in resected stage I NSCLC, and they found that pairs of gene combinations of *p16*, *CDH13*, *APC*, and *RASSF1A* were a risk factor for recurrence.[223]

Proteomic Analysis

Proteomic approaches involve the comprehensive investigation of proteins using two-dimensional gel electrophoresis and mass spectrometry. Through the development of high-throughput platforms, proteomics allowed for the simultaneous measurement of multiple protein products and/or protein modifications.[224] These processes are useful in detecting the dysregulation in malignancy as well as protein function. Moreover, proteomics has some advantage over genomics because protein biomarkers can be a more accurate signature of a disease state, as proteins are the actual functional players. Proteomics was extensively used to define the prognosis of patients with lung cancer. The expression level of many proteins such as phosphoglycerate kinase 1 (PGK1), annexin A3 (ANXA3), S100A11, and cytokeratins (CKs) has been reported to be associated with prognosis in lung cancer.[225–228]

MicroRNA

MicroRNAs (miRNAs) are small noncoding RNAs approximately 22 nucleotides long that play crucial roles in lung carcinogenesis through posttranscriptional regulation of tumor suppressor genes and oncogenes. There is evidence to support that miRNAs are dysregulated during tumor initiation and progression. Currently, there are more than 1200 human miRNAs, and many studies have demonstrated major differences in miRNA expression between lung tumors and noninvolved adjacent lung tissue.[229] Many studies have investigated the role of miRNAs in lung cancer as well as their role as diagnostic, prognostic, and therapeutic targets.[230]

The association between miRNA expression signatures and prediction of prognosis has also been evaluated in several studies. The high level of miR-708 in NSCLC was found to be associated with a reduced overall survival for never-smokers with lung adenocarcinomas.[231] Lu et al.[232] found that miRNA expression patterns between lung adenocarcinoma and squamous cell carcinoma significantly differed in 171 miRNAs, including Let-7 family members and miR-205. They also found two miRNA signatures that significantly differentiate the survival rates of these lung cancers. However, the role of miRNAs in the clinical setting remains unresolved, warranting large, prospective studies that demonstrate reproducibility.

CONCLUSION

Early recognition of initial lung cancer symptoms and specific clinical syndromes is very important for all physicians and for primary care physicians in particular. Increased awareness of alarming symptoms such as cough, hemoptysis, dyspnea, and weight loss may be a key factor in earlier detection of lung cancer, resulting in better outcomes. Diagnosis of lung cancer by its clinical presentation only is, however, not sufficient for detecting all lung cancers at an early stage. Screening of asymptomatic individuals at highest risk for lung cancer with use of low-dose CT has been shown to be efficient not only for diagnosing lung cancer at an early stage but also for substantially reducing lung cancer–specific mortality. Awareness of several clinical and molecular prognostic factors of lung cancer may hopefully become more important and relevant to the physician's clinical evaluation and may optimize personalized care of patients with lung cancer in daily practice.

21 Conventional Imaging of Lung Cancer

Patricia M. de Groot, Brett W. Carter, and Reginald F. Munden

SUMMARY OF KEY POINTS

- Low-dose multidetector computed tomography (CT) screening of active and former heavy smokers has been shown to decrease lung cancer mortality.
- The malignant potential of solid pulmonary nodules depends on their size, with larger nodules more likely to represent tumor. Nevertheless, solid nodules have a low overall malignancy rate (7%).
- Ground-glass nodules and part-solid nodules have a higher chance of malignancy than completely solid nodules, up to 63% in the case of mixed density solid and ground-glass lesions. The differential diagnosis for ground-glass lesions that persist after 3 months includes focal fibrosis, atypical adenomatous hyperplasia, and indolent adenocarcinoma.
- Chest CT with intravenous contrast is recommended for all patients with suspected or known lung cancer to assess primary tumor characteristics, nodal disease, and intrathoracic or extrathoracic metastases.
- Accurate staging of lung cancer is critical to inform management decisions and therapy. The seventh edition of tumor, node, and metastasis (TNM) staging from the International Association for the Study of Lung Cancer/American Thoracic Society is currently in use; proposed revisions for the eighth edition have been published.
- Magnetic resonance imaging (MRI) is useful in evaluating several factors that determine potential resectability of lung tumors including pericardial or myocardial invasion, brachial plexus involvement in the setting of superior sulcus tumors, and invasion of regional vasculature or the spinal cord in central tumors.
- MRI is also showing promise in detection of metastatic lymph nodes, displaying better sensitivity and accuracy compared with ^{18}F-2-deoxy-D-glucose-positron emission tomography–CT in some studies.
- Chest CT with contrast is useful in assessing lung cancer response to radiation or chemotherapy, surgical resection, and emergent conditions that may be associated with malignancy.

Primary lung cancer is the leading cause of cancer mortality worldwide and constitutes a major public health challenge. In the United States, lung cancer is as deadly as the next three causes of cancer deaths combined (prostate, colorectal, and pancreatic cancer in men; breast, colorectal, and pancreatic cancer in women).[1] In 2014, the incidence of lung cancer is estimated to be 224,210 cases, with lung cancer responsible for 86,930 deaths in men and 72,330 deaths in women in the United States.[1] In 2013 in the European Union, primary lung cancer caused approximately 187,000 deaths in men and 82,640 deaths in women, the latter constituting a 7% increase from 2009.[2] Nevertheless, the lung cancer epidemic is considered to have peaked in the developed world, and more than half of new lung cancer cases now occur in

developing countries.[3,4] In countries such as China, where widespread tobacco smoking has become a more recent event, lung cancer incidence and mortality rates are increasing.[4]

Primary carcinoma of pulmonary origin includes several distinct histologic types and may be divided into small cell lung cancer (SCLC) and nonsmall cell lung cancer (NSCLC). SCLC is a pulmonary neuroendocrine tumor with aggressive features. Other neuroendocrine malignancies of the lung are carcinoid and large cell neuroendocrine tumors.[5] NSCLC is more common overall than SCLC and encompasses adenocarcinoma and squamous cell carcinoma, as well as less frequently seen tumors of the lung such as large cell carcinoma, sarcomatoid carcinoma, and spindle cell sarcoma.

A shift in the prevailing lung cancer cell type occurred in the latter decades of the 20th century. In the 1950s, cases of squamous cell carcinoma outnumbered cases of adenocarcinoma, the second most common type of lung cancer, by a ratio of 17:1. Since that time, polycyclic aromatic hydrocarbons, a known carcinogen specifically associated with squamous cell carcinoma of the lung, have been reduced in manufactured cigarettes, with a relative decline in the incidence of squamous cell carcinoma.[6] However, the incidence of primary lung adenocarcinoma has increased during the same period. These cancers have been linked to tobacco-specific nitrosamines, which are still present in cigarettes in substantial quantities.[7–9] The use of cigarette filters, although reducing the risk of squamous cell carcinoma, has had no effect on the risk of adenocarcinoma.[10]

RADIOLOGIC PRESENTATION OF LUNG CANCER

Diagnostic imaging plays an important role in the diagnosis, workup, and staging of primary lung cancer. Conventional chest radiographs and computed tomography (CT) of the chest both have a role in identifying and evaluating abnormalities in the thorax. Chest CT is an essential tool in tumor staging and in determining clinical and surgical management.

On imaging, primary lung cancers vary in their appearance from a solitary pulmonary nodule to amorphous consolidation. They may also have varying densities, ranging from ground-glass attenuation (defined as slightly increased lung density through which vessels can be seen), to mixed ground-glass and solid density lesions, to solid tumors. A lung cancer may be cavitary at presentation or may cavitate during the course of treatment. The early, common, and uncommon imaging features of lung cancer are discussed in this chapter.

SOLITARY PULMONARY NODULE CHARACTERIZATION

Many lung cancers, particularly at the early stages, present as a solitary pulmonary nodule (up to 3 cm) or mass (greater than 3 cm), but only a small fraction of pulmonary nodules are actually cancerous.[11] Several features seen on imaging may help to differentiate malignant from benign nodules, the most important of which are size, density, and enhancement. Other important characteristics include border contour, shape, patterns of calcification, presence of macroscopic fat, and cavitation (Fig. 21.1). Location and multiplicity of nodules should also be noted.
Fig. 21.1. Squamous cell carcinoma of the lung in a 71-year-old woman. Axial computed tomography image with contrast material in (A) lung windows and (B) soft-tissue windows shows a sizeable, irregular, spiculated, heterogeneously enhancing mass in the left lower lobe in a patient with severe smoking-related emphysema. The large size, irregular borders, and enhancement are all characteristics associated with malignancy.

Size

The larger a nodule is at presentation, the higher the likelihood that it is malignant. For a solid, discrete pulmonary nodule, the risk of cancer is categorized according to size. A solid nodule up to 5 mm has a 1% risk of being cancer. Nodules between 6 mm and 10 mm have a 24% chance of malignancy, which increases to 33% for nodules 11 mm to 20 mm. Solid lesions greater than 20 mm in diameter have an 80% chance of malignant histology.[12] A lesion greater than 30 mm has a 93% to 99% rate of malignancy.[13,14]

Changes in nodule size are also an important prognostic consideration. Nodules that decrease in size over time are most likely infectious or inflammatory in etiology. Conversely, nodules that enlarge while under observation are considered malignant until proven otherwise. Consequently, established algorithms for managing pulmonary nodules are promulgated by the Fleischner Society. For follow-up of solid nodules, slight variations may exist, depending on the risk stratification of the individual. In a high-risk person such as a smoker, nodules up to 4 mm should have a single follow-up 12 months after presentation. Solid nodules greater than 4 mm and up to 6 mm should be reassessed by CT at 6 months to 12 months after presentation and then at 18 months to 24 months if unchanged. For nodules greater than 6 mm to 8 mm, the initial follow-up is at 3 months to 6 months, followed by reassessment at 9 months to 12 months and again at 24 months, if unchanged. Nodules greater than 8 mm may be followed-up with CT at 3 months, 9 months, and 24 months; alternatively, dynamic contrast-enhanced CT, positron emission tomography (PET), and/or biopsy could be performed.[15] Solid nodules identified on presentation should be followed up for a minimum of 2 years to establish stability and benignity. Interval nodule growth should prompt further workup, including biopsy.[16]

Density

Solid nodules have a low overall malignancy rate of 7%.[11] Subsolid nodules have a greater chance of being malignant than solid nodules and may represent primary adenocarcinomas of the lung.

Ground-Glass Opacity

Pure ground-glass lesions, those lesions with homogeneous transparent density through which underlying architectural features are seen, have an 18% chance of being malignant.[11] Very small ground-glass nodules, up to 5 mm, may reflect atypical adenomatous hyperplasia, which is premalignant and does not require CT follow-up, according to the Fleischner Society recommendations for subsolid nodules.[17] For lesions greater than 5 mm, the differential diagnosis includes focal fibrosis, atypical adenomatous hyperplasia, and indolent primary adenocarcinoma.[18] Neoplasms with pure ground-glass attenuation usually correspond with adenocarcinoma in situ, the type A lesion in the Noguchi classification scheme of pulmonary adenocarcinomas, although rarely, they may be of mixed subtype. Heterogeneous ground-glass lesions or lesions with internal alveolar collapse are compatible with Noguchi type B lesions.[19] Ground-glass adenocarcinomas have doubling times on the order of 384 days to 567 days.[19]

The presence of solid components mixed with ground-glass attenuation denotes a mixed-density, part solid nodule (PSN). These part solid and part ground-glass nodules have the highest malignancy rate (63%).[11] The larger size of the solid features is associated with worse prognosis;[17] these lesions correspond to Noguchi types B and C (Fig. 21.2). The development of solid density within a pure ground-glass opacity (GGO) under surveillance is an indication of transformation to a more aggressive lesion. An increase in diameter in an observed GGO is also a sign of progression (Fig. 21.3).[19] Papillary, tubular, acinar, and other subtypes of lung adenocarcinoma on imaging cannot be reliably distinguished; rather, the diagnosis is histologic.[20]

Initial follow-up for both pure GGOs and PSNs is performed 3 months after presentation to distinguish a potentially infectious or inflammatory lesion, which would be expected to decrease or resolve in this period.[17] Single GGOs greater than 5 mm in diameter that persist after 3 months without change should be reassessed annually for a minimum of 3 years, unless or until they show progression. Solitary PSNs are managed according to the size of the solid component. If the solid portion is less than 5
Fig. 21.2. Nonsmall cell lung cancer in a nonsmoking 63-year-old woman. Axial computed tomography image with contrast material in lung windows shows a large multilobulated right upper lobe lesion having both solid and ground-glass attenuation. The large solid component is suspicious for a more aggressive lesion. Examination of the biopsy specimen indicated invasive adenocarcinoma.

mm, follow-up for the nodule may be similar to that for a GGO, for a minimum of 3 years. Lesions with larger solid components persistent after 3 months should be reassessed by biopsy and/or resected.[17]

The presence of several GGOs and/or mixed-density lesions makes resection of all lesions impossible for some individuals. Multiple GGOs 5 mm or less should have a follow-up CT at 2 years and again at 4 years after presentation, in the absence of interval changes. Pure GGOs greater than 5 mm without a dominant lesion should undergo annual surveillance similar to that for a single GGO. Careful follow-up of these GGOs should be done in order to identify candidate tumors for limited resection based on progression or aggressive transformation. When a dominant lesion or lesions with part solid components are present in the setting of other nodules, biopsy and/or lung-sparing surgical resection is advised.[17]

Enhancement

Neoplastic pulmonary nodules have been shown to have increased vascularity compared with benign nodules, suggesting that nodule enhancement can be used as a distinguishing characteristic in evaluating indeterminate solid lesions.[21] The assessment process requires noncontrast CT images through the pulmonary nodule, which is then imaged at specific time points up to 4 minutes after administering intravenous contrast medium.[22] Hounsfield unit (HU) attenuation measurements are taken with a region of interest for every time point and the differential enhancement is calculated. A difference of 15 HU or less is strongly suggestive of benignity. With a 15-HU threshold, investigators have found 98% sensitivity but 58% specificity for malignancy.[21,22] Another study using a threshold of 30 HU with multidetector CT demonstrated 99% sensitivity for malignancy, with 54% specificity, a positive predictive value of 71%, and a negative predictive value of 87%.[22,23] Nevertheless, because of time constraints, need for technical expertise, availability of other noninvasive assessment methods such as PET–CT, and radiation dose to the patient, nodule enhancement studies are not frequently performed in the

nonacademic clinical setting. More recently, dual-energy CT, which has the capability of creating a virtual noncontrast image, has been investigated as a potential method of measuring nodule enhancement without multiple acquisitions, thus minimizing the radiation dose.[22]

Borders

A nodule with an irregular or shaggy border can raise suspicion for malignancy; however, infectious and inflammatory nodules may have a similar appearance. The degree of suspicion may rest on the overall constellation of radiographic findings, the individual's symptoms and demographic characteristics, and persistence over time. Cancers may be multilobulated, although smooth and well-circumscribed nodules may be malignant 21% of the time.[22,24] Spiculation in the periphery of a nodule correlates pathologically with a desmoplastic reaction of the nodule or tumor infiltration into the surrounding lung parenchyma and is present much more frequently in malignant nodules.[20,25] Many lung cancers are ill defined, hindering detection on radiographs.[26,27]

Shape

Although most lung cancers manifest as a nodule or mass, the overall shape of carcinomas varies. Some adenocarcinomas, particularly the mucin-producing subtype, can present as ill-defined parenchymal consolidation caused by mucin filling the alveoli; this is radiographically indistinguishable from pneumonia but will persist despite antibiotic treatment (Fig. 21.4). An uncommon manifestation of early lung cancer is a focally thickened or impacted bronchus, sometimes with peripheral inflammatory changes.[28,29]

Calcification

Calcifications within a nodule can be evaluated according to their pattern. Benign calcifications are central, diffuse, laminar, or so-called popcorn in shape.[13,28] Eccentric calcification is associated with malignancy. Nonetheless, preexisting calcifications in the lungs such as granulomas may become engulfed by a tumor, and carcinoid tumors can have punctate calcifications, making the presence of calcification less reliable in determination of benign disease.[28]

Adipose Content

Macroscopic fat within a pulmonary nodule can be identified visually and is measurable with a region of interest; HU measurement less than 1 is compatible with adipose tissue. The presence of macroscopic fat is an indication of benignity and favors the diagnosis of hamartoma, a smooth muscle neoplasm having no malignant potential. However, low attenuation in a nodule without the presence of actual fat can suggest necrosis or the presence of mucin.

Cavitation

Up to 22% of primary lung cancers demonstrate cavitation on CT imaging.[30] Squamous cell carcinomas of the lung are the most likely to exhibit this feature; however, primary lung adenocarcinomas will also cavitate. One type of cavitation occurs when tumors outgrow their blood supply and undergo central necrosis. Some adenocarcinomas exhibit a phenomenon of pseudocavitation caused by bronchial or alveolar expansion within the tumor (Fig. 21.5).[20] It is also possible for a lung cancer to arise in the wall of a preexisting cystic space.[31]

Nevertheless, infectious processes of the lung, including mycobacterial, fungal, and bacterial pneumonias, can also

cavitate, as can nodules related to vasculitis. Some early studies demonstrated that cavity wall thickness measured on radiographs could be a discriminating feature in distinguishing nonmalignant from malignant disease; however, results of other studies using CT have suggested that measuring wall thickness is not as useful.[30] Both inner cavity wall irregularity and notching, or focal lobulation of the outer cavity wall, have both been shown to occur more frequently in malignant than in benign cavitary lesions.[22,32]

Multiplicity

The implication of more than one lesion also depends on size and density. Multiple small, solid nodules that are smaller than 6 mm are most likely to be postinfectious/postinflammatory and are considered low risk for malignancy.[16,33] Conversely, numerous ground-glass nodules and/or PSNs are highly suggestive of multifocal synchronous primary adenocarcinomas.[34] The presence of two synchronous primary lung carcinomas of different histologic types is also possible but uncommon.[29]

Location

Lung cancers may be located in the peripheral or central aspect of the lungs. Statistically, more malignancies are found in the upper lobes, especially the right upper lobe.[35]

IMAGING WITH CHEST RADIOGRAPHS

The chest radiograph is by far the most commonly performed radiographic study, with almost 80.5 million chest radiographs
Fig. 21.3. Ground-glass lesion progressing over time in a 73-year-old woman. Axial computed tomography images in lung windows over an 8-year period. (A) Baseline image shows a nearly imperceptible ground-glass opacity in the superior segment of the left lower lobe; (B) after approximately 3 years, a small lobulated ground-glass opacity is visible in this region; (C) after another 3 years, the lesion continues to enlarge and demonstrates an air bronchogram; and (D) at the last time period, 8 years after the original presentation, the tumor has progressed in both size and density and is compatible with a primary lung adenocarcinoma. It was not resected because of multifocal adenocarcinomas in this patient.

performed in 2010 in short-term-stay US hospitals alone, not including associated facilities, specialty hospitals, and independent doctors' offices.[36] Radiographs are inexpensive and widely available, and the radiation dose is negligible (0.1 rem). Chest radiography is the first-line imaging modality for individuals with symptoms referable to the chest, such as cough, shortness of breath, hemoptysis, and chest pain. Chest radiographs are also obtained as baseline examinations before procedures, including surgery. The chest radiograph, therefore, provides an early opportunity to detect both symptomatic and asymptomatic lung cancers.
The error rate for the detection of lung cancer by chest radiography is generally accepted to be 20% to 50%, which is likely the result of a combination of factors.[27,28] Even with an adequate search pattern and search duration, limitations in human sight, technical aspects of the radiograph, and tumor characteristics can make identification of an early lung cancer challenging.[28]

Technical Factors

The radiograph itself may be of limited quality for a variety of technical reasons, including overpenetration or underpenetration of the chest by the photon beam or positioning variances such as rotation or lordosis. Objects external to the patient may cause artifacts. Although metal objects such as jewelry and clothing fasteners are easy to identify, nonmetal items such as buttons, hair, or clothing decorations may be confounding. Parts of the lung may be excluded from the field of view by faulty technique. Lastly, the ability of the patient to achieve full lung inspiration on the radiograph affects the conspicuity of lesions.[37] Visualization of nodules is enhanced by using higher peak kilovoltage (140 kVp), which accentuates contrast.[28]

Blind Spots on Radiography

Chest radiographs can have blind spots, many of them due to overlapping anatomic structures such as skeletal bones. Specific regions such as the hila, where the pulmonary arteries and veins and the airways converge, may also be difficult to evaluate (Fig. 21.6). Superimposed acute processes may mask findings of malignancy. Not infrequently, pneumonia can be the first indication of a central obstructing or partially obstructing lesion. Recurrent consolidations in the same location are highly suspicious (Fig. 21.7).[13] Consequently, radiographic follow-up to document resolution of pneumonia is advised. Chronic lung disease such as pulmonary fibrosis may also hinder identification of a focal abnormality. It is worth noting that preexisting chronic lung disease is a risk factor for lung cancer.

Fig. 21.4. Nonsmall cell lung cancer in a 71-year-old woman. This heterogeneous consolidation filling and expanding the left lower lobe on axial computed tomography in lung windows is proven by examination of a biopsy specimen to be a well-differentiated mucinous adenocarcinoma with bronchoalveolar features.
Fig. 21.5. Adenocarcinomas with central lucencies. (A) Axial computed tomography (CT) image in lung windows demonstrates multifocal lung opacities, some with pseudocavitation, in this 75-year-old man with primary lung adenocarcinoma having both mucinous and nonmucinous components, and (B) axial CT image in lung windows shows adenocarcinoma developing in the periphery of a preexisting cluster of emphysematous spaces in a 71-year-old woman.
Fig. 21.6. Nonsmall cell lung cancer in an 85-year-old man. (A) Posteroanterior chest radiograph shows hyperinflated lungs compatible with chronic obstructive pulmonary disease. A small opacity is seen partially overlying the right posterior sixth rib. Hazy opacity also appears along the left paratracheal region just above the aortic arch. This example demonstrates the difficulty of visualizing subsolid lung lesions, the blind spots associated with the mediastinum and overlapping bone structures, and satisfaction of search limitations. (B) Axial computed tomography image in lung windows demonstrates bilateral lung tumors, which were proven by examination of a biopsy specimen to be synchronous adenocarcinomas.

Characteristics of Lung Cancers Missed on Radiography

Retrospective studies of lung cancers not prospectively identified on chest radiography have demonstrated several common characteristics. In general, missed lung cancers were located in the upper lobes, although one study showed no difference in the location of missed and detected lung cancers.[26,27] Another characteristic was small nodule size, on average 16 mm to 19 mm.[26,27,38] An analysis of size differences in detection rate indicated that nodules 10 mm or smaller were missed 71% of the time. Nodules 10 mm to 30 mm in size were not detected 28% of the time. However, nodules 30 mm to 40 mm were missed at a rate of 12%, and nodules greater than 40 mm were identified 100% of the time. Centrally located nodules that were missed had a larger circumference than overlooked peripheral nodules.[27] Overlying anatomic structures contributed to difficulty in detecting lung cancers.[26,27] Many of the missed cancers had ill-defined borders and relatively low levels of density.[26,27] A high pretest probability of lung cancer has been shown to promote detection rates, and in two studies, underdiagnosis of lung cancers in women appeared to be related to lower clinical suspicion.[26,37]

Use of Special Radiographic Views

Disagreement exists over the importance of lateral projection in making a diagnosis of lung cancer. The authors of several studies have discovered a few cancers that could be visualized only on the lateral radiograph; although this represents a small number of cases, there is support for continued acquisition of the lateral chest radiograph in conjunction with the posteroanterior view (Fig. 21.8).[26] Oblique radiographs may also be helpful in determining whether an abnormality seen on standard views is external to the patient.

New Technology in Radiography

Technical advances in chest radiography have been made possible by digital radiographic technology.

Computer-Aided Detection

Computer-aided detection of pulmonary nodules on chest radiographs has been subject to the limitation of a high false-positive rate, but it does provide a so-called second reader effect by supporting the reading radiologist.[39] It has been shown that double reads improve interpretation accuracy;[28] however, in the current health-care system, practical reasons preclude having two trained radiologists read the same film. The use of computer-aided detection software systems has been shown to significantly enhance the accuracy and sensitivity of even experienced radiologists in detecting lung cancers on radiographs.[39,40] In one study, the computer-aided detection program was able to identify 40.4% of subtle or very subtle cancers.[40]

Dual-Energy Subtraction Radiography

Dual-energy subtraction technology uses two exposures of the frontal view of the chest obtained milliseconds apart at two different energy levels, or kVp. A postprocessing algorithm uses these exposures to virtually subtract the osseous structures from the radiograph, producing a soft tissue, thus providing a predominant image with greater conspicuity of lesions that are surrounded by air in the lungs, and fewer blind spots from overlapping skeletal structures (Fig. 21.9). Nevertheless, persistent limitations exist, including suboptimal evaluation of the retrocardiac space, the periphery of the lungs, and the retrosternal space.
Fig. 21.7. Nonsmall cell lung cancer in a 59-year-old woman. (A) Posteroanterior radiograph taken at the time of original presentation to an emergency center for symptoms of cough. A lingular pneumonia was reported. The patient was treated but lost to follow-up. (B) A repeat radiograph was not obtained until 10 months later, when the entire left upper lobe was consolidated. (C) Chest computed tomography (CT) image was obtained several days later, and axial CT image in soft-tissue windows demonstrates an obstructing tumor in the lingula, which was determined by examination of a biopsy specimen to be squamous cell carcinoma.

Early phantom studies showed improved detection of thoracic abnormalities with dual-energy subtraction technology,[41,42] and observer studies have shown increased accuracy of lung nodule identification by both trained radiologists and residents.[43] Although dual-energy subtraction technology has improved the detectability of all lung cancers, it is particularly helpful in identifying PSNs, which are the most likely to be malignant.[44] Dual-energy subtraction technology can be used concurrently with computer-aided detection, but this combination has not yet been rigorously investigated.

IMAGING WITH CT

The discovery of a nodule or persistence of a lung opacity on radiography can be an indication for CT evaluation.[45] In a subset of the population of smokers and former smokers, screening for lung cancer with low-dose multidetector CT has been shown by the National Lung Cancer Screening Trial to decrease lung cancer mortality.[46] In addition, lung nodules may be found incidentally during CT imaging for other reasons, such as motor vehicle trauma or pulmonary embolism evaluation in the emergency department.

Chest CT is much more sensitive than radiography for detecting lung nodules and more useful for characterizing abnormalities. CT allows for more accurate description of size and density of a lesion and can identify satellite lesions below the resolution of radiography. CT permits a more detailed inspection of the pleura, the mediastinum, the thoracic lymph node basins, and extrathoracic regions, including the liver and adrenal glands, both common sites of metastases from lung cancer.
Fig. 21.8. Adenocarcinoma in a 69-year-old woman. (A) Posteroanterior radiograph of the chest has slightly increased density in the region of the aortic arch and aorticopulmonary window. (B) The lesion is much easier to visualize on the lateral projection, in which a multilobulated tumor is seen anteriorly in the retrosternal space.

Blind Spots on CT

Several factors influence the recognition and diagnosis of lung cancer on CT. Small endobronchial lesions may be very subtle and difficult to see, necessitating meticulous examination of the airways.[28,47] Small pulmonary nodules are missed on CT up to 47% of the time, usually because of central and/or peribronchovascular location (Fig. 21.10).[47] Adjacent airspace disease, including pneumonia or atelectasis, can obscure findings of malignancy.[47] However, the Golden S sign denoting a central obstructing tumor with peripheral lobar collapse (classically, the right upper lobe) is highly suggestive of malignancy.[13] On contrast-enhanced CT scans, differential enhancement of atelectasis compared with tumor or infection can help identify underlying lung lesions.[47] The presence of intravenous contrast material also facilitates recognition of lymphadenopathy, particularly in the hilar regions, and of pleural involvement.[47,48] The presence of other major findings on chest imaging can distract the reader and may hinder identification of a small malignancy.[47,49]

Characteristics of Lung Cancers Missed on CT

The characteristics of lung cancers not detected on CT have been reviewed in several studies. The diameters of cancerous lesions missed on chest CT examinations are smaller than lesions missed on radiographs; the mean diameter in one study was 12 mm and in another was 9.8 mm for detection errors and 15.9 mm for interpretation errors.[49,50] A large proportion of the missed tumors were subtle GGOs correlating mostly with well-differentiated lung adenocarcinomas.[50,51] Central endobronchial lesions were most commonly missed in one study.[49] Location in the lower lobes and in the perihilar regions contributed to detection failure, as did preexisting lung disease.[49,50] A number of cancers were not prospectively identified in nonsmoking women.[52] An acknowledged limitation in these studies is the thick 10-mm collimation and image reconstruction CT technique common to most of the examinations reviewed.[49,50] A 5-mm collimation and image reconstruction algorithm is much more common on modern CT scanners, and even thinner collimation is standard in many academic centers.

New Technology in CT

Computer-Aided Detection

Computer-aided detection programs have also been developed to identify pulmonary nodules on CT (Fig. 21.11). Studies using computer-aided detection as a second reader have shown improved sensitivity in nodule detection.[53,54] False-positive results obtained using the software application are usually caused by vessels en face, vascular branch points, and/or artifacts.[22] Although use of computer-aided detection to identify ground-glass nodules is more complicated than for solid nodules, some studies have shown that computer-aided detection also improves detection of ground-glass and mixed-attenuation nodules.[54,55]

Maximum Intensity Projection

Maximum intensity projection images can facilitate the identification of small solid pulmonary nodules.[22] The improvement in reader sensitivity is similar to that of computer-aided detection.[23]

USE OF CT IN STAGING OF LUNG CANCERS

The revised version of the TNM staging system for NSCLC is discussed in detail in Chapter 25. Adopted in 2009 after the evaluation of 67,725 cases of NSCLC, this edition of the TNM staging system categorizes TNM features into groups that best align with prognosis and treatment of the disease.[56] This edition has also been recommended for staging of SCLC and bronchopulmonary carcinoid tumors.[57,58] Chest CT is routine for baseline staging of lung cancer and for surgical planning, if the disease is potentially resectable. The study should include the adrenal glands in their entirety. As a result, much of the liver will also be within the field of view, although the entire liver is not typically imaged. Use of intravenous contrast material is preferred if not contraindicated by the patient's allergy profile or by declining renal function.[59] Multidetector CT acquires continuous volume datasets, which can then be used to create multiplanar reformatted images for additional information.[13] Axial reconstructions are most optimal at 5 mm or less.
Fig. 21.9. Nonsmall cell lung cancer in a 43-year-old woman. (A) A small irregular density overlying the anterior right second rib is difficult to visualize on posteroanterior chest radiograph; (B) the dual-energy subtraction soft-tissue window projection accentuates the opacity and facilitates detection; and (C) chest computed tomography (CT) image with contrast material was obtained and axial CT image in lung windows demonstrates a focal ground-glass lesion compatible with an adenocarcinoma.

Tumor (T) Descriptors

Evaluation of lung tumors is first based on the size of the lesion, which correlates with prognosis. Smaller lesions have better outcomes: the 5-year survival for T1a lung carcinoma is 77%. By contrast, T4 lung cancer is associated with a 15% 5-year survival rate.

Accordingly, lesions up to 3 cm are T1, lesions up to 2 cm are T1a, and lesions greater than 2 cm up to 3 cm are T1b. The T2 category is divided into two parts: T2a lesions are greater than 3 cm to 5 cm, and T2b masses are 5 cm to 7 cm in size. T3 lesions are greater than 7 cm in diameter or located less than 2 cm from the carina. T4 tumors involve the carina directly.[56,60]

Attendant factors upstage the T descriptor, including invasion of adjacent structures and collapse of the surrounding lung (Fig. 21.12).

Direct Invasion of the Pleura

Tumors that abut a pleural surface, including the fissures, for a contact distance of greater than 3 cm, are considered suspicious for possible pleural invasion. Other findings that suggest invasion include eradication of the extrapleural fat plane, an obtuse angle between the tumor and pleural surface, and a tumor–pleura contact that exceeds the tumor height.[61] Nevertheless, pleural invasion is not conclusively identified by imaging in most instances, excluding frank invasion of the chest wall; the pathologic evaluation of the resected specimen is definitive. Bone destruction and/or tumor tissue extending between the ribs is consistent with chest wall invasion, considered T3, which necessitates an en bloc resection of chest wall with the tumor.[13]
Fig. 21.10. Nonsmall cell lung cancer in a 76-year-old man. (A) Axial computed tomography (CT) image in lung windows and (B) coronal CT reformatted image in lung windows demonstrate asymmetry of the central bronchovascular structures, with an expanded tubular opacity in the left upper lobe. This is a potential blind spot on CT examinations.

Fig. 21.11. Computer-aided detection of nonsmall cell lung cancer. Software algorithms detect potential nodular opacities on computed tomography images. Although some of the identified abnormalities are seen to be false-positive results, such as bronchovascular branch points when evaluated by the radiologist, the computer-aided detection software can also recognize lung cancers, as in this case.

Direct Invasion of the Mediastinum

Stranding of the mediastinal fat subjacent to the tumor, contact length greater than 3 cm along the mediastinal margin, and contact with the aorta of greater than 90° are suspicious for possible invasion of the mediastinum. Obliteration of the fat plane between the tumor and mediastinal structures is suspicious and also raises the possibility of mural invasion involving systemic and pulmonary vascular structures. Nevertheless, prediction of subtle mediastinal invasion with conventional imaging is low.[13,62] Frank invasion of the heart or trachea can be seen and represents T4 disease.

Satellite Nodules

The presence of small lung nodules in addition to the dominant lesion also upstages the tumor. Satellite nodules within the
Fig. 21.12. Several findings will upstage nonsmall cell lung cancer. Axial computed tomography (CT) images in soft-tissue windows show (A) pleural invasion; (B) frank chest wall invasion through the intercostal space; and (C) cardiac invasion. Satellite nodules in the same lobe as the primary tumor are considered T3 disease, as seen on (D) coronal reformatted CT image in lung windows.

same lung lobe as the primary malignancy constitute T3 disease. Nodules ipsilateral to the tumor but in a different lung lobe represent T4 disease. If the nodules are in the contralateral lung, they are considered metastatic, M1a.[56]

Postobstructive Collapse or Pneumonitis

Lobar collapse around a central obstructing lesion constitutes T2 disease.

Lymph Node (N) Descriptors

Involvement of lymph nodes by tumor also has an effect on prognosis. Nodal basins commonly affected by lung cancer include the supraclavicular chains, the compartments of the mediastinum, and the hilar regions. Nodal disease occasionally but infrequently can be seen in the internal mammary chains, the parietal spaces, or the axillary and retropectoral spaces.

Lymph nodes that measure 1 cm or more in short-axis diameter on CT are considered to be suspicious for nodal metastatic disease despite relatively low sensitivity and specificity.[13] However, not all metastatic lymph nodes meet the size criteria for enlargement and not all enlarged nodes are metastatic. An analysis of resected nodes measuring 2 cm to 3 cm found that 37% had no metastatic involvement.[63] When nodal disease is not identified on standard CT, ^{18}F-2-deoxy-D-glucose (FDG)-PET or PET–CT can be useful for identifying small malignant nodes as well as for guiding biopsies. Lymph node sampling is performed to confirm the presence of nodal disease based on suspicious CT or PET–CT findings.[64]

Absence of nodal metastatic disease is considered N0. The presence of hilar or intrapulmonary lymphadenopathy ipsilateral to the tumor constitutes N1 disease. Metastatic adenopathy in the ipsilateral mediastinum and/or subcarinal region qualifies as N2 disease. The spread of metastases to the contralateral mediastinum, the contralateral hilum, or the supraclavicular or scalene

Fig. 21.13. Nonsmall cell lung cancer in a 68-year-old woman. Axial computed tomography with contrast material in soft-tissue windows demonstrates bulky metastatic disease causing severe compression of the trachea above the carina and the esophagus. Early invasion of the superior vena cava appears, although the vessel remains patent.

nodes of either side denotes N3 disease and raises the stage to IIIB, which is considered unresectable.[56,65]

When extensive bulky nodal disease is present, compression and/or frank invasion of the mediastinal vascular structures is possible, with danger of superior vena cava syndrome. Tracheal and/or esophageal compromise is also a concern (Fig. 21.13).

Metastasis (M) Descriptors

Metastatic disease includes pleural disease, contralateral pulmonary parenchymal nodules, osseous lesions, and deposits in extrathoracic organs. Two categories are designated. M1a disease comprises intrathoracic metastases, including malignant pleural disease and pulmonary nodules contralateral to the index tumor (Fig. 21.14). Pericardial and myocardial metastases are also considered to be in the M1a category. M1b disease incorporates extrathoracic metastatic lesions (Fig. 21.15).[56,66] The distribution is based on outcome data showing that survival was significantly worse among patients with metastases outside the thorax than among patients with metastatic disease confined to the lung and pleura.[66]

A pleural effusion is seen in up to 33% of individuals who present with NSCLC. Etiologies include sympathetic and parapneumonic processes in addition to neoplasm, and so definitive characterization is required. Malignant pleural effusion can be a difficult diagnosis unless pleural nodularity is clearly evident on CT, as thoracentesis is positive in 65% of cases. Nevertheless, a second thoracentesis may identify up to 30% more individuals with malignant effusion, and repeat thoracentesis is advised as the next step in the investigation. If the diagnosis remains in doubt, thoracoscopy is used, with accurate diagnosis of pleural involvement in more than 95% of patients.[67]

When clinical examination is normal, the risk of discovering extrathoracic metastases on imaging is low. However, metastatic disease is found on imaging workup in more than 50% of patients with an abnormal clinical examination.[13] The relative frequencies of metastatic deposits in extrathoracic organs from NSCLC have been reported as 3% for adrenal gland, 5% for liver, 7% for bone, and 10% for brain.[13,68]

Adrenal Gland Imaging

CT imaging through the adrenal glands is recommended for staging of lung cancer and is almost invariably included as part of the dedicated chest CT.[13] The finding of an adrenal nodule should be evaluated, but statistically, benign adrenal adenomas are present in at least 10% of the general population. Characteristics of benign adrenal nodules include smaller size (<2 cm), low attenuation (<10 HU) on noncontrast studies, sharper definition, and lack of enhancement. Conversely, malignant nodules are often larger, have heterogeneous attenuation, and are often diffuse rather than focal. In indeterminate cases, in-phase and out-of-phase MRI can identify the presence of microscopic fat consistent with benign adenoma. PET–CT may also be helpful, as adenomas generally have little or only background FDG activity. Fine-needle aspiration biopsy can resolve additional questions.[13]

Liver Imaging

Lung cancer metastases to the liver are usually seen in the context of other metastatic disease to regional nodes and so rarely alter management.[13] Liver metastases were found in 3% of asymptomatic individuals with NSCLC in one meta-analysis.[69] The staging chest CT includes most of the liver in the field of view. Use of intravenous contrast medium improves identification and characterization of hepatic lesions.

Bone Imaging

Asymptomatic bone metastases are uncommon.[13] CT is more sensitive than radiography for the detection of small osseous lesions without pathologic fracture. Ill-defined lucencies within bone on CT images raise concern about metastatic deposits. Nuclear scintigraphy with technetium-99m or PET–CT can be used for evaluation, and some lesions may exhibit FDG activity before becoming radiographically evident.

Brain Imaging

Brain metastases from lung cancer are often not clinically apparent.[13] Therefore dedicated brain imaging with contrast-enhanced head CT or brain MRI is recommended, not just for symptomatic individuals but also for asymptomatic individuals with advanced local disease who are being considered for aggressive treatment. Occult brain metastases are more likely to occur with larger primary tumors. Squamous cell carcinomas are less likely to metastasize to the brain than are adenocarcinomas or SCLC.[13]

IMAGE-GUIDED BIOPSY

Transthoracic needle biopsy for tumor cell–type analysis and for confirmation of metastatic disease is most often guided by CT (Fig. 21.16), although a superficial lesion such as in the chest wall could be accessed using ultrasound guidance.[13] CT-guided biopsy has a reported accuracy rate of 80% to 95% in positive tumor identification. By contrast, transbronchial biopsy has good results with central endobronchial lesions, but its accuracy rate is less than 80% for peripheral tumors.[13] Surgical open-lung biopsy or video-assisted thoracoscopic surgery can be useful to obtain larger tissue samples but has increased associated morbidity.[9,70]

Currently, a core-needle biopsy is recommended to provide sufficient tissue for biomarker analysis performed once the cell type has been established. In cases of necrotic or cavitary lesions, the sample should be taken from the wall of the tumor rather than the acellular center.[13]
Fig. 21.14. Metastatic disease in the M1a category is limited to the thorax. (A) Axial computed tomography (CT) image in lung windows demonstrates a dominant right upper lobe tumor and a satellite nodule in the left upper lobe, compatible with metastasis in a 54-year-old man; (B) axial CT image in lung windows for another 61-year-old male never-smoker shows innumerable bilateral miliary metastases, associated in this case with a papillary adenocarcinoma; (C) axial CT image with contrast material in soft-tissue windows shows pleural nodularity and cytology-proven malignant effusion in this 63-year-old man with metastatic adenocarcinoma; and (D) axial CT image with contrast material in soft-tissue windows demonstrates several pericardial metastases in a 64-year-old woman with nonsmall cell lung cancer.

CT IMAGING OF RESPONSE TO THERAPY

Lung cancers may be treated with chemotherapy, radiation, or surgery or a combination of these modalities. Chest CT plays a crucial role in evaluating response to therapy and in assessing treatment complications.

Chemotherapy

Neoadjuvant chemotherapy may be administered in an effort to diminish tumor size before planned resection. Systemic chemotherapy is also the standard of care in cases of metastatic disease. Imaging with chest CT at regular intervals is useful to assess the efficacy of a chemotherapy regimen and to avoid unnecessary toxicity if the chemotherapy is ineffective.

Drug toxicity related to chemotherapy can manifest in the lungs as almost any pattern of interstitial pneumonia, including nonspecific interstitial pneumonia, usual interstitial pneumonia, organizing pneumonia, eosinophilia with pulmonary infiltrates, lymphocytic interstitial pneumonia, and desquamative interstitial pneumonia.[71] Drug toxicity typically occurs during treatment with a chemotherapy agent, and cessation of the offending agent usually results in improvement. Patients receiving multidrug therapy are at an increased risk of drug toxicity.[71] In some cases of pulmonary fibrosis, the damage cannot be reversed.[71]

CT findings suggesting possible drug toxicity include intralobular and interlobular septal thickening, nodular opacities, mosaic lung attenuation, diffuse alveolar opacities, migratory opacities, bronchovascular opacities, and honeycombing.[71]

Radiotherapy

Radiotherapy may be used as definitive treatment with curative intent for stage I or II lung cancer, particularly for individuals with comorbidities such as severe emphysema and cardiovascular disease that may make surgery inadvisable. In later-stage but resectable cancers, radiotherapy may be used as adjuvant therapy in conjunction with surgery for improved local control of disease; it can also be used for palliation.[72]
Fig. 21.15. Metastatic disease in the M1b descriptor includes metastases to the extrathoracic organs. (A) Axial computed tomography (CT) image with contrast material in soft-tissue windows shows a large, heterogeneously enhancing left adrenal mass, proven by examination of a biopsy specimen to be metastatic adenocarcinoma. (B) Axial CT image in bone windows demonstrates a lytic metastasis in the right T4 transverse process.
Fig. 21.16. Axial image from computed tomography–guided biopsy in lung windows with a patient in prone position shows the biopsy needle in the center of the large irregular right lung mass having histology consistent with undifferentiated small cell lung cancer.

Conventional opposed parallel beam radiotherapy has been largely supplanted in the past several years by three-dimensional (3-D) conformal radiotherapy and stereotactic ablative radiotherapy, which use multiple beams to minimize the radiation dose to normal structures while delivering a high dose to the tumor tissue.[72] Chest CT is used to ascertain response of the treated lesion, to monitor other potential effects of the radiation, and to exclude any recurrence within the radiation field or the appearance of metastatic disease outside of it.

Decreased size of the irradiated tumor is often observed soon after treatment, without any ancillary findings.[72] Radiation-induced changes in the surrounding lung parenchyma are categorized as early phase radiation pneumonitis, corresponding with the acute exudative and proliferative phases of alveolar damage and occurring 1 month to 6 months after completion of treatment, and late-phase radiation fibrosis with collagen deposition taking place from 6 months to 24 months after treatment cessation.[72–74] These changes are often progressive along a continuum, although radiation pneumonitis can spontaneously resolve. Although several factors influence radiation damage, including preexisting patient conditions, the degree of severity of the lung injury directly correlates with the radiation dose, particularly the percentage volume that receives greater than 20 Gy.[72,74] Clinically significant, symptomatic pulmonary toxicity (grade 2 and above) from radiation develops in up to 37% of patients receiving 3-D conformational radiotherapy and 4% of patients receiving stereotactic ablative radiotherapy, requiring steroid and other treatment. Some chemotherapy drugs, including bleomycin, doxorubicin, and busulfan, can increase radiation effects.[72]

The appearance of radiation-induced lung injury on CT has conventionally been described as having four patterns. Two of these, homogeneous slight ground-glass attenuation involving the radiation field and patchy consolidation within but not conforming to the radiation port, correspond with radiation pneumonitis. Discrete but nonuniform consolidation is the third pattern. Solid consolidation of the entire irradiated portion of the lung with volume loss, architectural distortion, and traction bronchiectasis represents the fourth pattern, radiation fibrosis.[73,75] Pleural effusion is also considered a treatment effect.[72]

With the newer radiation techniques, the resulting patterns of lung injury have somewhat different morphology and distribution. Focal ground glass or consolidation representing radiation pneumonitis is typically seen only in the area directly adjacent to the treated tumor, although discrete opacities can be seen in other parts of the radiation field.[72] Radiation fibrosis after 3-D conformational radiotherapy or stereotactic ablative radiotherapy can have a modified conventional pattern, similar to but less extensive than traditional radiation fibrosis. Focal fibrosis and traction bronchiectasis confined to the area around the tumor is classified as mass-like. A 1-cm wide linear
Fig. 21.17. Sequela of stereotactic ablative radiation, scar-like pattern of fibrosis. (A) Axial computed tomography (CT) image in lung windows shows a small heterogeneous left lower lobe tumor with pleural tethering compatible with a primary adenocarcinoma; (B) the beams from different directions used to treat the lesion as well as the diminishing radiation dose at specific distances from the target are documented in the radiation treatment-planning CT study; and (C) axial CT image in lung windows shows a small focal opacity in the left lower lobe with volume loss and minimal band-like scarring.

or plate-like opacity causing volume loss and replacing the original tumor is considered the scar-like pattern of fibrosis (Fig. 21.17).[72]

CT findings that should prompt suspicion of disease recurrence in the radiation field include development of a mass or cavitation within radiation fibrosis, new occlusion of dilated bronchi within the fibrosis, and/or late appearance or enlargement of an ipsilateral pleural effusion.[76] A recurrent tumor usually occurs within 2 years after completion of treatment.[72]

Surgical Resection

After surgical resection of lung tumors with lobectomy or pneumonectomy, periodic CT studies are used to exclude recurrent disease at the surgical site as well as to monitor for late metastatic disease. After surgical resection, patients are followed-up with contrast-enhanced chest CT every 3 months to 4 months for the first 2 years. In the absence of any concerning finding at the end of 2 years, these patients may have annual follow-up with noncontrast CT.

IMAGING OF EMERGENT CONDITIONS IN LUNG CANCER

In some circumstances, lung cancer can cause severe secondary abnormalities that require emergent identification and treatment.

Pulmonary Embolism

Malignancy is a known risk factor for coagulopathy, and the development of deep venous thrombosis and pulmonary thromboembolic disease is an important potential complication. Clinically unsuspected pulmonary emboli are seen in up to 4% of asymptomatic individuals with cancer on multidetector CT; the prevalence is higher with some types of malignancies, including melanoma and gynecologic tumors, among individuals with progressive disease and also among patients receiving chemotherapy.[77,78] Pulmonary emboli can manifest as pruning of pulmonary arteries distal to the clot (Westermark sign) or as a wedge-shaped infarct (Hampton hump sign) on chest radiography; however, radiographs are most often normal in the setting of pulmonary embolism. Use of contrast-enhanced
Fig. 21.18. Stump thrombus after right pneumonectomy. Axial computed tomography image with contrast material in soft-tissue windows shows a small dense opacity in the ligated right pulmonary artery, outlined by intravenous contrast material in the pulmonary arterial tree. The pneumonectomy space has an expected appearance, as it is entirely filled with fluid.

multidetector CT with thin 1.25-mm reconstructions is helpful for detection, localization, and assessment of clot burden. Emboli in the pulmonary arteries are outlined by intravenous contrast material, which is white on CT; they appear as low-density masses with often elongated shapes within the opacified vessels. The presence or absence of right ventricular strain should also be evaluated.[77]

Acute pulmonary embolism is different from stump thrombus, in which turbulent flow produces a small clot within a ligated pulmonary artery after pneumonectomy (Fig. 21.18); stump thrombosis is a recognized complication in 12% of pneumonectomy cases. Although systemic anticoagulation is not required in all cases, subsets of patients may require treatment.[79]

Superior Vena Cava Syndrome

Occlusion of the superior vena cava is associated with primary lung cancer in 50% to 80% of cases. Tumor tissue and/or metastatic lymphadenopathy can compromise the patency of the superior vena cava via extrinsic compression or vascular invasion.[77] Collateral circulation may develop if the process is sufficiently gradual, but acute obstruction may also occur. Superior vena cava syndrome is a clinical diagnosis, and associated imaging findings include widening of the mediastinum on radiographs and mediastinal soft tissue on CT, interruption of contrast material within the superior vena cava on contrast-enhanced CT, and opacification of collateral vascularity (Fig. 21.19).[77]

Central Airway Obstruction

Primary lung cancer is also the most common cause of endobronchial obstruction. The severity of clinical symptoms is related to the location of the lesion; "lesions in the upper airways can be acutely life-threatening if the airway is blocked."[77] Narrowing of the airway lumen can be extrinsic or it can result from a lesion of the bronchial wall. Stenting may be used to preserve patency if surgical resection is precluded. Radiation is also used to debulk tumors and improve air flow.[77]

IMAGING WITH MRI

Multidetector CT and FDG-PET–CT are routinely used to initially stage lung cancer, evaluate treatment response, and detect residual or recurrent disease. The role of MRI has historically been limited to evaluating superior sulcus tumors and identifying involvement of the mediastinum, chest wall, and spinal cord, but technologic advances have expanded the techniques available to radiologists and improved the image quality of MRI.[80] The applications of MRI have been extended to include the identification and characterization of pulmonary nodules, differentiation of lung cancer from other pulmonary processes, and detection of lymph node involvement and distant metastases as part of lung cancer staging.[81]

Identification of Pulmonary Nodules

Although multidetector CT is considered the standard criterion for identifying pulmonary nodules, several studies have been performed to assess the efficacy of nodule detection by MRI. In general, detection rates of 46% to 96% have been reported using a wide variety of MRI sequences on 1.5-T and 3-T systems.[82–86] The efficacy of MRI in detecting pulmonary nodules is most dependent on the size of the nodule and the specific imaging sequences used. For instance, Schroeder et al.[85] found sensitivities of 73%, 86.3%, 95.7%, and 100% for nodules measuring less than 3 mm, 3 mm to 5 mm, 6 mm to 10 mm, and greater than 10 mm, respectively, on T2-weighted half-Fourier acquisition single-shot turbo spin-echo sequences. Biederer et al.[83] demonstrated a sensitivity of 88% for 4-mm nodules on 3-D and two-dimensional gradient-echo sequences, as well as sensitivity, specificity, and positive and negative predictive values close to 100% for nodules greater than 5 mm on all MRI sequences other than T2-weighted half-Fourier acquisition single-shot turbo spin-echo.[83]

In general, the nodule detection rate is higher with spin-echo sequences than gradient-echo sequences.[82–86] Bruegel et al.[87] found sensitivities of 72%, 69%, and 63.4% for nodule detection on triggered short-tau inversion recovery, fast spin-echo, and short-tau inversion recovery sequences, respectively. This group reported that the sensitivities of sequences such as half-Fourier acquisition single-shot turbo spin-echo, inversion recovery half-Fourier acquisition single-shot turbo spin-echo, and precontrast and postcontrast volumetric interpolated 3-D gradient echo
Fig. 21.19. Superior vena cava obstruction. Axial computed tomography image with contrast material in soft-tissue windows demonstrates amorphous soft-tissue density in the region of the left brachiocephalic vein and superior vena cava. Numerous opacified collateral vessels appear in the left chest wall and in the mediastinum, which provide blood return to the right atrium; intravenous contrast material has reached the systemic arterial circulation as evidenced by the opacified aortic arch.

were less than other fast spin-echo sequences.[87] Both et al.[88] demonstrated sensitivities of 85% and 90% for nodules measuring greater than 4 mm on T2-weighted half-Fourier fast spin-echo and T1-weighted gradient-echo sequences, respectively.[88] Short-tau inversion recovery sequences alone have demonstrated sensitivities greater than 90% in detecting nodules measuring 3 mm and larger.[89] The efficacy of diffusion-weighted imaging in detecting pulmonary nodules has been reported. Koyama et al.[90] demonstrated a lower detection rate for diffusion-weighted imaging (85%) compared with short-tau inversion recovery (100%), and limited ability to detect small nodules and nonsolid adenocarcinomas on diffusion-weighted imaging.

Characterization of Pulmonary Nodules

The characterization of pulmonary nodules with conventional imaging is widely used but has limitations. For example, multidetector CT provides morphologic information only, and differentiating between benign and malignant nodules is limited to classic appearances of calcium or fat within the nodule. Dynamic contrast-enhanced CT has demonstrated high sensitivity but limited specificity in differentiating between nodules secondary to overlapping enhancement patterns in active granulomatous processes, hypervascular benign nodules, and malignant nodules.[91,92] Lastly, the effectiveness of PET and PET–CT is limited by false-positive results due to infection and inflammation and false-negative results in the setting of some adenocarcinomas and carcinoids.[93]

MRI also has limitations, but investigations show promise in improving characterization of nodules. On T1-weighted and T2-weighted spin-echo images, many pulmonary nodules, lung cancers, and metastases demonstrate low or intermediate signal intensity.[94–98] Short-tau inversion recovery sequences are better than T1-weighted and T2-weighted sequences at differentiating between benign and malignant nodules; however, their sensitivity, specificity, and accuracy are 83.3%, 60.6%, and 74.5%, respectively.[82] Koyama et al.[82] evaluated the efficacy of noncontrast multidetector CT and 1.5-T MRI in detecting pulmonary nodules and differentiating between benign and malignant nodules in 161 individuals. The sensitivity of nodule detection was higher for multidetector CT (97%) than short-tau inversion recovery turbo spin-echo sequences (82.5%), but the malignant nodule detection rates were similar (100% for multidetector CT and 96.1% for MRI). Several studies evaluating the efficacy of

diffusion-weighted imaging in characterizing pulmonary nodules have yielded mixed results. In general, malignant lesions demonstrate high signal intensity on diffusion-weighted imaging and low apparent diffusion coefficient due to increased cellularity, high tissue disorganization, and increased extracellular space tortuosity. Although diffusion-weighted imaging may be more beneficial than traditional T1-weighted and T2-weighted sequences, false-positive results due to infectious and inflammatory lesions and false-negative results in the setting of some low-grade adenocarcinomas and metastases limit its effectiveness.[99]

Ultrafast dynamic contrast-enhanced sequences have been used in dynamic perfusion MRI studies to differentiate between benign and malignant nodules. Malignant nodules typically demonstrate homogeneous enhancement on T1-weighted images after the administration of intravenous contrast material. Factors such as tumor angiogenesis, tumor necrosis, scarring, presence or absence of fibrosis, and tumor interstitial spaces result in some variability.[94–98,100] Information regarding enhancement patterns or blood supply obtained from dynamic contrast-enhanced MRI may be beneficial in distinguishing between benign and malignant nodules. Various dynamic MRI techniques have been used for this purpose, with reported sensitivities of 94% to 100%, specificities of 70% to 96%, and accuracies greater than 88%.[94–97,100]

Ohno et al.[98] demonstrated higher specificity and accuracy for MRI in differentiating between benign and malignant nodules compared with multidetector CT and FDG-PET. Specifically, the accuracies of dynamic contrast-enhanced MRI, dynamic contrast-enhanced multidetector CT, and PET–CT were 88.1%, 83.2%, and 83.7%, respectively. Currently, no imaging methodology is without limitations, and MRI remains an important tool in the armamentarium.

USE OF MRI IN STAGING OF LUNG CANCER

T Descriptors

MRI is superior to CT in differentiating lung cancers from other pulmonary processes such as atelectasis or consolidation. For instance, although many tumors demonstrate high signal intensity on T2-weighted imaging (Fig. 21.20), postobstructive atelectasis and pneumonitis typically demonstrate greater signal intensity than do malignancies.[101] On diffusion-weighted imaging, lung cancers demonstrate higher signal intensity than postobstructive atelectasis.[102] MRI is better than CT in evaluating the heart, pericardium, and great vessels and can be used to assess invasion of the cardiac chambers (Fig. 21.21), myocardium, or superior vena cava.[103]

One of the most important uses of MRI in the staging of lung cancer is the determination of mediastinal and/or chest wall invasion. Malignancies that invade only the mediastinal fat may be surgically resected, whereas malignancies that invade mediastinal structures are generally considered unresectable. The Radiologic Diagnostic Oncology Group first reported that MRI was significantly more accurate than CT in identifying invasion of the mediastinum.[80] In one study, Ohno et al.[103] evaluated 50 individuals with NSCLC and suspected mediastinal and/or hilar invasion with contrast-enhanced CT, cardiac-gated MRI, and noncardiac-gated and cardiac-gated MR angiography. Compared with contrast-enhanced CT and T1-weighted imaging, the reported sensitivity of 78% to 90%, specificity of 73% to 87%, and accuracy of 75% to 88% for MR angiography in identifying invasion of the mediastinum and hilum were greater.

The reported sensitivity and specificity for detection of chest wall invasion by CT are highly variable, with values of 38% to 87% and 40% to 90%, respectively.[104] Findings on MRI suggestive of chest wall invasion include infiltration or disruption of the normal extrapleural fat plane on T1-weighted sequences or hyperintensity of the parietal pleura on T2-weighted
Fig. 21.20. Nonsmall cell lung cancer in a 49-year-old woman. Axial T2-weighted magnetic resonance imaging (MRI) demonstrates a hyperintense nodule *(arrow)* with irregular margins in the right lung. Examination of a biopsy specimen indicated squamous cell carcinoma. Many primary and secondary malignancies of the lung demonstrate high signal intensity on T2-weighted MRI.
Fig. 21.21. Invasion of the cardiac chambers by a small cell lung cancer in a 57-year-old woman. Coronal balanced steady-state free precession magnetic resonance imaging (MRI) shows the primary tumor *(long arrow)* in the medial right upper lobe extending through the right superior pulmonary vein into the left atrium *(short arrow)*. MRI is superior to computed tomography in evaluating for involvement of the heart, pericardium, and great vessels.

sequences.[105,106] Short-tau inversion recovery sequences may demonstrate high signal intensity within the chest wall structures whose signal is otherwise suppressed by this technique (Fig. 21.22).[105] The administration of intravenous contrast material may assist in making the diagnosis.[105] Techniques such as cine MRI during breathing may be used to identify
Fig. 21.22. Superior sulcus tumor invading the chest wall in a 61-year-old man. (A) Coronal T1-weighted noncontrast; (B) T1-weighted postcontrast; and (C) short-tau inversion recovery magnetic resonance images demonstrate a large mass in the right upper lobe. Note the region of tumor enhancement and short-tau inversion recovery hyperintensity extending through the intercostal space into the chest wall, consistent with invasion.

chest wall invasion, as fixation of the tumor to the chest wall suggests involvement, but free movement of the tumor along the parietal pleura suggests absence of invasion.[107] One study using both dynamic cine MRI and CT demonstrated sensitivity, specificity, and accuracy of 100%, 70%, and 76%, respectively, for cine MRI, and 80%, 65%, and 68%, respectively, for CT.[107]

N Descriptors

The MRI sequences recommended for optimal detection of metastatic lymph nodes include cardiac-triggered and/or respiratory-triggered conventional or black-blood short-tau inversion recovery turbo spin-echo sequences.[81,108] Metastatic lymph nodes typically demonstrate high signal intensity on short-tau inversion recovery sequences, whereas normal lymph nodes show low signal intensity. Estimates of the sensitivity, specificity, and accuracy of short-tau inversion recovery turbo spin-echo imaging have been reported as 83.7% to 100%, 86% to 93.1%, and 86% to 92.2%, respectively.[81,108] Compared with CT, the sensitivity and accuracy of short-tau inversion recovery are much higher.[81] Another study demonstrated that the sensitivity and accuracy of MRI using short-tau inversion recovery sequences were much better than those of PET–CT, at 90.1% and 92.2%, compared with 76.7% and 83.5%, respectively.[108] Yi et al.[109] demonstrated no significant differences between whole-body MRI and PET–CT in determining nodal involvement and also reported that specific findings such as high signal intensity and eccentric cortical thickening or obliterated fatty hilum on T2-weighted black-blood turbo spin-echo sequences were reliable indicators of malignancy (Fig. 21.23). Nomori et al.[110] demonstrated that diffusion-weighted imaging was more accurate than PET in establishing nodal disease. However, the intrinsic low spatial resolution of diffusion-weighted imaging limits detection of small lymph nodes and localization of abnormal lymph nodes.

M Descriptors

FDG-PET–CT is the imaging modality of choice for detecting metastatic disease, and the addition of FDG-PET to conventional staging examinations has resulted in greater detection
Fig. 21.23. Pathologic lymphadenopathy in a 51-year-old man with nonsmall cell lung cancer. Axial T2-weighted magnetic resonance image demonstrates an irregular nodule *(long arrow)* in the right lung that represents the patient's primary lung cancer. Note the enlarged and slightly hyperintense right paratracheal lymph node *(short arrow)*. Examination of a biopsy specimen of the lymph node indicated malignant involvement. Studies have demonstrated that specific findings such as high signal intensity and eccentric cortical thickening or obliterated fatty hilum on T2-weighted black-blood turbo spin-echo sequences are reliable indicators of malignancy.

of extrathoracic metastases.[111] One study demonstrated similar accuracy between PET–CT (88.2%) and whole-body MRI (87.7%) for detecting metastatic disease,[112] and another demonstrated no significant differences between the diagnostic value of PET–CT and MRI in the preoperative staging assessment of NSCLC.[113]

PET and PET–CT are best at demonstrating osseous and soft-tissue metastases, whereas MRI is best at identifying brain,

liver, and adrenal metastases secondary to superior soft-tissue contrast.[101] The sensitivity of PET and PET–CT in detecting brain metastases is limited by hypermetabolism of the brain parenchyma. Therefore CT and/or MRI are recommended for detection of brain metastases (Fig. 21.24). Hepatic metastases typically manifest as enhancing lesions on T1-weighted

images after the administration of intravenous contrast material. Chemical-shift MRI techniques may be used to identify adrenal adenomas with a sensitivity of 100% and specificity of 81% and distinguish between adenomas and metastatic disease.[101] The loss of signal on T1-weighted out-of-phase imaging from an adrenal lesion is consistent with an adrenal adenoma (Fig. 21.25), whereas a persistent high signal is suggestive of metastasis (Fig. 21.26).

MRI OF RESPONSE TO THERAPY

Specific sequences such as dynamic contrast-enhanced and diffusion-weighted imaging with apparent diffusion coefficient have been used to assess the ability of MRI to detect response among patients treated with chemoradiation therapy. Chang et al.[114] suggested that dynamic contrast-enhanced MRI had the potential to predict early response in patients treated with bevacizumab, gemcitabine, and cisplatin. Yabuuchi et al.[115] reported a significant correlation between early changes in apparent diffusion coefficient and reduction in tumor size, as well as greater median progression-free survival and median overall survival in patients whose tumors demonstrated increases in apparent diffusion coefficient. Results from another study suggest that early changes in apparent diffusion coefficient values may be used to monitor early response of lung cancer to chemoradiation therapy.[116]

CONCLUSION

Conventional radiographic imaging studies play a crucial role in the detection and staging of lung cancer. Chest radiographs may provide the earliest opportunity to identify an unsuspected lung cancer. CT is essential for the characterization of abnormalities and determines preliminary staging for a tumor once a tissue diagnosis is established. MRI of localized regions in the chest can provide information, particularly regarding soft-tissue and neurovascular invasion. These imaging modalities work in concert with PET–CT and with surgical biopsy to guide management and treatment planning.

Fig. 21.24. Brain metastases in a 64-year-old man with nonsmall cell lung cancer. Axial contrast-enhanced T1-weighted magnetic resonance imaging (MRI) demonstrates a peripherally enhancing lesion *(arrow)* in the right posterior temporal/parietal lobe. Examination of a biopsy specimen indicated metastatic disease from the patient's lung cancer. Because the sensitivity of positron emission tomography (PET) and PET/computed tomography (CT) in detecting brain metastases is limited by hypermetabolism of the brain parenchyma, CT and/or MRI is preferred for identifying brain metastases.

Fig. 21.25. Left adrenal adenoma in a 54-year-old woman with nonsmall cell lung cancer. (A) Noncontrast axial computed tomography (CT) image demonstrates a well-circumscribed nodule in the left adrenal gland *(white arrow)* that did not meet the CT criteria for an adenoma. Axial T1-weighted (B) in-phase and (C) out-of-phase magnetic resonance images of the same patient show loss of signal *(white arrow)* on the out-of-phase imaging, indicating the presence of microscopic fat and highly suggestive of an adenoma.
Fig. 21.26. Left adrenal metastasis in a 49-year-old woman with nonsmall cell lung cancer. (A) Noncontrast axial computed tomography (CT) image demonstrates a well-circumscribed nodule in the left adrenal gland (*white arrow*) that did not meet the CT criteria for an adenoma. Axial T1-weighted (B) in-phase and (C) out-of-phase magnetic resonance images of the same patient show persistent high signal in the nodule. Examination of the specimen after CT-guided biopsy confirmed metastasis from the patient's nonsmall cell lung cancer.

22 Positron Emission Tomography Imaging of Lung Cancer

Jeremy J. Erasmus, Feng-Ming (Spring) Kong, and Homer A. Macapinlac

SUMMARY OF KEY POINTS

- ^{18}F-2-deoxy-D-glucose (FDG)-positron emission tomography–computed tomography (PET–CT) is routinely used clinically for diagnosis, staging, and radiation treatment planning and may have a role in prognosis and monitoring of treatment response.
- FDG-PET–CT is not optimal in determination of T descriptors (additional small lung nodules, locoregional invasion, etc.) as respiratory motion and or low-radiation-dose imaging degrade image quality.
- FDG-PET–CT has superior accuracy compared with CT in detecting hilar (N1), mediastinal (N2, N3), and extrathoracic (N3) nodal metastasis.
- FDG-PET–CT has superior accuracy compared with CT in detecting M1b and M1c (extrathoracic) metastasis.
- FDG-PET–CT detection of occult metastasis (M1b/M1c) increases as T and N descriptors increase and impact on management is greater in patients with more advanced disease.
- FDG uptake threshold such as standardized uptake value (SUV) is unreliable in differentiating inflammatory from metastatic disease.
- FDG-PET prognostic information is not dependable and may be confounded by limitations of SUV reproducibility.
- FDG-PET–CT metabolic tumor volume and total lesion glycolysis (which take into account tumor size and uptake of FDG) may be important prognostic factors.
- FDG-PET–CT may allow an early and sensitive assessment of antitumor effect after therapy.
- FDG-PET–CT improves accuracy of target delineation in radiation treatment planning.
- A PET–CT-defined tumor target is usually smaller than that defined by CT, and incorporation of PET–CT into radiotherapy planning can allow radiation-dose escalation without increasing side effects.
- FDG is the only Medicare-approved PET–CT tracer for evaluation of cancer.
- Novel PET radiotracers that interrogate different metabolic pathways beyond glycolysis, receptors, and targets are being evaluated in staging, response evaluation, and targeted therapy assessment.

PET using the radiopharmaceutical FDG, a D-glucose analog labeled with fluorine-18, complements conventional radiographic imaging for the evaluation of patients with nonsmall cell lung cancer (NSCLC). FDG-PET has an important role in the staging of NSCLC according to the tumor, node, and metastasis (TNM) system and is routinely used to improve the detection of nodal and extrathoracic metastases. FDG-PET is also currently used to improve the planning of radiation

therapy and is being evaluated for the assessment of prognosis and therapeutic response. By potentially allowing for an earlier and more sensitive assessment of the effect of antitumor therapy, FDG-PET may be predictive of the outcome of treatment and the survival of patients after treatment. This chapter will discuss the use of FDG-PET for the staging of disease, the planning of radiation therapy, and the assessment of outcome and prognosis, with an emphasis on the appropriate clinical use of FDG-PET for the treatment of patients who have NSCLC. In addition, the use of novel radiotracers that interrogate different metabolic pathways, receptors, and targets to overcome the potential limitations of FDG-PET in staging, as well as early response evaluation and monitoring of response to targeted therapies, will be reviewed.

STAGING OF LUNG CANCER

Size, Location, and Locoregional Invasion (T Descriptor)

FDG-PET is used together with CT because the integration of metabolic activity with the high-spatial resolution of CT is important for the evaluation of tumors in terms of size, location, and the degree of locoregional invasion (T descriptor) as well as for the determination of the anatomic location of regions of focally increased FDG uptake.[1,2] It is important to be aware that the relatively poor spatial resolution of PET limits its utility for the evaluation of the primary tumor. However, the CT component of integrated PET–CT also has shortcomings in terms of its ability to accurately demonstrate T descriptors such as the presence of additional small lung nodules and locoregional invasion as it is often performed during respiration and with a low-radiation-dose imaging protocol, both of which can compromise image quality. Nevertheless, FDG-PET improves the detection of nodal and distant metastases and frequently alters the treatment of patients.[3–8] Accordingly, this review of TNM staging will focus on the important role of PET imaging for the detection of nodal and distant metastases at the time of initial staging according to the seventh edition of the American Joint Committee on Cancer TNM staging system and will reference the proposals for the forthcoming eighth edition when applicable.[9–15]

Regional Lymph Nodes (N Descriptor)

The presence and location of nodal metastasis (N descriptor) are important when determining the treatment of and prognosis for patients with NSCLC and, because these descriptors adequately predict prognosis, they will be maintained in the forthcoming eighth staging system.[10,13,14] Lymph node maps, in which the node stations are numbered according to anatomic structures, are commonly used in an attempt to ensure uniformity when designating the clinical and pathologic extent of nodal metastases.[16,17] There is no universally accepted nodal map and the International Association for the Study of Lung Cancer has proposed a new lymph node map that reconciles the differences among the currently used maps.[18] However, while a precise and universally accepted nomenclature to describe lymph node involvement is essential for selecting appropriate
Fig. 22.1. A 49-year-old man with NSCLC who was being evaluated for surgical resection. (A) Axial contrast-enhanced CT showing a 2.5-cm nodule in the upper lobe of the right lung and a small node (short-axis diameter, 1 cm) in the ipsilateral mediastinum *(arrow)*. (B) Axial PET–CT scan showing increased FDG uptake in the nodule and in the right lower paratracheal lymph node. A biopsy was positive for nodal metastatic disease, and the patient underwent neoadjuvant chemotherapy followed by concurrent chemoradiation.

therapy and assessing the outcomes of treatment, a major shortcoming of clinical staging is the use of nodal size to detect metastatic disease. Toloza et al.,[19] in a meta-analysis of 20 studies (3438 patients) that was performed to evaluate the use of CT for staging of the mediastinum, found that the use of a short-axis diameter of more than 1 cm as the threshold for the detection of nodal metastasis was associated with a pooled sensitivity of 57% and a pooled specificity of 82%.

FDG-PET is more accurate than CT for staging of the mediastinum in terms of nodal involvement, and FDG-PET is being increasingly integrated into both surgical and radiation oncology treatment strategies for patients with NSCLC (Fig. 22.1).[3,4,6,20] Birim et al.,[4] in a meta-analysis of 17 studies (833 patients) in which PET was compared with CT for nodal metastasis detection in patients with NSCLC, reported that the overall sensitivity and specificity of FDG-PET for detecting mediastinal lymph node metastases were 83% (range, 66–100%) and 92% (range, 81–100%), respectively, whereas those of CT were 59% (range, 20–81%) and 78% (range, 44–100%), respectively. In addition, improvement in the accuracy of nodal metastasis detection has been reported in association with the use of integrated PET–CT as compared with the use of CT ($p = 0.004$) and PET ($p = 0.625$) separately.[1] However, in a recent study of 159 patients with NSCLC, the use of PET–CT for mediastinal N determination was associated with low sensitivity and accuracy.[21] Based on the evaluation of 1001 nodal stations (723 mediastinal, 148 hilar, and 130 intrapulmonary), the sensitivity, specificity, and accuracy of PET–CT for the detection of mediastinal nodal metastasis were 45.2%, 94.5%, and 84.9%, respectively. The sensitivity of PET–CT for the detection of malignant involvement was 32.4% (12 of 37) for nodes measuring less than 10 mm and 85.3% (29 of 34) for nodes measuring 10 mm or more. Although infrequently addressed, the timing of PET–CT imaging may affect N determination. Ideally, PET imaging for the evaluation of nodal metastasis in patients being evaluated for surgical resection should be performed in close temporal relationship to the anticipated date of resection. In this regard, there may be a meaningful association between the sensitivity of PET–CT and the time from imaging to resection.[22] Booth et al.[22] reported that the sensitivity and accuracy of PET–CT for N2 nodal detection were 64% and 94%, respectively, when performed less than 9 weeks before pathologic sampling,

compared with 0% and 81%, respectively, when performed 9 weeks or more before pathologic sampling.

Despite the superior accuracy of FDG-PET–CT over CT in terms of N determination, a limitation is the overlap in the appearance of malignant and benign lymph nodes as microscopic nodal metastases normally are not FDG-avid, whereas inflammatory lymph nodes can be FDG-avid. The use of an FDG uptake threshold such as the maximum standardized uptake value (SUV_{max}) to differentiate inflammatory from metastatic nodal disease has limited utility for clinical N determination as numerous factors, including the time to imaging after FDG administration and the type of scanner and image reconstruction algorithm used, can affect the thresholds selected. We are not aware of any prospective multicenter trial that has validated an FDG uptake threshold, and visual interpretation currently tends to be more accurate than SUV quantification.[23] When mediastinal lymph nodes are FDG-avid as determined on the basis of visual analysis or SUV, the number of false-positive results due to infectious or inflammatory etiologies is too high to allow for a confident diagnosis of nodal metastasis (Fig. 22.2).[21,24] In this regard, because the positive predictive value of FDG-PET is not optimal for diagnosing nodal metastasis, invasive sampling should be performed to confirm pathologically involved nodes (pN) disease when the PET and CT findings are indicative of nodal metastasis or when the CT and PET findings are incongruent.[24,25] In addition, even if PET–CT is negative for mediastinal nodal metastasis, the need for histologic confirmation persists because of the low sensitivity and accuracy of PET–CT for intrathoracic nodal staging.[21,24] However, it is important to emphasize that the precise role of FDG-PET with regard to invasive nodal evaluation is unclear. Although not universally accepted, the American College of Chest Physicians evidence-based practice guidelines recommend that invasive confirmation of the mediastinal nodes is not needed in patients with a peripheral clinical stage I NSCLC if PET of the mediastinum is negative.[25,26] Furthermore, a meta-analysis of 10 studies (1122 patients) indicated that occult nodal metastasis is not infrequent in patients with clinical stage T1-2N0 NSCLC but that PET and CT provide a favorable negative predictive value for the detection of mediastinal metastasis (0.94 for T1 disease and 0.89 for T2 disease), suggesting a low yield from invasive clinical staging for this subgroup of patients.[27]

Fig. 22.2. A 62-year-old man with a NSCLC in the upper lobe of the left lung who was being evaluated for surgical resection. This coronal PET–CT shows increased FDG uptake in the mass in the upper lobe of the left lung *(M)* and a small node (short-axis diameter, 1 cm) in the left supraclavicular region *(arrow)*. A biopsy revealed findings consistent with reactive lymphoid hyperplasia (abundant lymphoid tissue, germinal center fragments, increased large cells, tingible body macrophages) and absence of metastatic carcinoma. The patient underwent left upper lobectomy.

In an attempt to determine the need for invasive sampling after PET and CT imaging, de Langen et al.[28] performed a meta-analysis to evaluate the association between the size of mediastinal nodes and the probability of malignancy. The authors reported a 5% posttest probability for N2 disease in patients with a negative result on FDG-PET imaging in whom the mediastinal nodes measured 10 mm to 15 mm on CT and suggested that these patients should be treated with thoracotomy. In comparison, they reported a 21% posttest probability for N2 disease in patients with a negative result on FDG-PET imaging in whom the lymph nodes measured more than 16 mm on CT and suggested that these patients should have mediastinoscopy prior to thoracotomy. For patients with a positive result on FDG-PET, the posttest probability of malignancy was 62% when the nodes measured 10 mm to 15 mm on CT and 90% when the nodes measured more than 16 mm. Although the authors did not suggest any management strategies regarding histologic confirmation of nodal metastasis when the result on FDG-PET is positive, N2 and N3 disease should be histologically confirmed in patients who are potentially eligible for resection or adjuvant therapy.

The expanded role of nonsurgical management for patients with early-stage NSCLC and the definitive use of FDG-PET–CT to detect mediastinal nodal metastasis in high-risk patients or patients with advanced disease who are being evaluated for nonsurgical management underscore the importance of accurate nodal evaluation. In this regard, there have been attempts to improve the detection of mediastinal nodal metastasis when using FDG-PET–CT in the staging algorithm. The SUV_{max} of

the primary tumor has been used to predict the likelihood of microscopic nodal metastatic disease and to improve the accuracy of N staging.[29–31] Trister et al.[31] reported that a high SUV for the primary tumor was an independent predictor of occult mediastinal nodal metastasis in patients with clinical stage I and II NSCLC and recommended invasive staging of the mediastinum when the SUV is more than 6. In addition, in a study of 265 patients with NSCLC, Miyasaka et al.[29] reported that the SUV_{max} of the primary tumor was a significant predictor of pathologic nodal involvement, with pN1-2 disease being detected in 25 (41%) of 61 in whom the SUV_{max} was more than 10, compared with only 26 (12.7%) of 204 patients in whom it was less than 10 ($p < 0.0001$). The detection of nodal metastasis also may be improved by the use of point spread function (PSF) reconstruction along with PET–CT scanners. PSF reconstruction recently became commercially available, and, as a result of improved image contrast and reduced image noise, may be more sensitive for the detection of small-volume nodal metastases. Lasnon et al.[32] reported that PSF PET had higher sensitivity (97%), negative predictive value (92%), and negative likelihood ratio (0.04) than did conventional iterative reconstruction ordered subset expectation maximization PET (78%, 57%, 0.31, respectively) for nodal evaluation in patients with NSCLC. While improved sensitivity increases the likelihood of false-positive results, the authors concluded, on the basis of the significant improvements in sensitivity ($p = 0.01$), negative predictive value ($p = 0.04$), and low negative likelihood ratio that were observed in association with PSF reconstruction, that preoperative invasive nodal staging may be omitted in cases in which the result of PSF FDG-PET–CT is negative. A potential further advance in nodal assessment is the use of an artificial neural network (ANN). Toney and Vesselle[33] recently reported that an ANN overcame the subjectivity associated with the interpretation of PET, outperformed an expert FDG-PET–CT reader in terms of accuracy, and differentiated malignant and benign inflammatory lymph nodes with overlapping appearances on PET–CT. The ANN used four FDG-PET–CT-derived input parameters (primary tumor SUV_{max}; tumor size; node size; and FDG uptake at the N1, N2, and N3 stations) and correctly predicted the N descriptor in 99.2% of cases, compared with 72.4% for the expert reader.

Distant Metastasis

Distant metastases (M descriptor) are common in patients with NSCLC at the time of presentation and are currently subclassified into M1a metastases (additional nodules in the contralateral lung, malignant pleural effusion, pleural nodule[s], pericardial nodule[s]) and M1b (extrathoracic) metastases.[11,12] The forthcoming eighth edition proposals for the M descriptor maintain the M1a descriptor but the M1b will now be assigned to cases with a single extrathoracic metastasis, and M1c to those with multiple extrathoracic metastases in one or more organs.[13,15]

Although FDG-PET–CT can be useful in the evaluation of the intrathoracic and extrathoracic metastases, the role of FDG-PET in detecting M disease is not clearly defined. For instance, patients with early clinical stage (T1 N0) NSCLC have a low incidence of occult metastasis; thus extensive evaluation for metastasis in these patients may not be warranted.[34] Viney et al.[35] performed a randomized controlled trial to determine the appropriate role of FDG-PET in the clinical treatment of patients who have early stage NSCLC. In that study, 183 patients with early-stage lung cancer (>90% of who had T1 2N0 involvement) were assigned to conventional workup (92 patients) or to conventional workup and PET (91 patients). Compared with conventional staging, PET confirmed staging in 61 patients, staged the tumors as benign in two patients, and upstaged the tumors in 22 patients, including 11 patients

with N2 nodal metastatic disease and two patients with pleural metastasis. Distant metastases were rarely detected with PET (2 of 91 patients; <5%). Overall, the results of PET could have resulted in a change in treatment for 26% of the patients, with the avoidance of thoracotomy in 11 of 91 patients and with 13 of 91 potentially receiving neoadjuvant chemotherapy or chemoradiation therapy. However, because the general policy of the participating surgeons was to operate on patients with apparently completely resectable stage IIIA disease without any further evaluation, PET resulted in further investigation or other management changes in only 12 patients (14%).

In patients with more advanced disease, whole-body FDG-PET–CT has a greater impact on the accuracy of staging as well as on management. The American College of Surgeons Oncology Group reported that PET had a sensitivity, specificity, positive predictive value, and negative predictive value of 83%, 90%, 36%, and 99%, respectively, for M1 disease.[6] Whole-body PET imaging stages intrathoracic and extrathoracic disease in a single study and detects occult extrathoracic metastases in up to 24% of patients who are selected for curative resection (Fig. 22.3).[5,6,36] The incidence of detection of occult metastases has been reported to increase as the T and N descriptors increase (from 7.5% in early-stage disease to 24% in advanced disease).[36] In two studies with a relatively high proportion of patients with more advanced lung cancers that were considered to be resectable on the basis of standard clinical staging, PET imaging prevented nontherapeutic surgery in one of five patients.[5,6] A more recent prospective study, similar to the PLUS multicenter randomized trial conducted by van Tinteren et al.[5] but evaluating PET–CT rather than dedicated PET, demonstrated that 52 (63%) of 83 patients in the PET–CT group underwent surgery, with 13 (25%) of 52 thoracotomies being futile. By contrast, in the conventional staging group, 73 (80%) of 91 patients underwent thoracotomy, with 38 (52%) of 73 thoracotomies being futile.[5,37,38]

The widespread use of FDG-PET has changed the imaging algorithm that is used to detect metastases to specific organ sites, particularly the osseous skeleton, the adrenal glands, and extrathoracic lymph nodes. In this regard, FDG-PET–CT is particularly effective for detecting bone metastasis. A meta-analysis of 17 studies demonstrated that the pooled sensitivity and specificity for the detection of bone metastasis were 92% and 98%, respectively, for FDG-PET–CT, compared with 86% and 88%, respectively, for bone scintigraphy.[39] As a result, FDG-PET–CT has to a large extent replaced 99mTc-methylene-diphosphonate (MDP) bone scintigraphy for the evaluation of possible bone metastasis in patients with NSCLC (Fig. 22.4).[39–41] Specifically, 99mTc-MDP bone scintigraphy now has no additional utility for patients with NSCLC if FDG-PET is performed as part of the staging algorithm. In fact, discordant findings of skeletal metastasis between 99mTc-MDP scintigraphy and FDG-PET–CT have been reported to occur in 20% of patients with NSCLC.[42] This discordance is in large part due to the ability of FDG-PET to detect early bone metastasis and the failure of 99mTc-MDP scintigraphy to detect early neoplastic infiltration of bone marrow. FDG-PET–CT is also useful for detecting adrenal metastasis and for distinguishing benign from malignant adrenal masses that are detected with CT.[43] A meta-analysis of 21 studies (1391 lesions), including five studies that specifically focused on patients with lung cancer, demonstrated that FDG-PET had a combined sensitivity and specificity of 94% and 82%, respectively, for the detection of adrenal metastasis in patients with lung cancer.[43] Similar to the assessment of bone metastasis, FDG-PET has changed the imaging algorithm used to evaluate an indeterminate adrenal mass detected with CT and is now often used as the definitive imaging modality rather than magnetic resonance imaging (MRI), particularly when the adrenal mass is small (Fig. 22.5). In fact, adrenal masses

can be characterized with use of FDG-PET, and subsequent imaging is usually unnecessary.[43] If an adrenal mass in a patient with potentially resectable NSCLC has normal FDG uptake on PET, curative resection should be considered without further evaluation. If an adrenal mass has increased FDG uptake, biopsy should be performed to confirm metastatic disease. FDG-PET–CT has limitations in the evaluation of liver and brain metastases. Specifically, because of the high background uptake of FDG by normal brain tissue, the ability to detect brain metastasis is not optimal.[44] MRI is the current standard of care for patients with NSCLC who are undergoing evaluation of possible brain

Fig. 22.4. A 46-year-old woman with NSCLC in the upper lobe of the left lung who presented with shoulder pain. (A) Axial contrast-enhanced CT showing a spiculated nodule in the upper lobe of the left lung. Biopsy confirmed metastatic disease, and the patient was treated palliatively.

metastases, and FDG-PET–CT lacks the sensitivity and specificity to replace this diagnostic test.[45] Similarly, FDG-PET–CT has a limited role in the detection of hepatic metastases. Although FDG-PET–CT has a high specificity for the detection of occult hepatic metastases, it has a low sensitivity, and, accordingly, FDG-PET is not routinely used for this purpose.

Whole-body FDG-PET imaging improves the accuracy of staging in patients with NSCLC. However, focal increased uptake of FDG in extrathoracic lesions that are unrelated to the primary NSCLC can mimic distant metastasis. Accordingly, all extrathoracic FDG-avid lesions that potentially would alter patient management should be further imaged or biopsied to

confirm the diagnosis of distant metastasis. The rationale for this management approach is supported by the results of a prospective study that was performed to assess the incidence and diagnosis of a single site of extrapulmonary accumulation of FDG in patients with newly diagnosed NSCLC.[46] Of the 350 patients in the study group, 72 had solitary FDG-avid lesions. Sixty-nine of these patients underwent biopsy of the lesion; of these, 37 (54%) had a solitary metastasis, whereas 32 (46%) had a lesion that was unrelated to the NSCLC, such as a benign tumor or inflammatory lesion (26 patients) or a clinically unsuspected second malignancy or recurrence of a previously diagnosed carcinoma (6 patients).

PROGNOSIS

The widespread use of CT and the increase in lung cancer screening programs have resulted in the detection of small lung cancers, typically adenocarcinomas, with indolent to aggressive malignant behavior. A recent multicenter study involving 610 patients with clinical stage IA lung cancer validated the ability of FDG-PET–CT together with high-resolution CT to predict the malignant behavior and prognosis of early adenocarcinomas of the lung (Fig. 22.6).[47] The diameter of the primary tumor was 20 mm or less in 354 patients and more than 20 mm in 256 patients. The mean duration of follow-up after surgery was 41.8 months, and the rate of disease recurrence was 9.5% (58 patients). A significant difference in recurrence-free survival was identified between tumors with an SUV_{max} of 2.9 or less and those with an SUV_{max} of more than 2.9 (5-year recurrence-free survival ratio, 95% compared with 72%; $p < 0.001$). In addition, SUV_{max} was a significant prognostic factor for cancer-specific survival ($p < 0.001$). Furthermore, when combined with a high-resolution CT ground-glass opacity ratio {(1 – [maximum dimension of solid component of tumor on lung windows/maximum dimension of tumor on lung windows]) × 100}, the data were especially useful for predicting the malignant grade of tumors and patient prognosis. The prediction of the biologic behavior of small adenocarcinomas is important for the selection of the appropriate surgical option. In this regard, the frequency of lymphatic, vessel, or pleural invasion was only 2% among tumors with an SUV of 2.9 or less and a ground-glass opacity ratio of 25% or more, and the 1% incidence of nodal metastasis or recurrence in this group suggests that sublobar resection, rather than lobectomy, could be considered as definitive management.[47] The use of SUV to identify patients with clinical stage IA lung cancers that are appropriate for limited resection was also supported by a report involving 183 patients with clinical stage IA NSCLC who were evaluated with PET–CT and underwent resection.[45] The 5-year recurrence rate was 0% for patients with a corrected SUV (the ratio of the tumor SUV_{max} to the liver SUV_{mean}) of less than 1.0, compared with 22.9% for those with a corrected SUV of 1.0 or more, and the 5-year cancer-specific survival rates for these groups were 100% and 88.7%, respectively.[48]

The level of increased FDG uptake in the primary tumor at the time of diagnosis also has been used to predict prognosis, and this level may be prefaced on the correlation of the SUV_{max} of the primary tumor with tumor differentiation, necrosis, pathologic type, size, and epidermal growth factor receptor (EGFR) protein expression.[47,49–51] Bille et al.[49] evaluated the prognostic significance of SUV_{max} of the primary tumor in a study of 404 patients with NSCLC who underwent potentially curative resection after PET–CT. SUV_{max} of the primary tumor was significantly associated with survival ($p = 0.00016$). The median survival, 2-year survival, and 5-year survival rates were 26.4%, 88.4%, and 72.1%, respectively, for the 209 patients with an SUV_{max} of less than 8.6, compared with 19.6%, 71%, and 47.8%, respectively, for the 195 patients with an SUV_{max} of 8.6 or more. Because a high tumor SUV_{max} potentially could
Fig. 22.5. A 70-year-old woman with NSCLC of the upper lobe of the right lung and an adrenal mass. (A) Posteroanterior radiograph of the chest, showing a mass in the upper lobe of the right lung. Note the presence of an implantable cardioverter defibrillator. (B) Whole-body PET maximum intensity projection image showing increased FDG uptake in the mass in the right lung and the right adrenal mass *(arrow)*. *Asterisk* indicates normal renal excretion of FDG in a calyx. allow more appropriate use of neoadjuvant and adjuvant therapy, a subgroup analysis of patients with stage I disease (for whom international guidelines do not recommend adjuvant treatment) was performed; this analysis showed that the SUV did not independently predict survival.[49] However, patients with stage II, III, or IV disease who had received adjuvant chemotherapy had better survival if the SUV_{max} was below 8.7, and the authors postulated that these patients would benefit most from targeted adjuvant therapy.[49] These findings are consistent with the current consensus that adjuvant chemotherapy after complete resection can result in a significant and clinically meaningful survival advantage for patients with stage II to IIIA NSCLC although not for patients with stage 1B disease.[52,53] However, Cerfolio et al.,[54] in a retrospective study of 315 patients who underwent complete resection of NSCLC, found that patients with stage IB and stage II disease who had SUV values that were greater than the median value for their respective stages had lower disease-free survival rates at 4 years. The differences in disease-free survival between patients with stage IB disease (92% for the low SUV group, compared with 51% for the high SUV group) and stage II disease (64% for the low SUV group, compared with 47% for the high SUV group) were

significant (p = 0.005 and 0.044, respectively). When the results were stratified according to stage, the actual 4-year survival rates for the low and high SUV groups were 80% and 66%, respectively, for patients with stage IB disease; 64% and 32%, respectively, for those with stage II disease; and 64% and 16%, respectively, for those with stage IIIA disease.

Performance status and stage are firmly established as prognostic factors for patients with NSCLC, and small studies have indicated that FGD-PET may also be useful for determining the prognosis for patients with early and advanced NSCLC.[47,49,51,55–59] However, a prospective National Cancer Institute–funded American College of Radiology Imaging Network/Radiation Therapy Oncology Group cooperative group trial evaluating posttreatment FDG-PET at approximately 14 weeks after radiotherapy in patients with stage III NSCLC demonstrated limited utility for predicting the prognosis.[60] Two hundred and twenty-six patients had pretreatment FDG-PET, and 173 patients had posttreatment FDG-PET. Pretreatment SUV_{peak} and SUV_{max} values were not associated with survival, although a posttreatment SUV_{peak} value of more than 7 was significantly associated with survival ($p < 0.001$). Overall survival (OS) based on the study's prespecified posttreatment

Fig. 22.6. A 72-year-old man with stage I (T1b N0 M0) adenocarcinoma of the lung. (A) Axial contrast-enhanced CT showing a 2.5-cm nodule in the upper lobe of the right lung with ground-glass opacity and solid attenuation. (B) Whole-body maximum intensity projection FDG-PET image showing focal increased FDG uptake (SUV_{max} = 12.3) in the right upper lobe nodule. Note the absence of nodal and distant metastases. Fifteen months following lobectomy of the upper lobe of the right lung, the patient developed a metastatic lesion in the left lung. Primary stage I malignancies that have a high SUV tend to have a higher rate of recurrence. *SUV,* standardized uptake value.

SUV_{peak} cutoff value of 3.5 was not significantly different in patients with an SUV_{peak} less than 3.5 compared with those with an SUV_{peak} greater than 3.5 (p = 0.29). The authors concluded that the use of a simple posttreatment SUV cutoff value of 3.5 after chemoradiotherapy is not useful for the clinical management of patients. The authors postulated that because patients with a high SUV (>7) after chemoradiotherapy have poor outcomes, this subpopulation could be considered for early additional treatment.[60]

FDG-PET studies are often limited by small size, their retrospective nature, and variations in treatment protocols, particularly for patients with advanced-stage NSCLC. These factors, in part, may account for the contradictory reports in the literature regarding the applicability of prognostic information provided by FDG-PET for patients with NSCLC. Hoang et al.[56] performed a retrospective review of 214 patients with advanced-stage NSCLC who underwent FDG-PET at the time of the initial diagnosis. Univariate and multivariate analysis provided no evidence that the survival times were significantly different for patient subgroups that were defined according to SUV_{max}; the median survival time was 16 months for the 106 patients in whom the primary tumor had an SUV_{max} of less than 11.1, compared with 12 months for the 108 patients in whom it had an SUV_{max} of 11.1 or more. In addition, improved outcomes may be confounded by PET-induced stage migration and selection bias.[61,62] In a retrospective analysis involving 12,395 patients with NSCLC in the pre-PET and PET periods, there was a 5.4% decrease in the number of patients with stage III disease and an 8.4% increase in the number of patients with stage IV disease in the PET period, corresponding with an increase in PET use from 6.3% to 20.1%.[58] The use of PET predicted better survival for patients with stage III and stage IV disease. These data support the notion that stage migration is at least partially responsible for an apparent improvement in the survival of these patients.

A limitation of the studies in which the level of increased FDG uptake (as indicated by SUV) is related to survival is that the threshold SUV used for analysis ranges widely and reproducibility may not be robust. To improve reproducibility of SUV between scanners, some investigators have proposed that a ratio of tumor SUV_{max} to either liver or blood SUV_{max} be used rather than an absolute SUV_{max}.[63] The use of a ratio potentially overcomes the issue of the appropriate threshold SUV_{max} to use for the purpose of predicting survival. Additionally, the ratio potentially can eliminate the effects on SUV related to the use of different data-acquisition and reconstruction-processing protocols at different institutions.[64] Westerterp et al.[64] reported differences in SUV quantitation of as much as 30% among three different institutions. Furthermore, variables such as the time between the administration of FDG and image acquisition, blood glucose level, and respiratory motion during image acquisition can affect SUV. The European Association of Nuclear Medicine has published procedural guidelines to provide a minimum standard for the acquisition and interpretation of PET and PET–CT in order to decrease the variability of SUV and to allow comparison of multicenter trials.[65] A standardized PET protocol has been instituted in The Netherlands and serves as a model for wider application.[66] The standardization includes (1) patient preparation, (2) matching of scan parameters such as scan time per bed position and image acquisition mode (two-dimensional or three-dimensional), (3) matching of image resolution by prescribing reconstruction settings, (4) matching of data-analysis procedures by defining volume-of-interest methods and SUV calculations, and (5) a quality-control procedure for verification of scanner calibration and the use of a National Electrical Manufacturers Association image-quality phantom for the verification of activity concentration recoveries. In a recent multi-institutional trial, a National Electrical Manufacturers Association body phantom was used to determine a correction coefficient for each scanner that was then used to standardize the SUV data.[47] In addition, protocol-optimized images and compliance with European Association of Nuclear Medicine guidelines have been reported to allow for a reliable pretherapy and posttherapy evaluation when using different-generation PET systems.[67]

While the quantitative analysis of PET for the determination of prognosis may be confounded by the limitations of SUV reproducibility, other proposed techniques, including dual-phase PET and assessment of metabolic tumor burden, may improve the ability to determine prognosis.[68–71] Houseni et al.[68] reported that the change in SUV_{max} between early and delayed PET imaging during a single study was a strong independent predictor of prognosis for patients with adenocarcinoma of the lung. The median survival time was 15 months for patients in whom SUV_{max} increased by more than 25% between the two time points, compared with 39 months for those in whom SUV_{max} increased by less than 25%. In addition, FDG-PET–CT-assessed parameters reflecting metabolic tumor burden, such as metabolic tumor volume (MTV) and total lesion glycolysis (TLG), which take into account the size of the tumor as well as the uptake of FDG, are currently being investigated as prognostic factors.[69,70,72] Im et al.,[72] in a recent meta-analysis of 13 studies (1581 patients) performed to evaluate the prognostic value of MTV and TLG, reported that lung cancer patients with high MTV had a worse prognosis with a hazard ratio (HR) of 2.71 (95% confidence interval [CI], 1.82–4.02, $p < 0.00001$) for adverse events and an HR of 2.31 (95% CI, 1.54–3.47, $p < 0.00001$) for death.[72] Similarly, patients with high TLG had a worse prognosis with an HR of 2.35 (95% CI, 1.91–2.89, $p < 0.00001$) for adverse events and an HR of 2.43 (95% CI, 1.89–3.11, $p < 0.00001$) for death. Importantly, the prognostic value of MTV and TLG remained significant in a subgroup analysis according to TNM stage. Measurements of whole-body metabolic tumor burden with MTV and TLG have also been reported to be better prognostic indicators than SUV_{max} and SUV_{mean} in patients with NSCLC who are being assessed for surgical resection as well as for those with advanced disease who are receiving chemotherapy.[69–71] In a retrospective study of 106 patients (including 19 with stage I–II and 87 with stage III–IV lung adenocarcinoma), the MTV and TLG of each malignant lesion were measured prior to treatment and were summated to give whole-body MTV and whole-body TLG values for each patient.[71] Univariate survival analysis of patients with stage III–IV disease identified high whole MTV values (≥90) and high whole TLG values (≥600) as being significant predictors of poor progression-free survival (PFS; $p < 0.001$) and poor prognosis ($p < 0.001$). Multivariate survival analysis identified high whole MTV values and high whole TLG values as being independent predictors of poor PFS ($p < 0.001$) and prognostic predictors of poor OS ($p < 0.001$). However, in a survival analysis of patients with stage I–II disease, MTV and TLG were not independent prognostic predictors.[71] Similarly, in a retrospective study of 50 patients who underwent stereotactic body radiation therapy (SBRT) for stage I NSCLC, MTV and TLG were not correlated with OS.[73] However, the role of volume-based parameters of FDG-PET–CT in patients with stage I NSCLC after SBRT is unclear and requires further evaluation. Another recent study of 88 patients with stage I NSCLC (including 68 patients with T1 N0 M0 disease and 20 with T2a N0 M0 disease) who had FDG-PET–CT and then SBRT indicated that MTV and TLG were significantly associated with disease-free survival.[74]

Because of the inherent limitations of data obtained from retrospective studies with small numbers of patients, the role of FDG-PET in the treatment of NSCLC remains unclear. Cerfolio et al.[54] posed several questions regarding the appropriate use of FDG-PET for patients with NSCLC that are worthy of consideration: (1) Should patients with an early clinical-stage NSCLC and a primary tumor with a high SUV undergo more extensive imaging prior to resection to detect occult metastases? (2) Would a patient with an early-stage lung cancer who has a high SUV benefit more from adjuvant therapy than one with a low SUV, and would such a patient also benefit from neoadjuvant therapy? (3) Should the SUV be considered together with the clinical stage when determining therapy? and (4) Should patients with a high SUV have more intensive postoperative surveillance? While the definitive answers to these questions require multi-institutional prospective randomized trials, the evolving experience with FDG-PET indicates that FDG-PET will have an expanded role in the treatment of NSCLC.

THERAPEUTIC RESPONSE

The use of anatomic imaging to assess response according to World Health Organization criteria and Response Evaluation Criteria in Solid Tumors (RECIST 1.1) has limitations that may be overcome by FDG-PET imaging.[75,76] FDG-PET allows for an early and sensitive assessment of antitumor effect after therapy in patients with NSCLC.[54,77–81] Lee et al.[78] evaluated the role of FDG-PET–CT in predicting the early response to therapy in a study of 31 patients with stage IIIB–IV NSCLC who received standard chemotherapy or molecular-targeted therapy. A metabolic response after one cycle of systemic therapy had a significant correlation with best overall response ($p < 0.01$). Moon et al.,[82] in a recent study of patients with advanced NSCLC, reported that FDG-PET can potentially be useful to identify a subgroup of patients who would benefit from maintenance treatment after the completion of first-line chemotherapy. In terms of the response to cytostatic treatment regimens, FDG-PET–CT has been reported to predict the histopathologic response in patients undergoing neoadjuvant EGFR inhibition therapy with erlotinib.[83–85] Similar to the assessment of prognosis, the quantitative analysis of FDG-PET for the determination of therapeutic response is affected by many factors. Wahl et al.[86,87] have accordingly proposed criteria for the systematic and structured assessment of response to therapy. These guidelines (PET Response Criteria in Solid Tumors [PERCIST 1.0]) are being increasingly used in clinical trials and in structured clinical reporting and improve the quantitative analysis of FDG-PET in the determination of therapeutic response.

FDG-PET–CT is also being used to monitor the response of tumors to radiotherapy.[88–92] The SUV of the primary tumor and regional nodes after completion of radiotherapy has been reported to predict poor treatment response and tumor control.[91] A return of the tumor SUV to normal after treatment appears to be an accurate marker for complete response and a sensitive indicator of good prognosis.[88] The detection of residual and recurrent disease with FDG-PET–CT has been reported to have a sensitivity of 100%, a specificity of 92%, a positive predictive value of 92%, a negative predictive value of 100%, and a diagnostic accuracy of 96%.[91] The value of FDG-PET–CT in monitoring the response to treatment was highlighted in a review published in the *New England Journal of Medicine*.[93]

Studies on the use of FDG-PET–CT to evaluate the response to anticancer therapies have suggested that early metabolic changes after therapy are strongly predictive of clinical outcome in many disease states. The literature has been focused on FDG-PET–CT imaging that is performed at approximately 3 months after the completion of radiation therapy. In a prospective National Cancer Institute–funded American College of Radiology Imaging Network/Radiation Therapy Oncology Group cooperative group trial evaluating the correlation between FDG-PET–CT findings approximately 3 months after the completion of conventional concurrent platinum-based chemoradiotherapy in patients with stage III NSCLC, pretreatment SUV_{peak} and SUV_{max} were not associated with survival.[60] Posttreatment SUV_{peak} was associated with survival in a continuous variable model (HR, 1.087; 95% CI, 1.014–1.166; $p = 0.020$). However, when analyzed as
Fig. 22.7. A 53-year-old man with NSCLC and poor respiratory function was being treated with definitive intensity-modulated radiation therapy (IMRT) and concurrent chemotherapy. (A) Axial PET–CT scan, performed prior to treatment, showing complete obstructive atelectasis with consolidation of the middle lobe and focal increased uptake of FDG in the primary malignancy. (B) Computed dosimetric reconstruction used for IMRT with the highest radiation dose of 74 Gy *(white color line)* surrounding the location of the treated malignancy.

a prespecified binary value with a posttreatment SUV_{max} at a cutoff of 3.5 or greater, there was no association with survival and the authors concluded that while higher posttreatment tumor SUV is associated with worse survival, no clear prognostic threshold cutoff value is applicable for routine clinical use. While evaluation of posttreatment images is complicated by the presence of variable hypermetabolic inflammatory posttreatment changes, a limited number of studies have demonstrated that early FDG-PET–CT (performed 1 month to 2 months after treatment) is prognostic of survival and is more predictive than the CT response, stage, or pretreatment performance status.[92,94]

Recent investigators have shown an increased interest in performing FDG-PET–CT early during the course of treatment. Imaging that has been performed during the course of chemoradiation has shown markedly fewer inflammatory changes, suggesting that FDG-PET–CT during treatment may allow for an evaluation of the response to therapy. Most importantly, the ability to assess the response to therapy during the course of treatment would permit a change in therapy for patients who are not responding optimally. Researchers from The Netherlands reported a large intraindividual heterogeneity in the evolution of FDG uptake during the early course of radiation therapy.[95] The investigators reported a nonsignificant increase during the first week of radiation therapy (p = 0.05) and a small but significant decrease during the 2nd week (p = 0.02). Investigators from the University of Michigan demonstrated a greater and more significant reduction of peak FDG activity at 40 Gy to 50 Gy at 4 weeks to 5 weeks during the course of fractionated radiation therapy.[96] The regions of peak tumor FDG activity during radiation therapy correlated with those seen at 3 months after radiation therapy (R^2 = 0.7; p < 0.001). In 2008, abstracts presented by investigators from Stanford University at the meeting of the Radiological Society of North America and by investigators from Princess Margaret Hospital at the meeting of the American Society of Thoracic Radiation Oncology demonstrated a heterogeneous reduction of FDG uptake at about 4 weeks during radiation therapy. The Stanford group also reported a correlation between FDG uptake during radiation therapy and PFS. Indeed, the role of PET–CT in therapeutic monitoring is expanding rapidly because

of its ability to provide earlier and more robust identification of nonresponders or poor responders as compared with CT. Therefore PET–CT potentially can provide important benefits to individual patients by allowing early changes to alternative, more efficacious treatment or by avoiding the unnecessary toxicity related to ineffective therapy. In this regard, Choi et al.[97] reported that FDG-PET can be useful for personalizing therapeutic options for patients with advanced NSCLC who are receiving radiotherapy or chemoradiotherapy by identifying those with a high risk of residual cancer who could receive salvage therapy soon after the completion of standard therapy. In addition, RTOG 1106 is an ongoing randomized phase II trial that will perform PET–CT scan during RT with doses of around 40 Gy to 46 Gy to predict treatment response. In the experimental arm, PET–CT will be used to define the target for the boost phase of radiation therapy to raise the daily dose to the reduced target volume for the remainder of the treatment without increasing the doses to normal organs.

FDG-PET–CT FOR RADIATION TREATMENT PLANNING AND ADAPTIVE PLANNING

FDG is the only Medicare-approved PET–CT tracer for the evaluation of cancer, and FDG-PET–CT is the most widely available procedure used in daily oncology practice. FDG-PET–CT is being increasingly used for patients with NSCLC, including for diagnosis, staging, radiation treatment planning, and monitoring of the treatment response.[93,98–102] FDG-PET–CT plays an important role in target delineation during the planning of radiation treatment for patients with NSCLC[103–108] and has been shown to improve the accuracy of target definition (Fig. 22.7).[89,104,109,110] FDG-PET–CT helps differentiate the primary tumor from collapsed lung and/or adjacent normal tissue, such as large vessels, and defines the extent of disease in the chest wall. PET reduces interobserver variability compared with CT alone.[111] Integrated PET–CT further improves the consistency of target delineation.[95] A prospective clinical trial involving the use of PET–CT-based planning demonstrated isolated nodal failures in only one of 44 patients.[112] The tumor target that is defined on the basis of PET–CT is usually smaller than that defined on the basis

of CT; therefore the incorporation of PET–CT into radiotherapy planning has the potential to allow radiation-dose escalation without increasing side effects.[112,113] Tumor volume can be generated reliably with use of either a rigorous visual method or source-to-background ratio-based autodelineation.[95,114] The latter method also has shown good correlation with pathologic findings. MTV after chemotherapy or radiation therapy is not well defined. Investigators who are involved in the RTOG 1106 study are testing whether increasing the radiation dose on the basis of FDG-PET during treatment will lead to higher cure rates.

Novel Tracers

PET is one of the most important advances in biomedical science and is now incorporated into medical practice, particularly for the detection of disease, the planning of treatment, the monitoring of the response to treatment, and the detection of recurrence in patients with cancer. PET radionuclides are produced and incorporated into various compounds for measuring specific molecular processes in living patients. Multiple new PET tracers have been designed to interrogate various pathways beyond glycolysis, such as FDG-PET, which is accepted clinically as a marker of general cellular metabolism but has known limitations in discriminating viable cancer from active inflammation and has lower uptake in certain tumors such as prostate and breast cancer. These new tracers are being developed for the evaluation of various cellular processes, some of which may include amino acid transport, protein synthesis, fatty acid metabolism, receptors, and proliferation.

The clinical imaging of proliferation of both normal and cancerous tissue is important for evaluating tissue function and characteristics as it has the potential to improve our ability to monitor the response to therapy and to predict the outcome of treatment. More traditional imaging methods for assessing tumor size and growth (e.g., CT, MR, and sometimes ultrasound) may be limited because of the delay associated with cell death and may not manifest early. The ability of PET to assess metabolic activity noninvasively, quantitatively, and reproducibly makes it ideal for the assessment of tumor response and prognosis. Tumor growth relies on an increasing population of cells because of cell division. In contrast with normal cells, tumors grow out of control as they fail to respond to the normal homeostatic mechanisms that maintain the appropriate number of cells in the process of cell renewal. Originally, the technique for assessing the proliferation rate or DNA synthesis as a means of monitoring the response to therapy was based on the use of radiolabeled DNA precursors or nucleosides, which are incorporated into the DNA of cells during the S phase of the cell cycle. Because thymidine (TdR) is not incorporated into RNA, it was chosen early on as the best tracer for measuring cell proliferation, and the use of ³H-TdR and autoradiography allowed for the analysis of the kinetics of proliferation. These studies documented the variability of proliferative rates among tumors, and this was not unexpected since nonproliferating cells are common as well as high tumor cell death rates. Subsequently, C-11-labeled TdR was developed, which can be labeled at both the methyl and the two-ring position to noninvasively assess tumor proliferation in patients. However, kinetic analysis is required as the metabolites in the blood and CO_2 are present and need to be accounted for in the uptake analysis. Clinical studies have been performed to assess various tumors, including lung cancer. However, because of the short (20-minute) physical half-life of C-11 TdR, this procedure was limited to academic or research centers with direct proximal access to a cyclotron facility to perform these studies. More importantly, the biologic half-life of C-11 TdR was limited

because of its rapid in vivo degradation once injected intravenously in humans.

18F-labeled 3′-deoxy-3′-fluorothymidine (18F-FLT) was then developed partly because of its more favorable half-life as a tracer for imaging proliferation. Unlabeled FLT has been known for many years as an antiviral agent, particularly for human immunodeficiency virus therapy. In the simplified model of FLT retention (which is quite similar to FDG retention), FLT is taken up from the circulation by tumors and is transported into the cell, where it is trapped by phosphorylation by cytosolic thymidine kinase 1 (TK1). TK1 has been shown to have increased activity when cells are going through the S phase; thus FLT retention reflects proliferative activity. In vitro studies have shown a strong correlation between FLT uptake in growing cells and the S phase fraction. Tehrani et al.[115] reported that correlative PET studies of C-11 TdR and FLT showed comparable uptake patterns but that FLT had greater in vivo stability, resulting in improved imaging characteristics.

Shields et al.,[116] in a pilot study involving a patient with NSCLC, reported that PET demonstrated increased uptake of FLT in the primary lung tumor as well as in the liver and bone marrow, thereby limiting the usefulness of this tracer for identifying metastases in these sites. High liver uptake is seen only in humans (not in canines) as a result of increased glucuronidation of FLT in the human liver. FLT demonstrates minimal brain uptake, making it a better tracer than FDG (high background brain activity) for assessing brain tumor metabolism. FLT also demonstrates uptake in the gastrointestinal tract, which, like the bone marrow, has a substantial number of proliferating cells. Renal excretion with bladder accumulation was also noted.

When serial imaging is performed to assess prognosis and to evaluate the response to therapy, the reproducibility and repeatability of the PET technique is essential. de Langen et al.[117] evaluated the reproducibility of FLT PET measurements for nine patients with NSCLC and six patients with head and neck cancer. The patients were scanned twice within 7 days prior to receiving therapy. The maximum pixel value within the tumor (SUV_{max}) and a threshold-defined volume of 41% of the maximum pixel value with correction for local background (SUV41%) were used to quantify FLT uptake. SUV41% and SUV_{max} showed excellent reproducibility, and the authors concluded that when monitoring response using serial measurements of FLT, changes of more than 15% in SUV41%, and 20% to 25% in SUV_{max}, are likely due to the biologic effects of therapy rather than variability in measurements.[117] One of the strengths of PET is the ability to quantify the metabolic process being studied. Aside from the commonly used semiquantitative SUV measurements, measurements of metabolic active volumes may be a better index of viable (FDG) or proliferating (FLT) tumor. Frings et al.,[112] in a study of 20 patients with NSCLC, evaluated the repeatability of metabolic volume measurements with the use of both FDG (11 patients) and FLT (9 patients) on the basis of four semiautomated three-dimensional volume-of-interest methodologies. The study set the ranges by which significant differences in measured volumes of interest could be considered change and represented more than measurement variation.[118] The most precise quantification of PET studies has been done with proof of concept that FLT PET imaging provides a valid and independent measure of DNA synthetic rate. One such study was performed in 17 patients with 18 tumors using multiple kinetic models, which involved blood sampling with metabolite analysis.[119] This study concluded that compartmental analysis of FLT PET images can yield robust estimates of FLT uptake, which correlated with in vitro measures of tumor proliferation.

Most clinical studies of FLT PET have involved patients with lung cancer. Yamamoto et al.,[120] in a prospective study of 18 patients with newly diagnosed NSCLC, compared FDG and FLT PET findings with immunohistochemical correlation using Ki-67 as an index of proliferation. The sensitivity was 72% for FLT and 89% for FDG. False-negative FLT PET findings were reported for four of five patients with bronchioloalveolar carcinoma, which is similar to the known low FDG uptake in these slow-growing tumors. The mean FLT SUV was significantly lower than the mean FDG SUV, and a significant correlation was observed between the FLT SUV and the Ki-67 index. Although FLT uptake correlated significantly with proliferative activity, the correlation was not better than that for FDG uptake ($p < 0.0001$). Similar findings were reported in a larger study of 68 patients with NSCLC, in which FLT SUV$_{max}$ was significantly correlated with Ki-67 and CD105-MVD (microvessel density; $r = 0.550$ and $r = 0.633$, $p = 0.001$ and $p = 0.001$, respectively).[121] There was also some correlation with CD31-MVD (microvessel density) and CD34-MVD, both of which are markers of angiogenesis ($r = 0.228$ and $r = 0.235$, $p = 0.062$ and $p = 0.054$, respectively). These findings indicate a complex situation in which FLT uptake in patients with lung cancer is influenced by multiple factors, including angiogenesis. In another prospective study, involving 25 patients with suspected lung cancer, static and dynamic ^{18}F-FLT PET images were acquired prior to surgical resection and were compared with the expression of Ki-67 and TK1 as determined with immunohistochemical staining.[122] The analysis revealed that static FLT SUV$_{max}$ uptake from 60 minutes to 90 minutes correlated with the overall ($p = 0.57$, $p = 0.006$) and maximal ($p = 0.69$, $p < 0.001$) immunohistochemical expressions of Ki-67 and TK1 but not with TK1 enzymatic activity ($p = 0.34$, $p = 0.146$). Correlation between TK1 activity and TK1 protein expression was limited to immunohistochemical scoring for maximal expression. No significant correlations between TK1 enzyme activity and K (FLT) were observed. The study suggested that FLT uptake and retention within cells may be complicated by a variety of still undetermined factors in addition to TK1 enzymatic activity.

Prospective clinical studies have demonstrated that FLT uptake in lung cancers is consistently lower than FDG uptake, with lower sensitivity, higher specificity, and higher positive predictive value. In the study by Yamamoto et al.,[123] 36 of 54 patients with pulmonary nodules had lung cancer. On the basis of visual analysis, the sensitivity of FLT for the detection of lung cancer was 83%, the specificity was 83%, and the accuracy was 83%. The corresponding values for FDG were 97%, 50%, and 81%, respectively. On the basis of semiquantitative analysis, the sensitivity of FLT was 86%, the specificity was 72%, and the accuracy was 81%. The corresponding values for FDG were 89%, 67%, and 81%. The same group then studied 34 patients with NSCLC to compare FLT with FDG preoperatively.[124] For the detection of primary tumor, the sensitivity was 67% for FLT, compared with 94% for FDG ($p = 0.005$). The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of lymph node staging on a per-patient basis were 57%, 93%, 67%, 89%, and 85%, respectively, for FLT PET and 57%, 78%, 36%, 91%, and 74%, respectively, for FDG ($p > 0.1$ for all comparisons). Two of the three distant metastases were detected with FLT and FDG-PET.

Multiple studies have been performed to assess the utility of FLT PET for evaluating the response to treatment. Early response changes in ^{18}F-FLT uptake have been observed after the start of chemotherapy and radiation therapy in a pilot study of five patients with locally advanced lung cancer, with imaging performed on days 2, 8, 15, or 29 after therapy.[125] This study provided proof of concept of the potential to monitor the changes in both tumor and normal tissues during therapy. It also provided background for the further development of response-adapted radiotherapy.

Kahraman et al.[120] compared FDG and FLT PET in a study of 30 patients with stage IV NSCLC who were being treated with erlotinib. Volumetric parameters were used to compare TLG for FDG and tumor lesion proliferation for FLT at baseline, 1 week, and 6 weeks after erlotinib therapy. A lower cutoff value of 20% or 30% reduction in FLT uptake was used to define metabolic response. Patients with lower early and late residual TLG and tumor lesion proliferation had a significantly prolonged PFS. Zander et al.[126] reported the results of a phase II trial in which 34 patients with untreated stage IV NSCLC were evaluated with both FDG and FLT PET during erlotinib therapy. Changes in FDG and FLT uptake after 1 week and 6 weeks of erlotinib treatment were compared with nonprogression as measured with CT after 6 weeks of treatment, PFS, and OS. Changes in FDG uptake after 1 week of therapy predicted nonprogression after 6 weeks of therapy, with an area under the receiver operating characteristic curve of 0.75 ($p = 0.02$). Patients with an early metabolic FDG response (cutoff value, 30% reduction in peak SUV) had significantly longer PFS and OS. Early FLT response also predicted significantly longer PFS (HR, 0.31; 95% CI, 0.10–0.95; $p = 0.04$) but did not predict OS or nonprogression after 6 weeks of therapy. The authors concluded that early FDG-PET response predicts OS, PFS, and nonprogression at 6 weeks. This prospective trial illustrates the continued value of FDG-PET for predicting therapeutic benefit even without knowledge of EGFR mutation status. Early FLT response was not predictive for identifying patients with EGFR mutations with response to therapy or with stable disease. It will be interesting to see if the advantage of FDG-PET over FLT PET imaging will be maintained in a larger cohort of patients.

Overall, FLT PET imaging technique as a noninvasive, quantitative method for measuring tumor proliferation has demonstrated a strong correlation with tumor proliferation indices, particularly Ki-67 scores, as was reviewed in a meta-analysis study.[127] Studies comparing FLT and FDG in terms of the early response to treatment and the prediction of outcome after therapy have yielded mixed results, with FDG overall demonstrating better correlation with the prediction of early response and prognosis. Finally, the natural biodistribution of FLT with high background activity in the bone marrow and liver may ultimately limit its overall clinical utility as it will fail to identify metastatic disease in these areas, which are common sites of lung cancer spread (Fig. 22.8).

Angiogenesis is the formation of new blood vessels, a process that involves the migration, growth, and differentiation of endothelial cells lining the inside wall of blood vessels. Angiogenesis inhibitors that can stop or slow the growth and spread of tumors have been developed. Bevacizumab is a Food and Drug Administration (FDA)-approved monoclonal antibody that recognizes and binds to vascular endothelial growth factor, which then is unable to activate the vascular EGFR. Bevacizumab has been approved for the management of various solid tumors, including NSCLC, in combination with other drugs.[128] The FDA has approved other drugs with antiangiogenic activity, including sorafenib, sunitinib, pazopanib, and everolimus, for cancer therapy. Several new PET angiogenesis imaging agents recently have been developed to target the αvβ3 integrin, which is expressed on activated endothelial cells during angiogenesis. The αvβ3 integrin has a pocket in which the peptide arginine–glycine–aspartic acid (RGD) can bind with high affinity. RGD is then cyclized and labeled with ^{18}F for imaging with PET. These imaging agents are intended to improve patient selection
Fig. 22.8. ^{18}F-labeled 3′-deoxy-3′-fluorothymidine (^{18}F-FLT) PET–CT scanning was performed for a patient with metastatic NSCLC of the lower and middle lobes of the right lung. (A) Whole-body maximum intensity projection image showing uptake in the malignancy in the lower lobe *(arrow)*. Note the high background activity in the bone marrow and liver and the low background activity in the brain. (B) Axial FLT PET–CT scan showing FLT uptake in the tumor in the lower and middle lobes, indicating proliferating tumor at both sites. Note the intense FLT uptake in the thoracic vertebrae and sternal body, which may limit detection of osseous metastases in these sites.

and subsequent monitoring of the response to therapy because not all patients respond to these targeted therapies.[129] The first PET tracer for which clinical data are available is ^{18}F-galacto-RGD, which has been shown to have very favorable imaging characteristics, with high metabolic stability and high radiochemical yield.[130] The first pilot study involved nine patients (including 5 patients with melanoma, 1 with chondrosarcoma, 1 with soft-tissue sarcoma, 1 with renal cell cancer, and 1 with pigmented villonodular synovitis).[131] There was good uptake in tumors, with the SUV ranging from 1.2 to 10.0. There was also notable uptake in the spleen and intestines, with fast excretion

via the kidneys and minimal uptake in the other organs. Subsequent expansion of the clinical study to 19 patients with similar types of tumors (melanoma and sarcoma) again demonstrated the favorable biodistribution in humans, with higher uptake in tumors with high contrast.[132] However, the clinical acceptance of this tracer has been hampered by the complex labeling procedure for its production. More recently, ^{18}F-fluciclatide (formerly known as ^{18}F-AH111585) has been developed with a high yield and a less complex radiosynthesis procedure.[133] The initial study, which involved eight healthy volunteers, demonstrated a favorable biodistribution with a predominance of renal excretion, with high background activity noted in the liver and gastrointestinal tract.[134] The dosimetry and safety profile were comparable with those of other common clinical PET tracers. The phase I study, involving seven patients with breast cancer, demonstrated good tumor uptake, with no adverse side effects noted. The metabolic stability of the tracer was demonstrated by means of chromatographic assessment of blood samples. The tumor uptake pattern was notable for a predominant peripheral distribution along the tumor rim. One patient with liver metastases had low uptake because of the high background activity in the liver, but other sites of metastases, including bone, pleura, and nodes, showed high uptake of the PET tracer. ^{18}F-fluciclatide was further evaluated in a multicenter proof-of-concept trial that included patients with NSCLC.[135] The uptake pattern and biodistribution showed minimal activity in the lungs, mediastinum, bone marrow, and brain, and thus this could be a suitable agent for potentially identifying the primary nodal involvement and distant metastases. Most recently, ^{18}F-fluciclatide was used to assess the response of human glioblastoma xenografts to treatment with the antiangiogenic agent sunitinib.[136] ^{18}F-fluciclatide detected changes in tumor uptake after acute antiangiogenic therapy markedly earlier than any significant volumetric changes were observable (Fig. 22.9). These results suggest that this imaging agent may provide clinically important information for guiding patient care and monitoring the response to antiangiogenic therapy. These data are exciting as there are very few data on response monitoring with the use of αvβ3 PET imaging. The Stanford group recently described the pharmacokinetic and dosimetry data for imaging αvβ3 integrin levels using ^{18}F-FPPRGD2.[137] The authors demonstrated that the biodistribution of ^{18}F-FPPRGD2 is favorable and that its primary application is likely to be PET for the evaluation of patients with brain, breast, or lung cancer.

Overall, imaging of angiogenesis with PET tracers shows great potential as angiogenesis is a hallmark of cancer and several FDA-approved targeted agents are available. The biodistribution of these tracers is favorable to lung cancer imaging as there is minimal background activity in the lungs and mediastinal nodes, as well as in the brain and bone marrow (common sites of distant metastases). However, the high uptake in the liver may deter detection of small-volume metastatic disease in this site. The early data are encouraging for the potential use of these agents for patient selection, tumor staging, and monitoring of response to antiangiogenic therapy.

Numerous in vivo and in vitro studies have shown that the oxygen tension within solid tumors influences the ability of the cells to respond to radiation therapy. Hypoxia in malignant tumors can affect the outcome of anticancer treatments. Oxygen is believed to act as a potent radiosensitizer, and hypoxic tumors are relatively resistant to radiotherapy because of their lack of oxygen. In addition, hypoxia triggers several processes such as angiogenesis and enhanced glycolysis that may lead to more aggressive clinical behavior and broad therapeutic resistance. However, proven noninvasive methods to determine the degree of hypoxia within these tumors are not currently available.
Fig. 22.9. A patient with adenocarcinoma in the lower lobe of the right lung after chemotherapy. (A) Whole-body ^{18}F-fluciclatide maximum intensity projection image showing uptake in the right lower lobe of the right lung. Note the lack of cerebral and cerebellar brain activity; the focus of uptake in the pituitary correlates with a known pituitary adenoma. Note also the high background activity in the bowel, moderate uptake in the liver, and low activity in the marrow. The primary excretion of the tracer is via the kidneys, which is seen as uptake also in the urinary collecting system and the bladder. (B) ^{18}F-fluciclatide PET–CT scan showing uptake in the cavitary adenocarcinoma in the lower lobe of the right lung.

Considerable efforts have been put forth to develop methods and imaging techniques for measuring oxygen and hypoxia in tissues. PET–CT has been used for several years as a noninvasive imaging technique to study tumor hypoxia, with several radiotracers in development. Radiolabeled 2-nitroimidazole compounds offer a minimally invasive (requiring only an intravenous catheter), less technically demanding technique compared with the Eppendorf electrode method (the current criterion standard). In addition, because all sites of disease can be imaged, the sampling bias inherent in electrode methods is not present in association with 2-nitroimidazole PET–CT. ^{18}F-fluoromisonidazole (FMISO) was proposed as a tracer for determining tumor hypoxia in vivo with PET in 1984. Several experimental and clinical studies have indicated that FMISO uptake in tissues is correlated with tissue oxygen tension. Therefore FMISO PET–CT allows noninvasive differentiation between hypoxic and normoxic tumors. FMISO has been shown to selectively bind to hypoxic cells both in vitro and in vivo, and it has been used quantitatively to assess tumor hypoxia in different tissues in patients with cancer involving the lung, brain, head, and neck.[138–140] As hypoxia is one of the most important prognostic factors in cancer of the head and neck and NSCLC, Eschmann et al.[99] examined whether FMISO uptake could predict tumor recurrence after radiation therapy in a study involving 40 patients (including 26 patients with cancer of the head and neck and 14 patients with NSCLC). At 4 hours after injection, tumor-to-mediastinum (or tumor-to-muscle) ratios were used to quantify uptake and the kinetics of FMISO uptake were described with time-activity curves to stratify patients into defined groups. These results showed that a tumor-to-muscle cutoff of 1.6 in patients with cancer of the head and neck or a tumor-to-mediastinum ratio cutoff of 2 in patients with NSCLC could differentiate patients who subsequently had recurrence of disease from those who did not. Only three (27%) of 11 patients with ratios less than these cutoff values had recurrent disease. FMISO PET demonstrated the ability to image and quantify hypoxia. Tumor cells exhibiting hypoxia were more resistant to radiation therapy than adequately oxygenated tumor cells. The researchers found that high uptake of FMISO correlated with greater risk of tumor recurrence. They also found that a high ratio of uptake of FMISO by tumor tissue compared with uptake by muscle tissue correlated with a higher rate of tumor recurrence. Gagel et al.,[101] in a study involving a population of patients with NSCLC, reported that FMISO PET allowed for the qualitative and quantitative definition of hypoxic subareas that may correspond with the sites of local recurrences. The degree of FMISO uptake may predict response to radiotherapy and freedom from disease as well as OS. An ongoing trial (RTOG 1106/ACRIN6697) is testing the value of FMISO for predicting the response of stage III NSCLC to concurrent chemoradiation.

CONCLUSION

FDG-PET is routinely used to improve the detection of nodal and extrathoracic metastases in patients with NSCLC who are being assessed for curative resection. FDG-PET imaging has the potential to allow more appropriate selection of patients for surgical resection and neoadjuvant and adjuvant therapy and allows improved planning for radiation therapy. In a limited number of studies, FDG-PET has been useful for the evaluation of prognosis and treatment response. In addition, novel PET radiotracers may assist therapeutic decisions and overcome the potential limitations of FDG-PET in the staging of tumors, the prediction of prognosis, and the assessment of therapy. However, it is currently unclear how to appropriately incorporate FDG-PET and the novel tracers into clinical decisions regarding therapy and prognosis. Although prospective multi-institutional trials and standardization of PET imaging protocols are required for the true utility to be determined, the evolving experience with PET imaging indicates a greater role in the treatment of NSCLC.

23 Diagnostic Workup for Suspected Lung Cancer Confined to the Chest

Nicholas Pastis, Martina Bonifazi, Stefano Gasparini, and Gerard A. Silvestri

SUMMARY OF KEY POINTS

- In the context of disease confined to the chest, mediastinal staging is crucial for determining the best curative treatment strategy, especially for nonsmall cell lung cancer (NSCLC).
- Urgent referral for chest imaging is recommended for patients who present with hemoptysis or any of several symptoms or signs that are unexplained or persistent.
- Chest radiograph is the main radiographic investigation in the primary care setting in the diagnostic workup for suspected lung cancer.
- Features suggestive of intrathoracic invasion are important clues that help to distinguish between benign and malignant nodules.
- ^{18}F-2-deoxy-D-glucose-positron emission tomography is an essential tool for the diagnosis and staging of disease in patients with radiographic and clinical findings consistent with lung cancer.
- Indeterminate nodules or negative mediastinal findings require additional procedures to obtain a tissue diagnosis.
- The method for definitive diagnosis and staging of lung cancer depends on the suspected cell subtype (small cell lung cancer or NSCLC), the size and location of the primary tumor, the presence or absence of radiographic findings suggestive of mediastinal involvement, and the overall clinical status of the patient.
- Flexible bronchoscopy should be offered to every patient with central lesions on computed tomography for whom nodal staging does not influence treatment.
- Transbronchial needle aspiration is increasingly being supplanted by endobronchial ultrasound fine-needle aspiration.
- Endoscopic ultrasound may be used to increase the number of mediastinal node stations amenable to nonsurgical sampling.
- Staging the mediastinum is of paramount importance in the diagnostic workup for suspected lung cancer confined to the chest, as it dictates treatment options and prognosis.

Lung cancer remains the leading cause of cancer-related death worldwide, with a 5-year survival rate of approximately 15%, as more than two-thirds of patients present with locally advanced or metastatic disease for which curative treatment is no longer feasible.[1,2] Hence, the prevention and early detection of lung cancer are crucial to achieving a substantial reduction in mortality. An early diagnosis could be obtained by systematic screening of high-risk individuals or by prompt referral of symptomatic patients. Patients with lung cancer present a diagnostic challenge in that they often present with myriad symptoms and signs that are common and nonspecific (e.g., weight loss and fatigue) or that are directly related to the primary lesion, to intrathoracic spread, to paraneoplastic syndromes, or to distant metastasis.[3] Because of this ambiguity in presentation, risk factors need to be identified in patients with a higher likelihood of having lung cancer. Smoking is the leading risk factor, but lung cancer does not develop in all long-term heavy smokers and cancer is developing in an increasing proportion of patients with no history of tobacco smoking.[4] In fact, older age, previous diagnoses of other cancers, family history of lung cancer, and exposure to occupational carcinogens seem to increase long-term risk independent of smoking.[5]

The initial evaluation should focus on careful physical examination and history taking to identify patients with suspected lung cancer who should have additional studies, such as a serum chemistry profile, a complete blood count, a calcium level, and testing of liver function, as well as noninvasive imaging studies such as radiographs, computed tomography (CT), and positron emission tomography (PET). According to the third edition of the American College of Chest Physicians (ACCP) evidence-based clinical practice guidelines on the diagnosis and management of lung cancer (2013),[6] the goal of the initial evaluation of patients with suspected lung cancer is to assess key issues related to the patient's overall health, the probability of cancer, and the probability of metastatic disease, as these factors have an impact on every other step of the diagnosis, staging, and treatment process. To optimize the management of lung cancer, the most appropriate biopsy target must be identified and any comorbidities that might limit treatment options should be addressed. The first step should be to identify whether the disease is still confined to the chest, as this factor has an impact on the need for and location of biopsies as well as on the prognosis. In this context, mediastinal staging becomes crucial for determining the best curative treatment strategy, especially for nonsmall cell lung cancer (NSCLC).[7]

If surgery is being considered, the final component of the initial evaluation should be a physiologic assessment of pulmonary function. To stratify the patient's operative risk, testing of lung function—specifically, measurements of forced expiratory volume in 1 second and carbon monoxide diffusion in the lung—is a helpful predictor of morbidity and mortality in those undergoing lung resection.[8]

This chapter focuses on the diagnostic workup for suspected lung cancer that is confined to the chest and provides an extensive description of potential clinical and radiographic features as well as a practical approach to establishing the final diagnosis and staging.

CLINICAL FEATURES

Symptoms related to the primary tumor include cough, breathlessness, hemoptysis, and chest discomfort. A persistent cough and dyspnea, likely due to an endobronchial mass or postobstructive pneumonia, are the most common symptoms. These symptoms

occur in up to 75% and 60% of patients, respectively, and may be associated with wheezing and stridor. Intermittent, aching chest discomfort is noted by approximately 50% of patients at the time of diagnosis. Hemoptysis is rarely severe and usually only consists of blood streaking of the sputum.[8,9] Forty percent of patients present with symptoms and signs related to intrathoracic spread involving the nerves, chest wall, pleura, vascular system, and/or viscera as a result of either direct extension or lymphatic spread. Recurrent laryngeal nerve palsy is more common in left-sided tumors and usually causes hoarseness. Phrenic nerve paralysis leads to an elevated hemidiaphragm and presents as breathlessness in patients who already have compromised respiratory function. A Pancoast tumor involves either the right or left apex in the superior sulcus near the brachial plexus and commonly infiltrates the eighth cervical and first and second thoracic nerve roots, causing pain, cutaneous temperature change, and muscle wasting along the relevant nerve root. It may present with Horner syndrome as a result of involvement of the sympathetic chain and stellate ganglion, causing unilateral enophthalmos, ptosis, miosis, and ipsilateral anhidrosis. Chest wall invasion can cause painful soft-tissue masses or rib destruction. Pleural effusion may be related to direct extension of the primary tumor, to implantation of tumor metastasis, or to mediastinal lymphatic obstruction and is typically heralded by dyspnea or chest pain.[8,9]

Superior vena cava syndrome is the result of direct obstruction of the superior vena cava by the primary tumor or by enlarged right paratracheal metastatic lymph nodes, causing face or arm swelling; dyspnea; venous distention in the neck, upper chest, and arms; headache; upper limb edema; dizziness; drowsiness; blurring of vision; cough; and dysphagia. Lung cancer accounts for 46% to 75% of all cases of superior vena cava obstruction, and the most common histologic subtype is small cell lung cancer (SCLC).[8,9]

Paraneoplastic syndromes represent a group of clinical disorders that are associated with malignant lesions but are not directly related to the physical effects of primary or metastatic tumors. Paraneoplastic syndromes occur in at least 10% of patients with lung cancer, especially SCLC, irrespective of the extension and size of the primary tumor, and may be the first manifestation of the disease. They include a myriad of endocrine, neurologic, skeletal, renal, metabolic, hematologic, cutaneous, and collagen vascular syndromes, which are likely due to the production of bioactive substances either by the tumor or in response to the tumor (e.g., polypeptide hormones, hormone-like peptides, antibodies or immune complexes, prostaglandins, or cytokines; Table 23.1). Hypercalcemia, the syndrome of inappropriate antidiuretic hormone secretion, Cushing syndrome, digital clubbing, hypertrophic osteoarthropathy, hematologic abnormalities, and hypercoagulable disorders are the most common syndromes observed.[8,9] Nonspecific symptoms include weakness and weight loss.

Delays in achieving a final diagnosis after the initial onset of symptoms can occur at several steps. First, the patient may notice a new symptom or a change in the usual respiratory symptoms, but some months may pass before he or she sees a physician.[10] Additional time may then be required for the physician to obtain imaging studies of the chest, for the patient to be referred to a specialist, or for the specialist to establish a final diagnosis.[11] Hamilton et al.[12] evaluated the positive predictive values of symptoms and physical signs and identified so-called red flags that were independently associated with lung cancer in multivariable analyses; these red flags included hemoptysis, anorexia, weight loss, fatigue, dyspnea, persistent cough, chest pain, and digital clubbing.

According to the National Institute for Health and Clinical Excellence (NICE) clinical guideline on the diagnosis and treatment of lung cancer, an urgent referral for chest imaging is recommended for patients who present with hemoptysis or any of several symptoms or signs (including cough, chest and/or shoulder pain, dyspnea, weight loss, hoarseness, finger clubbing, features suggestive of metastasis from a lung cancer, and cervical and/or supraclavicular lymphadenopathy) that are unexplained or persistent (lasting for more than 3 weeks). Smokers and ex-smokers who are older than 40 years of age and have persistent hemoptysis, signs of superior vena cava obstruction, and stridor should be offered an urgent referral to a member of the lung cancer multidisciplinary team, usually the chest physician, while awaiting the results of chest imaging.[13]

HISTORY

History taking should focus on major baseline risk factors, including smoking, occupational exposure (mainly to asbestos),[14] family history of lung cancer, previous diagnosis of other malignancy, preexisting nonmalignant lung diseases (e.g., chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis,

TABLE 23.1 Paraneoplastic Syndromes

Syndrome	Type of Lung Cancer	Causative Agents
Acromegaly	Carcinoid tumors; small cell	Growth hormone-releasing hormone; growth hormone
Carcinoid syndrome	Carcinoid tumors; large cell Small cell	Serotonin
Ectopic adrenocorticotropic hormone (ACTH) syndrome	Small cell Carcinoid tumors	ACTH corticotropin-releasing hormone
Encephalomyelitis/subacute sensory neuropathy	Small cell	Anti-Hu antibody and Hu-D antigen
Granulocytosis	Nonsmall cell	Colony-stimulating factor (CSF); granulocyte–CSF Granulocyte-macrophage CSF Interleukin (IL)-6
Hypercalcemia	Nonsmall cell (usually squamous cell)	Parathyroid hormone-related peptide; parathormone
Hyponatremia	Small cell Nonsmall cell	Arginine vasopressin Atrial natriuretic peptide
Lambert–Eaton syndrome	Small cell	Anti-P/Q channel antibody and P/Q-type calcium channel (antigen)
Retinopathy	Small cell	Antirecoverin antibody and specific antigen specific to photoreceptor cells (recoverin)
Thrombocytosis	Nonsmall cell Small cell	IL-6
Thromboembolism	Nonsmall cell Small cell	Procoagulants Inflammatory cytokines Tumor interaction with host cells

tuberculosis, and previous pneumonia), and socioeconomic deprivation.[8] Finally, residence in or travel to an area with endemic fungal pathogens could suggest a benign infectious disease in the correct clinical context.

IMAGING FEATURES AND DIAGNOSTIC ACCURACY

Radiography plays a crucial role in the diagnostic workup for suspected lung cancer.[15] The main investigation in the primary care setting is the chest radiograph. The radiographic appearance of lung cancer at the time of the initial presentation may vary. Lung cancer occurs more often on the right side rather than on the left side and in the upper lobes rather than in the lower lobes, with a predominance in central locations.[8] Up to 40% of the radiographic findings associated with lung cancer are related to central tumors causing airway obstruction with secondary atelectasis and lung parenchyma consolidation. However, although a radiograph of the chest may lead to the identification of a suspected lung mass, it lacks sufficient resolution to differentiate benign from malignant disease, and, if a previous radiograph is not available to demonstrate stability over 2 years, the patient will need additional evaluation.[7] A negative result does not exclude lung cancer, especially if there is a high pretest probability. Stapley et al.[16] retrospectively reviewed the medical records of 247 patients with lung cancer to assess radiographic findings in the primary care setting and reported that more than 10% of patients had had negative radiographic findings in the 3 months before diagnosis. Moreover, negative findings on chest radiographs may occur with any cancer symptom other than hoarseness.[16] Therefore the standard imaging study for patients with suspected lung cancer is conventional contrast-enhanced CT of the chest, as it provides anatomic details such as the location, shape, margins, and attenuation characteristics of the primary lesion; the proximity of the lesion to surrounding structures; the extent of invasion of the chest wall; and the presence or absence of suspected mediastinal lymph node involvement.[17] Other advantages of CT are its widespread availability and its relatively low cost in comparison with more advanced imaging modalities, such as PET–CT (PET combined with CT) or magnetic resonance imaging (MRI).

In the case of a solitary lesion without any apparent evidence of lymph node involvement, atelectasis, or postobstructive pneumonia, specific morphologic characteristics may help to differentiate benign disease from malignant disease (Table 23.2). For this purpose, CT images should be thin slice, with contiguous 1-mm slices made through nodules. Lesions that are larger than 3 cm and that are located in the upper lobe are more likely to be malignant. Spiculated, lobulated, and ragged margins as well as notches and concavity in the margins are highly predictive of

lung cancer, whereas smooth borders usually suggest a benign lesion. However, as many as one-third of lesions with smooth borders are malignant. A ground-glass attenuation surrounding a nodule may signify hemorrhagic infarction and is known as the so-called CT halo sign. This finding has been associated with aspergillosis, Kaposi sarcoma, granulomatosis with polyangiitis, and metastatic angiosarcoma. Adenocarcinoma in situ (previously known as bronchioalveolar carcinoma) also can produce a halo as a result of its lepidic growth. Tentacle or polygonal margins occur in association with fibrosis, alveolar infiltration, and collapsed alveoli.[17] Regarding calcifications, laminated or concentric calcifications with a dense central core, diffuse and solid calcifications, or popcorn calcifications suggest a benign lesion. Although there is no specific pattern associated with malignancy, punctate and eccentric calcifications may be associated with lung cancer. Cavitation can occur in association with malignant nodules (most commonly squamous cell carcinoma) as well as benign diseases, including abscesses, infectious granulomas, vasculitides, early Langerhans cell histiocytosis, and pulmonary infarction. A cavity wall thickness of less than 5 mm is suggestive of a benign etiology, whereas irregular walls and a wall thickness of more than 15 mm are usually (although not always) associated with malignant lesions.[17]

Lung nodules can be classified as solid or subsolid. Subsolid nodules can be part solid and part ground glass or can be pure ground-glass nodules (GGNs), defined as focal increased lung attenuation through which normal parenchymal structures such as airways, vessels, and interlobular septa are still visible. GGNs are frequently multiple, and the approach to these nodules is beyond the scope of this chapter. According to the International Association for the Study of Lung Cancer, the American Thoracic Society, and the European Respiratory Society, the presence of solid components in the GGN is associated with more invasive pathologic features, as subsolid nodules frequently represent the histologic spectrum of adenocarcinomas, including atypical adenomatous hyperplasia, adenocarcinomas in situ, minimally invasive adenocarcinomas, and lepidic-predominant adenocarcinomas. However, because of their slow growth rate and low metabolic activity, the differential diagnosis between benign and malignant subsolid lesions remains quite problematic. In fact, another relevant factor to take into account, which requires the availability of previous CT images, is the growth rate. Malignant nodules have a volume-doubling time of 20 days to 400 days, although the majority of cancers double in volume within 100 days. A doubling time of more than 400 days is usually associated with benign disease, whereas a doubling time of less than 20 days indicates very rapid growth and strongly suggests infectious processes.

TABLE 23.2 Morphologic Features on Computed Tomography Suggestive of Malignant or Benign Disease[17]

Morphologic Characteristics	Malignant Disease	Benign Disease
Size	>3 cm	≤3 cm
Margins	Spiculated, lobulated, ragged, notches and concavity, halo (adenocarcinoma in situ, Kaposi sarcoma, angiosarcoma), rarely smooth (up to a third of cases)	Smooth, halo (aspergillosis, granulomatosis with polyangiitis), polygonal, rarely spiculated (lipoid pneumonia, focal atelectasis, tuberculoma, and progressive massive fibrosis)
Calcifications/attenuations	Punctate, eccentric	Laminated and concentric, dense central core, diffuse and solid, popcorn (hamartoma)
Cavitations	Irregular and thicker walls (>15 mm)	Cavity wall thickness <5 mm (abscesses, infectious granulomas, vasculitides, early Langerhans cell histiocytosis, pulmonary infarction)
Ground glass[3]	Subsolid GGNs (atypical adenomatous hyperplasia, adenocarcinomas in situ, minimally invasive adenocarcinomas and lepidic-predominant adenocarcinomas)	Pure GGNs
Growth rate	Doubling time, 20 to 400 days	Doubling time, <20 days (infectious process) or >400 days

GGN, Ground-glass nodule.

The presence of features suggestive of intrathoracic invasion is an important clue that helps to distinguish between benign and malignant nodules. Although numerous criteria have been used to define lymph node involvement, the most widely used criterion is a short-axis diameter of more than 1 cm on a transverse CT image. In a systematic review of the medical literature relating to the accuracy of CT staging of the mediastinum, the median sensitivity and specificity of CT for identifying mediastinal lymph node metastasis were 55% and 81%, respectively.[7] Although these studies were statistically heterogeneous, the findings are similar to the results of meta-analyses addressing the accuracy of CT for staging of the mediastinum in NSCLC, which have demonstrated very low sensitivity, ranging from 51% to 64%.[18,19] In fact, as many as 20% of patients who have T1 N0 M0 disease diagnosed on the basis of CT imaging are still found to have positive lymph node involvement on the basis of surgical lymph node sampling. Moreover, although pooled specificity values (range, 76% to 84%) are higher overall than the sensitivity values, a consistent rate of lymph nodes that are defined as malignant on the basis of CT is actually benign.[20]

The increasing availability of ^{18}F-2-deoxy-D-glucose (^{18}FDG)-PET in clinical practice has allowed the technique to become an essential tool for the diagnosis and staging of disease in patients with radiographic and clinical findings consistent with lung cancer. ^{18}FDG-PET is very accurate for differentiating benign from malignant lesions with nodules as small as 1 cm and may also detect clinically unexpected distant metastasis. Increased cellular uptake, defined as a standardized uptake value of more than 2.5, is a common property of both neoplastic and inflamed tissues. However, the sensitivity for lesions smaller than 1 cm is quiet low, likely due to lower metabolic activity, well-differentiated low-grade malignancies not being detected, and a high false-positive rate from inflammation. For mediastinal staging, PET has been shown to have both higher sensitivity and specificity than CT. A meta-analysis of data on PET demonstrated pooled estimates of 74% (95% confidence interval [CI], 69% to 79%) and 85% (95% CI, 82% to 88%) for sensitivity and specificity, respectively.[21] However, in the context of a cancer that is still confined to the chest and thus is potentially curable, the rate of false-positive findings, which may result in missed opportunities for surgical resection, is too high. Moreover, some studies have shown a direct correlation between the accuracy of PET and increasing lymph node size on CT, where the sensitivity is higher (but specificity is lower) when nodes are enlarged.[21]

Newer-generation integrated PET–CT imagers have combined the advantages of both modalities, allowing correlation between CT (which demonstrates anatomic details) and ^{18}FDG-PET (which identifies aspects of tumor function and metabolism). For differentiating between malignant and benign lung nodules, PET–CT is associated with a significantly higher specificity than CT or PET alone because of the ability to discard false-positive uptake on PETs on the basis of the morphologic findings on CT.

Lastly, dynamic MRI is an emerging diagnostic tool for the differential diagnosis and staging of lung cancer. One advantage of this tool is that it does not involve the use of ionizing radiation. Available data suggest that MRI is at least as accurate as CT in evaluating the mediastinum,[22,23] and because MRI can detect differences in intensity between normal tissues and tumor, it may be superior in the ability to detect tumor invasion into the mediastinum, chest wall, diaphragm, or vertebral bodies.[22,24–27] In fact, MRI excels in the delineation of superior sulcus tumors, including tumors that involve the neural foramina, spinal canal, and brachial plexus.[28] ACCP and NICE guidelines currently state that MRI should not routinely be performed to assess the stage of the primary tumor, but that MRI is useful for patients with superior sulcus tumors.[7,13]

Overall, the available data indicate that when the findings of noninvasive imaging (combined PET–CT, PET or CT alone,

and MRI) suggest malignancy, it represents an excellent guide to determine the proper technique to achieve the final diagnosis and staging. However, especially in the context of a suspected lung cancer that is confined to the chest and a high baseline suspicion of disease, indeterminate nodules or negative mediastinal findings require additional procedures to obtain a tissue diagnosis.

DIAGNOSTIC APPROACH FOR ESTABLISHING A DEFINITIVE DIAGNOSIS AND STAGING

As previously stated, the method for definitive diagnosis and staging of lung cancer depends on the suspected cell subtype (SCLC or NSCLC), the size and location of the primary tumor, the presence or absence of radiographic findings suggestive of mediastinal involvement, and the overall clinical status of the patient.[21]

The ACCP guidelines recommend that, for patients in whom SCLC is suspected on the basis of radiographic and clinical findings, the diagnosis should be confirmed with whatever method is easiest (sputum cytology, thoracentesis, bronchoscopy, or transthoracic fine-needle aspiration).[21] For patients in whom NSCLC is suspected, the method of achieving a diagnosis is usually dictated by the presumptive stage of the disease, as the main goal is to maximize the yield of the selected procedure by establishing both diagnosis and staging with one test and avoiding unnecessary invasive tests.[7] The NICE guidelines also recommend choosing investigations that give the most information about diagnosis and staging with the least risk to the patient.[13] After distant metastases have been ruled out, lung cancer presentation can be separated into four categories with respect to intrathoracic radiographic characteristics: (1) extensive mediastinal infiltration by tumor, (2) enlarged discrete N2 or N3 nodes, (3) central tumor or a tumor with enlarged N1 nodes but a normal mediastinum, and (4) peripheral small tumor with normal-sized lymph nodes.[7] For patients who have extensive infiltration of the mediastinum, defined as a mass that infiltrates and encircles the vessels and airways such that mediastinal lymph nodes are no longer visible, the diagnosis of lung cancer should be established with the least-invasive and safest method. In cases in which mediastinal involvement (stage III) is suspected, sampling the mediastinum rather than the primary tumor offers the advantage of diagnosis and staging in one procedure.

In patients with discrete mediastinal lymph node enlargement on CT or PET, mediastinal involvement must be confirmed, and, for that purpose, endoscopic techniques such as endobronchial ultrasound (EBUS) or endoscopic ultrasound (EUS)-guided sampling are preferred as a first step over surgical staging, as they are less invasive and less costly than mediastinoscopy. However, in cases in which the results of EBUS or EUS are negative, mediastinoscopy is recommended. The absence of findings suggestive of mediastinal involvement on both CT and PET images has a high negative predictive value, except in the case of a centrally located tumor or N1 lymph node enlargement. These factors make the chance of N2 or N3 involvement relatively high (20% to 25%) and the use of a technique such as EBUS, EUS, or combined EBUS and EUS-guided needle aspiration is suggested to confirm the staging. Conversely, in the presence of peripheral lung nodules, the chance of mediastinal involvement is quite low.[7]

Different techniques are available to achieve the diagnosis of the primary tumor, and the choice among them is largely guided by the size and location of the lesion. Sputum cytology is particularly useful for the evaluation of patients who have a centrally located tumor and patients who have hemoptysis. However, if sputum cytology is negative for carcinoma, additional testing is recommended.

For patients with suspected lung cancer who have a pleural effusion, thoracentesis is recommended to diagnose the cause of the effusion. If cytologic examination of pleural fluid is negative, image-guided pleural biopsy or medical or surgical thoracoscopy

is recommended. However, if CT of the chest shows pleural thickening or pleural nodules and/or masses, image-guided needle biopsy may be considered as a first approach.[21]

Endoscopic Techniques for Diagnosis and Staging

Over the past decade, endoscopic techniques (bronchoscopy and esophageal endoscopy) have emerged as procedures of choice for the diagnosis and staging of lung cancer. With the addition of real-time ultrasound guidance, endoscopic procedures have demonstrated accuracy for mediastinal staging, with pooled sensitivities comparing favorably with that of the traditional criterion standard, mediastinoscopy.[7] In addition, endoscopic techniques are associated with lower morbidity and mortality and are more cost effective than mediastinoscopy.[29,30]

Flexible Bronchoscopy

Flexible bronchoscopy should be offered to every patient with central lesions on CT for whom nodal staging does not influence treatment. In addition, patients with suspected lung cancer may have symptoms due to endobronchial involvement that require airway inspection with bronchoscopy for tissue sampling in order to make a diagnosis or to guide further interventions. Endobronchial biopsies provide the highest sensitivity (74%), followed by brushings (61%), and washings (47%).[31] A combination of these methods provides a diagnosis in 88% of cases.[26] Endobronchial needle aspiration may provide deeper penetration with less hemorrhage, and the use of this method in addition to forceps biopsies and brushings may improve sensitivity to 95%.[32,33]

The sensitivity of bronchoscopy for peripheral nodules is lower than for central lesions. Transbronchial needle aspiration (TBNA) and transbronchial biopsy have provided the highest sensitivity, followed by transbronchial brushings and lavage or washing.[34,35] However, the overall diagnostic accuracy largely depends on the size of the suspected primary tumor, as it has been reported to be 34% for lesions smaller than 2 cm.[21] Therefore for patients with suspected peripheral lung nodules with an indeterminate likelihood of malignancy, for whom a tissue diagnosis is required before surgical resection, appropriate techniques of sampling include fluoroscopic guidance, radial EBUS, electromagnetic navigation bronchoscopy, and transthoracic needle aspiration (TTNA). When the lesion is moderately to highly suspicious for lung cancer, an upfront surgical excision performed via thoracoscopy is the most definitive method for establishing a diagnosis.[21]

EBUS Fine-Needle Aspiration

Although still associated with high diagnostic yield in expert hands, TBNA is increasingly being supplanted by EBUS fine-needle aspiration. At best, TBNA can be used for selective mediastinal staging, as only subcarinal and right paratracheal lymph nodes are reliably sampled by most bronchoscopists.[36] Because of its limitations, TBNA has a low pooled sensitivity of 39% (95% CI, 17% to 61%), as reported by Holty et al.[37] in a meta-analysis of 13 studies.[7] The use of real-time ultrasound to directly visualize the target during EBUS fine-needle aspiration has solved major deficiencies associated with traditional TBNA.[38] EBUS–TBNA is a versatile and accurate tool for the simultaneous diagnosis and staging of mediastinal and hilar lymph nodes or masses. Its range includes the highest mediastinal lymph nodes (station 1), upper paratracheal lymph nodes (stations 2R and 2L), lower paratracheal lymph nodes (stations 4R and 4L), subcarinal lymph nodes (station 7), hilar lymph nodes (station 10), and interlobar lymph nodes (station 11). From a technical standpoint, para-aortic lymph nodes (station 6) and aortopulmonary window

or subaortic lymph nodes (station 5) typically require a surgical approach, whereas paraesophageal lymph nodes (station 8) and pulmonary ligament lymph nodes (station 9) are usually best accessed with use of EUS fine-needle aspiration (Fig. 23.1).

Because of its safety and accuracy, the uses of EBUS have been expanded to include preoperative mediastinal staging and tissue acquisition for the purposes of molecular analysis and immunohistochemical staining.[39–41] Complications such as severe bleeding and infection are almost negligible, and the rate of pneumothorax is 0.07% to 0.2%.[42–45]

Clearly, EBUS–TBNA is superior to CT and PET for mediastinal staging.[46] Two meta-analyses of studies evaluating the use of EBUS–TBNA for mediastinal staging, by Adams et al.[36] (disease prevalence, 46%) and Gu et al.[42] (disease prevalence, 68%), showed pooled sensitivities of 88% (95% CI, 79% to 94%) and 93% (95% CI, 91% to 94%), respectively.

In addition, in a large systematic review of related studies by the ACCP in which 2756 patients met the criteria for mediastinal staging, the median sensitivity was 89% (range, 46% to 97%), the median negative predictive value was 91%,[7,36,42] and the overall specificity and positive predictive value were both 100%.[1,12,17]

The sensitivity of EBUS–TBNA is higher for enlarged and/or PET-positive lymph nodes (94%; 95% CI, 93% to 96%) than for normal-sized and PET-negative lymph nodes (76%; 95% CI, 65% to 85%).[42] Without rapid on-site evaluation, at least three aspirations per node should be obtained. The use of rapid on-site evaluation can further reduce the number of aspirations without reducing the accuracy of the method.[34,47,48] Unlike the traditional TBNA, needle size (i.e., 22 gauge vs. 21 gauge) does not substantially change the sensitivity of EBUS–TBNA.[48,49]

EUS Needle Aspiration

Primarily because of its superior ability to sample the posterior mediastinum through the esophageal wall, EUS may be used to increase the number of mediastinal node stations amenable to nonsurgical sampling.[50] Like EBUS, EUS is performed with use of real-time ultrasound. EUS needle aspiration can be used to sample inferior pulmonary ligament, paraesophageal, subcarinal, left paratracheal, and aortopulmonary window node stations (stations 9, 8, 7, 4L, and 5). Anterolateral paratracheal locations (stations 2R, 2L, and 4R) are commonly involved in patients with lung cancer but are not sampled reliably with this technique.[50,51] No major complications have been reported in association with this technique, and minor complications such as transient fever, sore throat, cough, nausea, and vomiting are rare (prevalence, 0.8%).[52]

A systematic review in the 2013 ACCP guidelines and a meta-analysis by Micames et al.[52] demonstrated that the overall sensitivities of EUS needle aspiration for mediastinal staging were 89% and 83%, respectively.[7] The sensitivities of the method were higher for enlarged lymph nodes (50% to 66%) than for normal-sized lymph nodes (87% to 92%). The overall false-negative rate was 14%.[7,52]

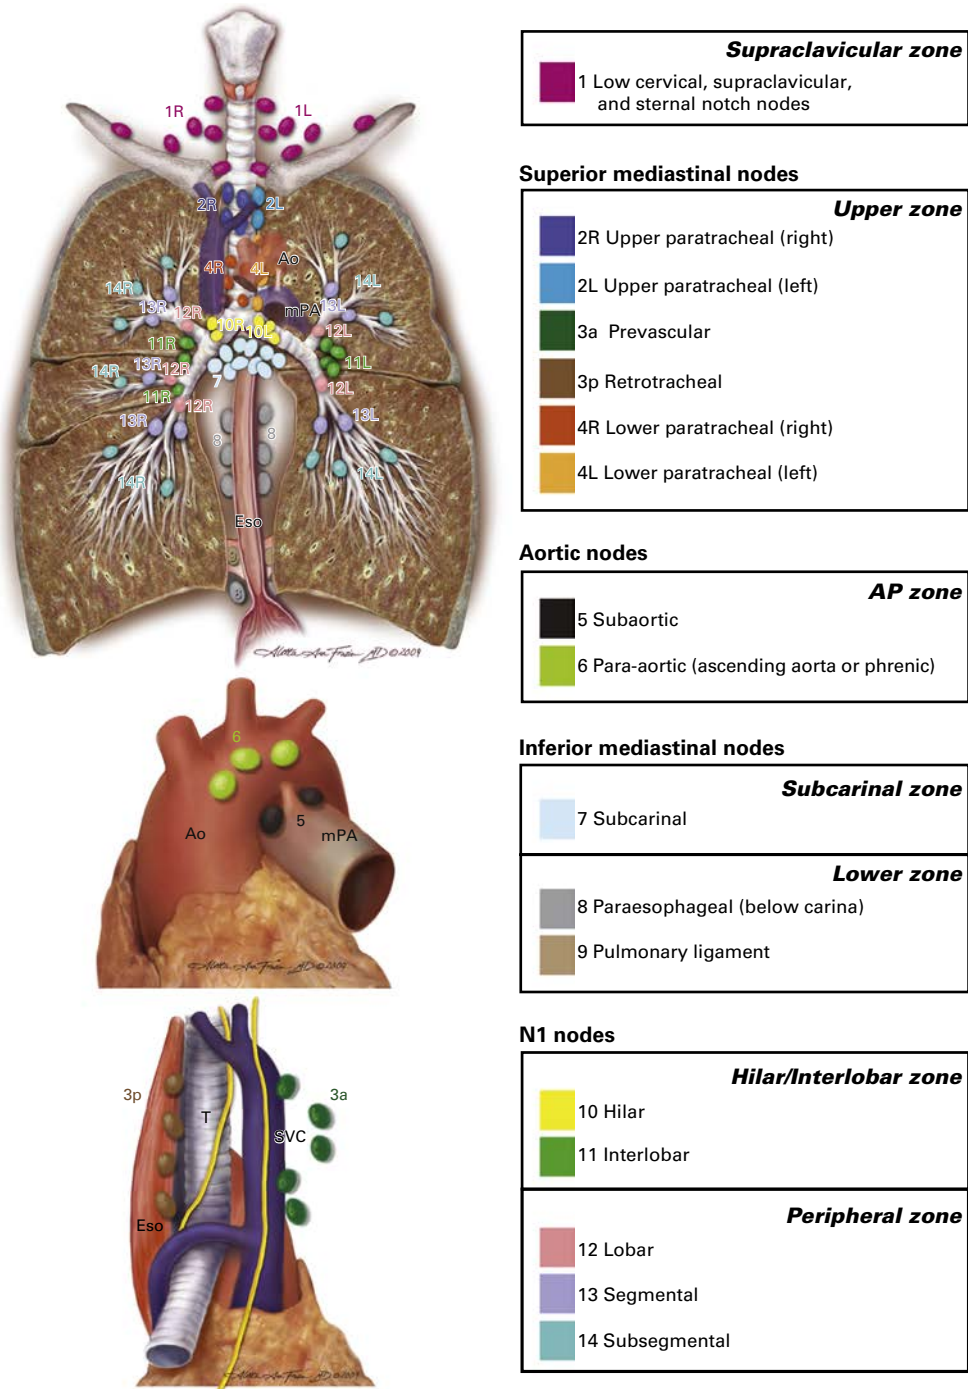
In a pooled analysis of data from 2433 patients with evaluable lung cancer, EUS was shown to have a sensitivity and specificity of 89% and 100%, respectively.[53–76] For patients with lung cancer without adenopathy on CT, EUS has been shown to sample nodes as small as 3 mm in diameter, which is useful given the high incidence of metastasis in normal-sized lymph nodes in patients with lung cancer.[77] The findings of surgical studies indicate that it may be possible to predict the location of mediastinal lymph node metastases at certain levels based on the location of the tumor. This relationship may influence the use of EUS for some patients without adenopathy on CT images of the chest. Lymphatic pathways favor spread to aortopulmonary window nodes from left upper lobe tumors and to subcarinal nodes from left and right lower lobe lesions.[78] EUS has been studied for the evaluation of


Fig. 23.1. International Association for the Study of Lung Cancer map of regional lymph nodes for the determination of N descriptor during tumor, node, and metastasis (TNM) staging of lung cancer. *Ao,* Aorta; *AP,* aortopulmonary, *Eso,* esophagus; *SVC,* superior vena cava, *T,* trachea. *(Reprinted with permission from International Association for the Study of Lung Cancer.* Staging Manual in Thoracic Oncology. *Orange Park, FL: Editorial Rx Press; 2009.)*

patients with known lung cancer without enlarged mediastinal lymph nodes on CT and has detected mediastinal involvement (stage III or IV disease) in up to 42% of cases.[53]

Unlike other methods of mediastinal staging, EUS has the capability to stage lung cancer from locations outside the mediastinum. The left lobe of the liver, a substantial part of the right lobe of the liver, and the left (but not the right) adrenal gland can be identified and sampled in 97% of patients.[79] In addition, left pleural effusions can be visualized and sampled during EUS.

Combined EBUS and EUS Needle Aspiration

When combined, EUS and EBUS have shown superior yield to that than when the techniques are used alone. A pooled analysis of data from seven studies (811 patients) showed a sensitivity and specificity of 91% and 100%, respectively.[7,55,59,60,80–83] When used in tandem, these procedures are complementary by providing near-complete access to the mediastinum for staging and are particularly useful for evaluation of a radiographically normal

mediastinum.[55,60] In a randomized controlled trial of patients with (suspected) NSCLC, staging with EUS and mediastinoscopy was compared with mediastinoscopy alone and was shown to have greater sensitivity for detecting mediastinal node metastases and also led to fewer unnecessary thoracotomies.[80]

The combined use of EBUS and EUS provides the opportunity to reach nearly all mediastinal lymph nodes except for para-aortic and prevascular nodes.[81,84] The procedure may be performed either with the sequential use of two dedicated echo-endoscopes or with an EBUS scope placed first in the airway and then in the esophagus.[85] In a 2013 meta-analysis, Zhang et al.[86] found that combined EBUS and EUS needle aspiration had a pooled sensitivity of 86% and had greater sensitivity than either EBUS–TBNA alone (75%) or EUS needle aspiration alone (69%) for staging the mediastinum of patients with lung cancer. Wallace et al.[74] reported that combined EBUS and EUS needle aspiration can decrease the requirement for further surgical procedures by approximately 30%. In a systematic review of seven studies (811 patients), combined EBUS and EUS needle aspiration had an overall sensitivity and negative predictive value of 91% and 96%, respectively, which were slightly higher than those of each technique alone.[7]

TTNA and Core Biopsy

TTNA and core samples are commonly obtained from pulmonary nodules or masses via CT guidance but may be obtained with ultrasound guidance in select cases in which the tumor abuts the pleural surface. The sensitivity and specificity of CT-guided TTNA are 90% and 97%, respectively.[31]

It should be noted that in most cases, TTNA or other nonsurgical biopsy techniques for peripheral pulmonary lesions do not eliminate the need for surgery, especially in patients with a high pretest probability of cancer, unless a clear noncancerous diagnosis can be made.[87] Nonetheless, TTNA may be unavoidable for patients who are not candidates for surgery but must have tissue diagnosed before treatment, patients who are likely to have noncancerous lesions, patients who request that a diagnosis be confirmed before surgery, and patients who must have confirmation of metastatic disease.

The major risks of TTNA include a 15% rate of pneumothorax and a 1% rate of major hemorrhage.[88] Although pneumothorax may be life threatening and may lead to tension physiology without treatment, most cases do not require treatment (tube thoracostomy is necessary in 6% of biopsies).[88,89] The major risk factors for the development of pneumothorax include the presence of emphysema, a smaller lesion size, and a greater depth of needle penetration from the pleural surface to the edge of the lesion.

CONCLUSION

Staging the mediastinum is of paramount importance in the diagnostic workup for suspected lung cancer confined to the chest, as it dictates treatment options and prognosis. Despite advances in imaging modalities and the increased accuracy of PET–CT for noninvasive staging of the mediastinum, tissue sampling remains necessary to confirm mediastinal node disease. Endoscopic techniques, including EBUS, EUS, or combined EBUS, should now be considered first-line procedures for mediastinal staging because of their excellent accuracy and safety profile. These techniques are complementary to a thorough history, physical examination, and imaging modalities.
